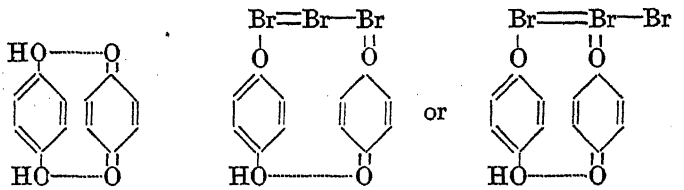
The orange compound (yield, 10 g.) was best recrystallised from acetic acid or chloroform; m. p. 136° (Found: C, 34·1; H, 3·8; Br, 49·5; *M*, cryoscopic in naphthalene, 456, 479. Calc. for $C_{14}H_{17}O_4Br_3$: C, 34·4; H, 3·5; Br, 49·1%; *M*, 489).



This compound has also been obtained by Hantzsch and Denstorff (*Annalen*, 1906, **349**, 39), who only gave a bromine determination, by the action of bromine on dimethylpyrone hydrobromide. They recognised it as a perbromide, and we have confirmed this by obtaining several characteristic reactions for perbromides, some of which were carried out quantitatively, although in the reaction with ammonia only about two-thirds of the theoretical amount of nitrogen were evolved.

On being warmed with water, the compound loses its colour and dissolves, except for a small quantity of a yellow oil (Found: ionisable Br, 37·0%). On standing with water for 3 days, however, only a trace of the yellow oil remained, and the ionisable bromine was then 46·9%. The yellow *oil* does not crystallise on keeping and cannot be distilled (Found: Br, 58·1. $C_7H_6O_2Br_2$ requires Br, 56·7%). Aqueous potassium hydroxide behaves in a similar manner to water (Found: ionisable Br, 46·1%).

The action of heat on the orange compound is complex. If kept just at its m. p. it loses colour, and then solidifies on cooling. If more strongly heated, it chars and gives off hydrogen bromide, the product being almost entirely soluble in water, and consisting chiefly of dimethylpyrone hydrobromide, mixed with a small

quantity of (probably) the bromodimethylpyrone, which, however, could not be separated. The small amount of insoluble *substance* was a yellow, non-crystallisable oil (Found : Br, 61·4%).

The orange compound resembles quinhydrone in some respects, *e.g.*, reaction with water and possession of colour, and this suggests a similarity in molecular constitution :

The action of a larger amount of bromine on dimethylpyrone was tried : 10 g. of the pyrone and 26 g. of bromine in chloroform solution. After evaporation of the chloroform, the residue was treated with water, and the insoluble portion recrystallised from dilute alcohol. A colourless compound resulted; m. p. 163° (Found : C, 29·8; H, 2·6; Br, 56·3. Calc. for $C_7H_6O_2Br_2$: C, 29·8; H, 2·1; Br, 56·7%). This compound had been previously obtained by Feist and Baum (*Ber.*, 1905, **38**, 3562). On being boiled with water it gives bromoacetone. It does not form salts with acids, and its solution in alcohol does not give an immediate precipitate with silver nitrate. On being heated with sodium ethoxide solution, it turns deep red in colour.

If excess of bromine is allowed to react with dimethylpyrone in the absence of a solvent, the mixture becomes warm, and on boiling it evolves hydrogen bromide and eventually becomes solid. Extraction with alcohol leaves a crystalline residue, which is almost insoluble in most solvents. From hot acetic anhydride, however, a *substance* separates in bunches of needles, m. p. 229° (darkening at 227°) (Found : C, 19·3; H, 1·2; Br, 71·5. $C_7H_4O_2Br_4$ requires C, 19·1; H, 0·9; Br, 72·7%). This compound is very stable, being unaffected by metallic sodium in boiling benzene solution, or by warm concentrated sulphuric or nitric acids, from solutions in which it is precipitated unchanged on the addition of water. Heating with ammonia in a sealed tube at 140° or boiling with sodium hydroxide solution, however, effect decomposition, which is very far-reaching in the former case.

A curious iodine compound was obtained by one of the authors (J., 1900, **77**, 1116; 1921, **119**, 1550) by the action of iodine on the barium salt of diacetylacetone. Bromine has now been found to give a similar compound; it was added slowly with shaking to an aqueous suspension of the barium salt (45 g.), and dilute hydro-

chloric acid then precipitated 9 g. of the *substance*, which was recrystallised from dilute alcohol; m. p. 106°; b. p. *ca.* 310° (decomp.) (Found: C, 38·6; H, 3·4; Br, 36·6. *M*, microcryoscopic in camphor, 236. $C_7H_7O_3Br$ requires C, 38·4; H, 3·2; Br, 36·5%; *M*, 219). In all its reactions it resembles the iodine compound. It can be boiled with the strongest sodium hydroxide, or with sodium ethoxide, without decomposition, and is reprecipitated on adding an acid. Cold concentrated sulphuric acid does not decompose it, and although it does not react with cold sodium carbonate solution, on warming, carbon dioxide is evolved. With bleaching-powder solution, it gives a precipitate of calcium carbonate. With ferric chloride, it gives a red precipitate. It can also be made by the action of bromine on the sodium salt of diacetylacetone. It forms a *monobenzoyl* derivative, m. p. 112° (Found: C, 51·8; H, 3·7; Br, 24·5. $C_{14}H_{11}O_4Br$ requires C, 52·0; H, 3·4; Br, 24·8%); and with phenylhydrazine it yields a *compound*, m. p. 142° (decomp.) (Found: N, 8·8; Br, 26·3. $C_{13}H_{13}O_2N_2Br$ requires N, 9·1; Br, 25·9%).

An unsuccessful attempt was made to produce a corresponding chlorine compound by the action of chlorine on the barium salt of dimethyl pyrone.

THE RALPH FORSTER LABORATORIES OF ORGANIC CHEMISTRY,
UNIVERSITY COLLEGE, LONDON. [*Received, June 30th*, 1927.]

CCLXXXVIII.—*The Application of the Hydrogen Electrode to Organic Bases: Piperidine, and its Use as an Alkaline Buffer.*

By EDMUND B. R. PRIDEAUX and FRANK L. GILBERT.

THE dissociation constants of organic bases rest on conductivity determinations alone, whilst the hydrogen-ion concentrations of their partly neutralised solutions are either calculated from these constants or determined by colorimetric methods. It would seem desirable to test these results with the hydrogen electrode, as has been done in the case of acids. It has long been known that this electrode is untrustworthy with ammonia and some amines (Bottger, *Z. physikal. Chem.*, 1899, **24**, 253), and it has also been stated (Kolthoff, *Biochem. Z.*, 1925, **162**, 289) that the alkaloids are susceptible to catalytic reduction at the surface of a hydrogen electrode. The possibility of carrying out an electrometric titration on hydrazine has, however, been established by Gilbert (*J. Amer. Chem. Soc.*, 1924, **46**, 2648). This base is unstable in most respects, but is resistant to reducing agents. Although the numerical results

were not given in the paper, one can infer that the first constant was in fairly good agreement with the value, 3×10^{-6}, based on Bredig's measurements of conductivity.

Piperidine seemed to be eminently suitable for testing the constant derived from conductivity, since it is a moderately strong base which obeys the dilution law, and it was deemed to be stable towards platinum–hydrogen. The dissociation constant according to Bredig is $1{\cdot}6 \times 10^{-3}$, and $\lambda_0 = 216$, expressed in modern units (*Z. physikal. Chem.*, 1894, **13**, 191). The value used by Hantzsch and Sebaldt (*ibid.*, 1900, **33**, 129) is 232 at 25°. In the case of the hydrochloride, at $v = 1024$, $\lambda = 110$; if 2·5 units be added, according to the usual rule, $\lambda_0 = 112{\cdot}5$; since the mobility of the chlorine ion is 75·5, that of the piperidinium ion is 37·0, and, that of the hydroxyl ion being 196, λ_0 for piperidine is found to be 233. On combining this with the λ values of Bredig (converted into ohms) for $v = 32$ and 256, one finds $K = 1{\cdot}42 \times 10^{-3}$ and $1{\cdot}30 \times 10^{-3}$, respectively. These are rather higher than the constants of Hantzsch and Sebaldt (*loc. cit.*), *viz.* :

Temp.	=	15°	20°	25°
10^3K	=	1·11	1·15	1·20

from which, by interpolation, the constant at 18° is $1{\cdot}14 \times 10^{-3}$, $p_K = 2{\cdot}94$. We consider this constant to be a more satisfactory basis for calculations than the uncorrected constant of Bredig. We have tested its validity for expressing the p_H values obtained during neutralisation by (*a*) a potentiometric and (*b*) a colorimetric titration.

(a) *Electrometric Titration.*—The usual circuit for potentiometric titrations was set up, containing a cadmium cell, which was checked against an N.P.L. Standard, a capillary electrometer, and a metre slide wire, which had been calibrated against an accurate resistance box. A platinised platinum–hydrogen electrode of the Hildebrand type dipped into an open beaker which contained the solution of piperidine. The other half-cell was an N/10-potassium chloride–calomel electrode, the two solutions being connected by a salt bridge of saturated potassium chloride–agar.

To the N/10-piperidine solution, N-hydrochloric acid was added with stirring. The balance point on the bridge-wire became steady at once, and readings were taken after each addition of acid. The *E.M.F.*, E_c in table, of the hydrogen half-cell against an electrode in N-hydrogen ion is equal to the *E.M.F.*, E in table, corresponding to the balance-point minus 0·338. The readings are given as c.c. of hydrochloric acid added to a given volume of piperidine :

c.c.	=	2·1	2·45	2·75	3·0	3·2	3·4
E	=	0·962	0·943	0·914	0·845	0·502	0·461
E_c	=	0·624	0·605	0·576	0·507	0·164	0·123

$\Delta E/\Delta C$ assumes a high value between 3·0 and 3·2 c.c.; the subsequent readings correspond to solutions beyond the equivalence point.

The possibility of a satisfactory electrometric titration is thus demonstrated. Some of these results were used in determining p_K (see below), the following p_H values being calculated from $E_c/0{\cdot}058$:

E_c =	0·624	0·605	0·576	0·507	0·164	0·123
p_H =	10·75	10·45	9·92	8·73	2·84	2·12

Electrometric Determination of K.—Since the middle part of the neutralisation is of particular importance in determining K, another experiment was carried out (with a different volume of piperidine) from an earlier stage in the neutralisation and with 0·55N-acid, in order to obtain a greater accuracy in the values of x, the fraction of base neutralised. The values of p_K are calculated from the equation

$$p_K = \log (1 - x)/x + p_{K_W} - p_H,$$

where p_{K_W} has its usual significance and is equal to 14·13 at 18°.

The potentiometric titration of 0·1N-piperidine with 0·55N-hydrochloric acid.

HCl (c.c.).	E_c.	p_H.	100x.	p_K.	HCl (c.c.).	E_c.	p_H.	100x.	p_K.
0·65	0·682	11·8	17·8	2·99	2·10	0·637	10·95	57·4	3·05
0·95	0·672	11·6	26·0	2·98	2·40	0·620	10·75	66·0	3·09
1·24	0·665	11·43	33·9	2·99	2·65	0·607	10·55	73·3	3·14
1·60	0·652	11·23	43·7	3·00		0·605	10·45	80	3·09
1·85	0·645	11·1	51·0	3·01		0·576	9·92	90	3·26
1·95	0·640	11·05	53·4	3·02					

Thus the potentiometric constant is distinctly lower (p_K higher) than that derived from conductivity results; the constancy is very satisfactory, the trend up to $x = 0{\cdot}50$ being very slight, less indeed than in the case of most acids. Thus it has been shown by Michaelis and Kruger (*Biochem. Z.*, 1921, **119**, 307) that the p_K of acetic acid when 50% neutralised is 4·665, whilst that of the free acid is 4·733; there is therefore a decrease of 0·068 in p_K, or an increase in the constant. Although it is not possible to determine the potentiometric p_K with sufficient accuracy on aqueous solutions of free piperidine, we do know that the change of p_K over a large range of neutralisation is only about 0·02. If, however, p_K of the pure base is 2·94, the difference between this and the value prevailing at 50% neutralisation is 0·07—of the same order as the difference for acetic acid, but in the opposite direction. While, therefore, the constant increases during neutralisation in the case of typical weak acids, it decreases in the case of this weak base. It is intended to test other bases,

in order to find whether this behaviour is characteristic of the class.

The increases in the constants of acids may be plausibly attributed to the presence of the increasing amount of salt formed during the neutralisation, since the addition of sodium chloride, or other neutral salt, has a marked effect in the same direction (Michaelis and Kruger, *loc. cit.*).

The present effect, however, is not a salt effect, as was proved by the following experiments. Sodium chloride was added to the solutions under investigation so as to preserve a constant concentration of chloride, equal to that which would have been attained at the end of the neutralisation. Had the drift in the constant been a salt effect, the balance point would have been altered in the first stages of neutralisation, so as to give a constant p_K equal to the slightly higher value obtained in the nearly neutralised solution.

Addition of NaCl to 30 c.c. of piperidine at various degrees of neutralisation.

100 x.	Balance point on bridge, without NaCl.	Weight of NaCl added (g.).	Balance point in presence of NaCl.
10	51·2	0·158	51·2
30	49·7	0·117	49·8
50	48·7	0·088	48·7
80	46·4	0·035	46·5

Hence the *E.M.F.*'s and the p_H values are not affected by moderate amounts of neutral salt, the presence of which, therefore, does not account for the slight trend in K in the case of solutions which are more than 50% neutralised.

(b) *Colorimetric Titration.*—It is clear from the above results that the calculation of p_H during neutralisation from the constant which is based on conductivity will give numbers about 0·2 unit higher than those determined by the hydrogen electrode. It remains to be found whether these latter p_H values have the same effect on indicators as those derived from known buffer solutions.

We have selected the buffers of Ringer : 0·15*N*-Na_2HPO_4 + 0·1*N*-NaOH (p_H 11—12), and one of Sörensen's : 0·2*N*-$Na_2B_4O_7$ + 0·1*N*-NaOH or HCl (p_H 11—8). These solutions were matched against the piperidine at various stages of neutralisation, by using the B.D.H. "universal indicator," which can be made to show changes within 0·1 in p_H over the range involved. To 10 c.c. of the *N*/10-piperidine solution were added counted numbers of drops of the 0·55*N*-hydrochloric acid, from a dropping pipette, 22 drops of which were equal to 1 c.c. When the colour matched that of the buffer solution containing the same concentration of indicator, the % of neutralisation was recorded.

No. of drops.	p_H of buffer.	$100x$.	p_K.	No. of drops.	p_H of buffer.	$100x$.	p_K.
9	11·74	22·5	2·93	35	10·05	87·5	3·23
18	11·19	45	3·02	36	9·84	90	3·33
22	11·01	55	3·03	37	9·50	92·7	3·53
33	10·33	82·5	3·12	38	9·41	95·0	3·43
34	10·15	85·0	3·23	39	9·21	97·5	3·33

The values determined by the hydrogen electrode are therefore confirmed, and the slight trend in K_B is again found, the values of p_K rising more sharply when neutralisation is nearly complete.

In all the middle part of its neutralisation interval, piperidine will make an excellent buffer solution: the p_H values may be calculated from $p_K = 3{\cdot}00 \pm 0{\cdot}02$ between 15 and 55% neutralisation. In an $N/10$-solution of piperidine which has been 50% neutralised by $0{\cdot}5N$-hydrochloric acid, p_K is found, both by the hydrogen electrode and by indicators, to be $11{\cdot}10 \pm 0{\cdot}05$. This is an accurately defined reference point for the measurement of acidity.

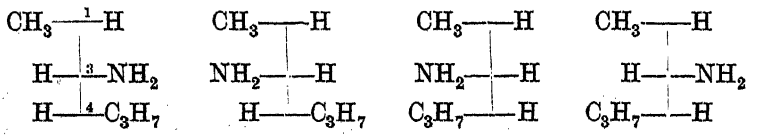
NOTTINGHAM.

[*Received, July 16th*, 1927.]

CCLXXXIX.—*Researches in the Menthone Series. Part V.* d-neoiso*Menthylamine.*

By JOHN READ and GEORGE JAMES ROBERTSON.

THE constitutional formula of the menthylamines admits of the existence of four optically inactive and eight optically active forms, and of these the only stereoisomerides remaining to be prepared and characterised are the *neoiso*menthylamines (compare J., 1926, 2209, 2223). Wallach (*Annalen*, 1898, **300**, 278) obtained two bases, now called *l*-menthylamine and *d-neo*menthylamine, by heating *l*-menthone with ammonium formate. We regard both these bases as derivatives of *l*-menthone (*loc. cit.*); since, however, under the conditions of the experiment *l*-menthone is transformed partly to *d-iso*menthone (this vol., p. 1278), we considered that the reaction product should contain a corresponding proportion of formylated *iso*menthylamines. By applying the knowledge already acquired of the derivatives of active forms of the three known bases, we have been able to prepare from this product a new salicylidene (*o-hydroxybenzylidene*) derivative, m. p. 99—100°, $[\alpha]_D$ — 17·9°, which must be regarded as an active form of salicylidene*neoiso*menthylamine (J., 1926, 2225).



We have already shown that *d-iso*menthone, when oximated and reduced, yields *d-iso*menthylamine. *l*-Menthone yields *l*-menthyl-

amine in a similar way, and gives a mixture of *l*-menthylamine and *d-neo*menthylamine in reaction with ammonium formate. By analogy we anticipated that *d-iso*menthone would furnish *d-iso*-menthylamine and *l-neoiso*menthylamine in the last-named reaction. A careful scrutiny of the data suggests that *d-iso*menthylamine may exist in the formylated mixture, although it has not yet been isolated therefrom; the new lævorotatory salicylidene derivative, however, yielded upon hydrolysis a feebly dextrorotatory neoiso-*menthylamine*, having $[\alpha]_D + 9°$ in chloroform. The *hydrochloride* also was dextrorotatory, having $[\alpha]_D + 20{\cdot}9°$ in dilute aqueous solution. All the other derivatives, nine in number, as yet prepared from the base display rather small lævo-rotations, thus fulfilling the anticipated tendency. Since, however, the free base is dextrorotatory, we propose to name it *d-neoiso*menthylamine. The subjoined summary of melting points and specific rotatory powers indicates some of the more important relationships existing between the four optically active forms under discussion. The values of $[\alpha]_D$ were observed in water for the hydrochlorides and in chloroform for the other derivatives (compare J., 1926, 2225):

		Menthylamines.

	$[\alpha]_D$	−119·2	+30·0	+77·6	−17·9

From these data it is evident that no striking general similarity exists between derivatives of the *neo*- and *neoiso*-menthylamines (compare J., 1926, 2224); further, of the four supposed benzomenthylamides described by Tutin and Kipping (J., 1904, **85**, 73) two only can now be regarded as pure substances. The data are of particular interest when considered in conjunction with the configurational scheme advanced some time ago for the menthylamines (J., 1926, 2213) and reproduced below with the amendment

that the *trans*-configuration is adopted, in place of the *cis*-, for menthone (compare this vol., p. 1278) :

l(or *d*)-Menthylamine. (I.) | *d*(or *l*)-*neo*-Menthylamine. (II.) | *d*(or *l*)-*iso*-Menthylamine. (III.) | *d*(or *l*)-*neoiso*-Menthylamine. (IV.)

The adoption of configuration (II), rather than (IV), for *d-neo*-menthylamine (J., 1926, 2213) is now supported by the fact that the sense of the optical rotation undergoes a change throughout the series of substitution derivatives in passing from (I) to (II), but not in passing from (I) to (IV). Further generalisations may also be made which appear to accord with the suggested configurational scheme. Excluding β-naphthalenesulphon-*d-iso*-menthylamide, which is only feebly active, and also the hydrochlorides, which differ from the other derivatives in being ionisable, it is remarkable that the reversal of the asymmetry of carbon atom (3), carrying the characteristic amino-group, invariably changes the sign of the optical rotation. On the other hand, the reversal of the asymmetry of either of the carbon atoms (1) or (4) does not affect the sign of the optical rotation.

With regard to numerical values, it is seen that the derivatives of *trans*-menthone (I and II) possess greater rotatory powers than the derivatives of *cis*-menthone (III and IV). The most striking numerical relationships yet observed between the optical rotatory powers of corresponding members of the four series are shown by the formyl and acetyl derivatives: the sum of (I) and (IV) is in each instance practically equal in amount, but opposite in sign, to that of (II) and (III); similar results are obtained by comparing the sum of (I) and (III) with that of (II) and (IV), and the sum of (I) and (II) with that of (III) and (IV). These relationships do not hold for the other derivatives described in this communication, but it is hoped to pursue the subject in order to ascertain whether any definite principle of optical superposition can be discerned in this remarkable series of stereoisomerides.

The action of nitrous acid on the four types of stereoisomeric menthylamines is of particular interest. It must be recognised that the configurations which have been assigned to these substances are based largely upon the assumption that the stereoisomeride which passes most readily into a particular menthol when treated with nitrous acid is configurationally similar to that

menthol, the accompanying Δ^3-menthene being attributed in such instances to the occurrence of a Walden inversion (compare J., 1926, 2213). Thus, *l*-menthylamine and *d-iso*menthylamine yield the largest proportions of *l*-menthol and *d-iso*menthol, respectively, when treated with this reagent. Accepting these processes as the normal ones, the simultaneous formation of partly racemised *d*-Δ^3-menthene takes place through a Walden inversion, leading to the intermediate production of *d-neo*menthol and an optically active *neoiso*menthol, respectively; these alcohols, since they possess a hydrogen atom (4) in the *cis*-configurative position to the hydroxyl group (3), then undergo dehydration. The formation of partly racemised *d*-Δ^3-menthene as the main product in the remaining instances of *d-neo*menthylamine and *d-neoiso*menthylamine is accordingly regarded as the normal procedure. *l*-Menthol, which we now show to be present in small amount in the product yielded by *d-neo*menthylamine, will in this instance arise by virtue of a Walden inversion, and it appears that *d-neoiso*menthylamine yields *d-iso*menthol in a similar way.

l-Menthylamine, *d-neo*menthylamine, *d-iso*menthylamine, and *d-neoiso*menthylamine may all be utilised as sources of *d*-Δ^3-menthene, in varying yields, by the action upon them of nitrous acid (compare also Tschugaeff, *Ber.*, 1899, **32**, 3333). In these changes, carbon atom (1) alone retains its asymmetry, and a proof is thus afforded that the spatial disposition of the groups about this atom is similar in the four stereoisomeric bases concerned, as indicated in our configurational scheme. An interesting distinction between the substances is provided by the observation that the salicylidene derivatives of the menthylamines and *iso*menthylamines are phototropic, while those of the *neo*menthylamines and *d-neoiso*menthylamine are not.

Experimental.

Isolation and Characterisation of d-neoiso*Menthylamine.*—The crude oily form-*d-neo*menthylamide obtained by heating *l*-menthone with ammonium formate (Wallach, *Annalen*, 1898, **300**, 283) was dried in ether solution and distilled under diminished pressure. The first fraction consisted of menthone, but 85% of the material passed over at 160—166°/9 mm. as a clear, pale yellow syrup, which yielded about 30% of its weight of crystalline form-*d-neo*menthylamide when kept overnight in contact with dry ether. After separation of the crystals by filtration and removal of the ether, the remaining syrup had $n_D^{15°}$ 1·4840 and $[\alpha]_D^{15°}$ − 21·1° in chloroform ($c = 4·3$). Examination showed that the aqueous layer formed in the reaction could be discarded.

The clear solution obtained by hydrolysing the syrup with hydrochloric acid (*Annalen*, 1893, **276**, 308) was rendered alkaline and steam-distilled; the distillate, when carefully neutralised with hydrochloric acid and evaporated to dryness, yielded a colourless, crystalline mass of a mixture of menthylamine hydrochlorides. A non-volatile part of the alkaline mixture, having b. p. 166—176°/9 mm., $[\alpha]_D^{15°}$ + 6·6°, proved to consist of unchanged formyl derivative; selective hydrolysis had thus occurred. In subsequent hydrolyses, the boiling with concentrated hydrochloric acid was therefore continued for 4—5 hours after the syrup had dissolved; the mixture of menthylamine hydrochlorides then obtained had $[\alpha]_D^{15°}$ — 4° in water (c = 5·1).

Attempts to separate the constituents of this mixture by treatment with ether, acetone, methyl alcohol, and other organic solvents yielded unsatisfactory results. Fractional extraction of the liberated base from its solution in ether by agitation with four successive equal quantities of 0·6*N*-hydrochloric acid yielded fractions of hydrochloride having $[\alpha]_D^{15°}$ — 8·4°, — 5·3°, — 4·6°, and + 1·9°, respectively, in aqueous solution (c = 4·5). A certain degree of separation was thus effected, but the best results were obtained by preparing the salicylidene derivative directly from the mixture of hydrochlorides having $[\alpha]_D^{15°}$ — 4°, described above. When recrystallised twice from light petroleum and once from alcohol, material made in this way yielded about 8% of pure *salicylidene*-d-neois*omenthylamine*. This substance forms yellow needles, m. p. 99—100°, $[\alpha]_D^{15°}$ — 17·9° in chloroform (c = 2·3). (Found: C, 78·7. $C_{17}H_{25}ON$ requires C, 78·75%). A mixture of this derivative with about an equal amount of salicylidene-*d*-*neo*menthylamine (m. p. 98—99°) melted at 74—78°.

Hydrolysis was best effected by boiling the substance (12 g.) for 3·5 hours with a mixture of sulphuric acid (8·5 c.c.) and water (72 c.c.). Salicylaldehyde was extracted with ether, and d-neois*omenthylamine hydrochloride* was then prepared by steam-distilling the basified liquid into the requisite amount of dilute hydrochloric acid. The crystalline powder obtained upon evaporation was very soluble in alcohol or water, and practically insoluble in light petroleum or ether. When dissolved in boiling acetone containing a trace of methyl alcohol, it crystallised with difficulty in fine, silky needles, which did not melt below 250°; $[\alpha]_D^{15°}$ in water (c = 3·1) was + 20·9° (Found, by titration: Cl, 18·4. $C_{10}H_{21}N,HCl$ requires Cl, 18·5%). Free d-neois*omenthylamine* is a liquid which resembles the stereoisomeric menthylamines in its odour. The approximate rotatory power was determined by extracting with chloroform the base liberated from a known weight of hydrochloride

(1·669 g.); the dried chloroform solution (50 c.c.) gave $[\alpha]_D^{15°}$ + 9° (α_D^{15} + 0·30° in a 1-dcm. tube).

The *formyl* derivative is a viscid oil, having $[\alpha]_D^{15°}$ − 3·9° in chloroform (c = 4·4). The *acetyl* derivative is very soluble in organic solvents; it crystallised from light petroleum in needles which softened at 87°, melted at 99—100°, and showed $[\alpha]_D^{15°}$ − 2·6° in chloroform (c = 2·7). The *benzoyl* derivative crystallises from alcohol in fine, silky needles, m. p. 151°, $[\alpha]_D^{15°}$ − 10·4° in chloroform (c = 2·3). The β-*naphthalenesulphonyl* derivative, after three recrystallisations from alcohol, formed hard aggregates, m. p. 120°, $[\alpha]_D^{15°}$ − 10·7° in chloroform (c = 2·9). *Benzylidene*-d-neoiso*menthylamine* separates from hot methyl alcohol in coarse, colourless needles, m. p. 68—69°, $[\alpha]_D^{15°}$ − 34·2° in chloroform (c = 2·0). A mixture with benzylidene-*l*-menthylamine (m. p. 69—70°) melted at 45—51°. d-neoiso*Menthylcarbamide* crystallised from ether–light petroleum in fine needles, m. p. 115—116°, $[\alpha]_D^{15°}$ − 3·1° in chloroform (c = 1·9). d-neoiso*Menthylphenylcarbamide* forms small needles, m. p. 149—150°, $[\alpha]_D^{15°}$ − 12·1° in chloroform (c = 2·5); the pure derivative was readily obtained in 75% yield. d-neoiso*Menthylphenylthiocarbamide* crystallises from ether–light petroleum in well-developed prisms, m. p. 99°, $[\alpha]_D^{15°}$ − 6·7° in chloroform (c = 3·0).

Action of Nitrous Acid on d-neo*Menthylamine and* d-neoiso-*Menthylamine.*—1. *d-neo*Menthylamine hydrochloride (50 g.), obtained by hydrolysing form-*d-neo*menthylamide (m. p. 114—116°), was treated with nitrous acid in the usual manner (this vol., p. 1280). The product contained tarry matter. When distilled it yielded a first fraction (16 g.) having b. p. 57—83°/11 mm., $[\alpha]_D^{15°}$ + 58·6° (in ether; c = 1·8), $n_D^{15°}$ 1·4555, and a second fraction (4·2 g.) having b. p. 83—102°/11 mm., $\alpha_D^{15°}$ − 18·12°, $[\alpha]_D^{15°}$ − 20·1°, $n_D^{15°}$ 1·4630. The latter fraction had an odour of menthol; when heated with phthalic anhydride, it yielded a product which, after two recrystallisations from light petroleum containing a little alcohol, had m. p. 111°, $[\alpha]_D^{15°}$ − 81·5° (in chloroform; c = 2·1). A mixture of this substance with *l*-menthyl hydrogen phthalate (m. p. 112—113°) melted at 111—113°; it was therefore diagnosed as slightly impure *l*-menthyl hydrogen phthalate (compare Pickard and Littlebury, J., 1912, **101**, 109).

2. *d-neoiso*Menthylamine hydrochloride (6 g.) was treated similarly, a little dilute hydrochloric acid being added during the progress of the reaction. The crude product (3 g.) when distilled yielded a first fraction (2·1 g.) having b. p. 76—109°/21 mm., $\alpha_D^{15°}$ + 17·64°, $n_D^{15°}$ 1·4591, and a second fraction (0·6 g.) having b. p. 90—100°/9 mm., $[\alpha]_D^{15°}$ + 5·5° (in alcohol; c = 3·7), $n_D^{15°}$

1·4675. The second fraction, which showed no tendency to crystallise, possessed an odour of *iso*menthol (this vol., p. 1280).

Phototropy of Salicylidenementhylamines.

Of the twelve possible stereoisomeric salicylidenementhylamines, nine have now been described, the remaining three being the derivatives of *d*-menthylamine, *l-neoiso*menthylamine, and *dl-neoiso*menthylamine. The nine stereoisomerides are all normally pale yellow in colour, but it is remarkable that certain of them display phototropy, while the others do not. When exposed for a few minutes to sunlight or to bright daylight, salicylidene-*l*-menthylamine assumes a deep orange colour, but reverts to pale yellow when kept for a while in subdued daylight or in the dark. A less pronounced change of a similar kind is exhibited by the three salicylidene*iso*menthylamines, and to a slight extent by salicylidene-*dl*-menthylamine, but the three salicylidene*neo*menthylamines and salicylidene-*d-neoiso*menthylamine are unaffected by the treatment indicated. Salicylidene-*dl*-menthylamine was originally obtained as a liquid (J., 1926, 2227), but when kept for several months it changed to a pale yellow, crystalline mass, which softened at 60° and melted indefinitely at about 80°. It is hoped in due course to undertake a more detailed study of the phototropy of these derivatives.

The authors are indebted to the Carnegie Trust for a Teaching Fellowship which enabled one of them (G. J. R.) to take part in the work. The investigations are being continued.

CCXC.—*Reactions of Sodium Compounds of Aromatic Ketones. Part I. Synthesis of Triarylcarbinols and of Triarylmethane Dyes.*

By ERNEST HARRY RODD and FRANK WILLIAM LINCH.

IT has been known for many years that aromatic ketones form compounds with metallic sodium in an inert solvent. The literature of the subject, from the original observation by Beckmann and Paul (*Annalen*, 1891, **266**, 1) that benzophenone forms a coloured compound with sodium, is usefully summarised in *Ann. Reports*, 1925, **22**, 123—126. Workers in this field have hitherto confined themselves to unsubstituted ketones such as benzophenone and phenyl diphenylyl ketone, and have studied the decomposition

products of the sodium ketyls with water, oxygen, iodine, and methyl iodide with the object of elucidating their structure. Schlenk and his co-workers state that benzophenone forms a blue monosodio-derivative, probably containing tervalent carbon, and a violet disodio-derivative, $CPh_2(ONa)Na$; the disodio-compound of phenyl diphenylyl ketone was actually isolated (*Ber.*, 1914, **47**, 487).

We were attracted by the possibility of preparing triarylmethane dyes by the interaction of the sodio-derivatives of suitably substituted ketones with halogenated aromatic compounds. The observation by Frey (*Ber.*, 1895, **28**, 2514), that triphenylcarbinol is formed from benzophenone and bromobenzene in ether in the presence of sodium, made the project appear feasible. Blicke had also observed the formation of triphenylcarbinol from benzaldehyde, bromobenzene, and sodium, and he assumed the intermediate formation of benzophenone (*J. Amer. Chem. Soc.*, 1924, **46**, 2560).

Experiments at once showed that Michler's ketone, *pp'*-tetramethyldiaminobenzophenone, when heated with chlorobenzene in the presence of sodium, gave, after treatment of the product with water, the expected carbinol, which was readily converted into the well-known dyestuff, malachite green. The formation of the sodio-compound of the ketone is extremely slow in ether on account of the low solubility of the ketone and the low b. p. of the solvent, but in benzene or toluene at 80—100° the reaction is much more rapid, and these solvents are suitable for carrying out the synthesis. The reaction has been extended to a number of chlorinated hydrocarbons, including *o*-chlorotoluene, 4-chloro-*m*-xylene, chloro-*p*-xylene, α- and β-chloronaphthalene, and chloroanisoles. In place of Michler's ketone, *pp'*-tetraethyldiaminobenzophenone has been used; with chlorobenzene, this gives the carbinol corresponding with the dye, brilliant green. The condensation of the ketone with the chloro-compound requires two atoms of sodium per mol. of ketone for its completion; by the use of this proportion, with a slight excess of chloro-compound, there is little unchanged ketone and no sodium left at the end of the reaction. The reaction may therefore be expressed by the equations:

$$R_2CO + 2Na = R_2C(ONa)Na;$$
$$R_2C(ONa)Na + R'Cl = R_2R'C(ONa) + NaCl.$$

From our subsequent study of the ketyl compound, however, it is doubtful whether there is ever present any appreciable concentration of the disodio-compound (see following paper).

By means of this reaction several new dyes, not hitherto described because not readily obtainable by known methods, have been prepared. The yields are generally substantial; the carbinols

obtained have in some instances been difficult to purify, whilst in other instances good yields of the pure triarylcarbinol were readily obtained. The yield and quality of carbinol obtained vary with the reaction conditions and with the mobility of the reacting chlorine atom. As by-products, diaryls may be formed by the reaction $2RCl + 2Na = R{\cdot}R + 2NaCl$. On the other hand, the ketyl compound may undergo decomposition with formation of by-products, and may even react with toluene when this is used as solvent. The decomposition of the ketyl compound and its reactions will be discussed in Part II (following paper).

Attempts have been made to obtain dye-bases by heating the ketyl compounds with many other benzenoid chloro-compounds. The presence of groups which may be attacked by sodium, such as nitro- and amino-groups, is always inimical to the reaction. Dichloro-compounds, such as *p*-dichlorobenzene and 4 : 4′-dichlorodiphenyl, gave dye-bases, but difficulty was experienced in purifying them; whilst more highly chlorinated compounds, such as tetrachlorotoluene, only gave traces of dye-base, under the conditions used.

In purifying some of the carbinols obtained, it was observed that, when the dye salts were basified with ammonia, the basified product had an abnormally high nitrogen content. It was eventually proved that basification with ammonia gave, not the carbinol, but the corresponding amine, *e.g.*, $C(NH_2)(C_6H_4{\cdot}NMe_2)_2(C_6H_4Me)$. A similar observation has been made by Noelting and Saas (*Ber.*, 1913, **46**, 953), who obtained the amine $C(NH_2)(C_6H_4{\cdot}NMe_2)_3$ by the action of ammonia on an aqueous solution of crystal violet.

Experimental.

pp′-Tetramethyldiaminodiphenyl-o-tolylcarbinol, $[(CH_3)_2N{\cdot}C_6H_4]_2C(OH){\cdot}C_6H_4{\cdot}CH_3$.—A mixture of 13·4 g. of *pp′*-tetramethyldiaminobenzophenone, 2·3 g. of sodium, 7 g. of *o*-chlorotoluene, and 50 c.c. of dry toluene was heated in a closed flask provided with a stirrer at 100—105° for 16 hours. The ketone dissolved to a pale yellow solution, but as the reaction proceeded the mixture darkened and a light brown, crystalline powder gradually separated. A little water was added to the reaction mixture, and the toluene and any excess of *o*-chlorotoluene were removed by steam-distillation. The brown, gummy residue of impure carbinol became semi-solid on standing. From the aqueous liquor, a small quantity of *p*-dimethylaminobenzoic acid was obtained by neutralisation with acetic acid. The crude carbinol was extracted with ligroin, filtered from insoluble residue, and the solution evaporated. The carbinol so obtained was dissolved in 100 c.c. of boiling 10% oxalic acid solution and filtered from in-

soluble matter. The oxalate separated on cooling in green, bronzy crystals. These were redissolved in 100 c.c. of hot water and a further amount of insoluble matter was filtered off. This latter contained a little unchanged Michler's ketone. The residue left when the crude carbinol was extracted with ligroin consisted mainly of a product crystallising from toluene in colourless needles, m. p. 190°, which has been identified as *pp'*-tetramethyldiaminodiphenylbenzylcarbinol, $[(CH_3)_2N\cdot C_6H_4]_2C(OH)\cdot CH_2\cdot C_6H_5$. The mode of formation and properties of this substance will be discussed in Part II. The solution of the oxalate of the carbinol was basified with excess of sodium hydroxide. The blue precipitate of pp'-*tetramethyldiaminodiphenyl*-o-*tolylcarbinol* was filtered, washed, dried, boiled out with ligroin, and recrystallised from alcohol. It forms small colourless needles, m. p. 132·5°, becoming light blue on exposure to air. Yield, 8 g. (Found : N, 7·8. $C_{24}H_{28}N_2O$ requires N, 7·8%). The carbinol is moderately soluble in the cold in the usual organic solvents, and readily soluble in warm alcohol and toluene.

When the oxalate is basified with ammonia, pp'-*tetramethyldiaminodiphenyl*-o-*tolylmethylamine* is obtained, which, when recrystallised from ligroin–toluene, has m. p. 163° (Found : N, 11·7. $C_{24}H_{29}N_3$ requires N, 11·7%).

In concentrated sulphuric or hydrochloric acid, the carbinol gives a reddish-brown solution which turns green on addition of water, finally changing to blue. The oxalate gives an intense blue solution in water and a greenish-blue solution in alcohol. Aqueous solutions of the salts of the carbinol dye tannin-mordanted cotton greenish-blue.

Reduction of the carbinol with zinc and 2*N*-hydrochloric acid gave *pp'*-tetramethyldiaminodiphenyl-*o*-tolylmethane, white, glistening needles from alcohol, m. p. 102° (compare Noelting and Gerlinger, *Ber.*, 1906, **39**, 2042).

4-Chloro-*m*-xylene condenses similarly with Michler's ketone to give pp'-*tetramethyldiaminodiphenyl*-m-4-*xylylcarbinol*. This base crystallises from alcohol in small, colourless needles, m. p. 145°.

pp'-*Tetramethyldiaminodiphenyl*-p-*anisylcarbinol*,

$$(NMe_2\cdot C_6H_4)_2C(OH)\cdot C_6H_4\cdot OMe.$$

—A mixture of 13·4 g. of Michler's ketone, 2·3 g. of sodium, 7·5 g. of *p*-chloroanisole, and 50 c.c. of toluene was heated in a boiling water-bath for 12—16 hours in a closed flask with a stirrer. The crude carbinol, obtained by treating the product with water and removing toluene by steam-distillation, was converted into the *oxalate*, which crystallised in bronzy nodules. These were redissolved in hot water, filtered from a little ketone, and the solution was basified with ammonia; the bluish-white *carbinol* was filtered off, washed with a little alcohol, and dried. It separated from ligroin partly as

gum and partly as crystals; yield, 5·8 g. The latter crystallised from benzene–ligroin in almost colourless needles, m. p. 153° (Found: C, 76·6; H, 7·4; N, 7·5. $C_{24}H_{28}O_2N_2$ requires C, 76·6; H, 7·4; N, 7·4%). The carbinol dissolves in organic acids, *e.g.*, oxalic and acetic acids, to give intense green solutions. Mineral acids give brown solutions turning green on dilution with water. Solutions of the salts dye tannin-mordanted cotton greenish-blue.

pp′-*Tetramethyldiaminodiphenyl*-β-*naphthylcarbinol*.—A mixture of 6·7 g. of Michler's ketone, 1·2 g. of sodium, 4·5 g. of β-chloronaphthalene, and 30 c.c. of dry toluene was stirred for 4½ hours in a boiling water-bath. A dark-coloured product separated during the heating, and on cooling, a copious, grey, crystalline deposit was obtained. This was filtered, washed with a little toluene, and warmed with water; the crude carbinol then remained as a yellow, crystalline powder. The main impurities are unchanged ketone, β-chloronaphthalene, and an appreciable amount of ββ-dinaphthyl. The crude carbinol was purified by conversion into the crystalline oxalate and basification with ammonia; yield, 4·1 g. The *carbinol* crystallises best from aqueous pyridine (in needles) or from benzene–ligroin (in prisms), m. p. 181° (Found: N, 7·0. $C_{27}H_{28}N_2O$ requires N, 7·1%).

pp′-*Tetraethyldiaminodiphenyl*-β-*naphthylcarbinol*.—The reaction proceeds similarly with equivalent amounts of tetraethyldiaminobenzophenone, β-chloronaphthalene, and sodium. In this case the carbinol is easy to purify owing to its sparing solubility in hot alcohol, the impurities being readily soluble. The alcohol-extracted *carbinol*, recrystallised from benzene–ligroin, forms colourless plates, m. p. 177° (Found: N, 6·2. $C_{31}H_{36}N_2O$ requires N, 6·2%). Yield, 51%. The carbinol forms green salts with acids, and aqueous solutions of such salts dye tannin-mordanted cotton a bright yellowish-green.

pp′-*Tetramethyldiaminodiphenyl*-α-*naphthylcarbinol*.—This carbinol is obtained when α-chloronaphthalene is heated with Michler's ketone and sodium. Owing to the greater reactivity of the α-chlorine atom, a much larger proportion of αα-dinaphthyl is formed and this product collects in the portion insoluble in oxalic acid. The crude carbinol is best purified by solution in hot toluene and partial precipitation with ligroin. pp′-*Tetramethyldiaminodiphenyl*-α-*naphthylcarbinol* crystallises from acetone in colourless needles, m. p. 167° (Found: N, 7·0. $C_{27}H_{28}N_2O$ requires N, 7·1%). pp′-*Tetramethyldiaminodiphenyl*-α-*naphthylmethylamine*, obtained by basifying the oxalate with ammonia, has m. p. 186° (Found: N, 10·3. $C_{28}H_{29}N_3$ requires N, 10·6%).

[illegible], MANCHESTER. [*Received, June 8th*, 1927.]

CCXCI.—*Reactions of Sodium Compounds of Aromatic Ketones. Part II. Their Reaction with Methyl and Methylene Groups and their Products of Decomposition.*

By Ernest Harry Rodd and Frank William Linch.

In the preceding paper, it was shown that Michler's ketone and its ethyl homologue combine with sodium in an indifferent solvent to form ketyl compounds which react with aryl chlorides to form triarylcarbinols. Further examination of these ketyl compounds has shown that they are remarkably reactive and that by their means syntheses of a hitherto unrecorded type can be effected. In the course of experiments on the action of sodium on Michler's ketone in toluene solution, a product was obtained in considerable quantity which was eventually proved to be *pp'*-tetramethyldiaminodiphenylbenzylcarbinol, and could only have been produced by the action of the ketyl compound on the methyl group of the toluene. This compound was found to be identical with that obtained as a by-product in the preparation of a triarylcarbinol from Michler's ketone and *o*-chlorotoluene by the action of sodium in toluene solution (Part I). Further experiments showed that the ketyl compound readily reacts with methyl and methylene groups which are generally only attacked by powerful oxidising agents. By this reaction we have been able to prepare with facility a number of new compounds which would be obtainable by known methods only with considerable difficulty.

The Reaction between Michler's Ketone and Toluene in the Presence of Sodium.—It has been shown by previous workers (see Part I) that benzophenone and other aromatic ketones form disodio-compounds, $CR_2(ONa)Na$. If a similar compound were formed by Michler's ketone, it should give, when decomposed by water, Michler's hydrol (tetramethyldiaminobenzhydrol). We attempted to prepare the hydrol by heating Michler's ketone in toluene solution with two atomic proportions of sodium, and obtained, besides the expected hydrol and other by-products which will be discussed later, a considerable yield of pp'-*tetramethyldiaminodiphenylbenzylcarbinol* (I). When benzene was used as solvent instead of toluene, no trace of this compound was formed.

The evidence for the constitution of the compound is as follows. Analysis indicated the formula $C_{24}H_{28}ON_2$, and a molecular-weight determination in camphor gave 350 (calc., 360). The compound shows the properties of a colour base, giving deep blue solutions when dissolved in dilute mineral or acetic acids, but when the solution is

heated the colour disappears. This colour change is due to the formation of a new base having the composition $C_{24}H_{26}N_2$, which has been identified as *ββ-tetramethyldiaminodiphenylstyrene* (II), m. p. 135°. The new base is evidently formed from the first by the loss of the elements of water, and since salt formation first occurs, the formation of the styrene may be represented thus:

$$CH_2Ph\cdot C(OH)\!<\!\begin{matrix}C_6H_4\cdot NMe_2\\C_6H_4\cdot NMe_2\end{matrix} \xrightarrow{HCl} CH_2Ph\cdot C\!<\!\begin{matrix}C_6H_4\cdot NMe_2Cl\\C_6H_4\cdot NMe_2\end{matrix}$$

(I.) (Blue.)

$$\xrightarrow{\text{on heating}} CHPh{:}C\!<\!\begin{matrix}C_6H_4\cdot NMe_2,HCl\\C_6H_4\cdot NMe_2\end{matrix} \text{ (II.)}$$

(Colourless.)

By oxidation of the tetramethyldiaminodiphenylbenzylcarbinol with lead peroxide in dilute hydrochloric acid in the cold, phenylacetic acid is obtained, whilst oxidation of the styrene compound readily gives first a greenish-blue dyestuff and then benzaldehyde. The styrene compound is stable to boiling alcoholic potassium hydroxide, but when fused with potassium hydroxide it gives Michler's ketone. All these reactions confirm the constitutions assigned to the two new bases.

The conversion of the carbinol into the styrene derivative is best effected by boiling it for a short time with 10% hydrochloric acid; when the solution is cooled the styrene separates as a sparingly soluble, white, crystalline *dihydrochloride*. This property facilitates the detection of the carbinol and the purification of the styrene. The dihydrochloride is hydrolysed by water with precipitation of the base. A characteristic property of this styrene, and of other similar compounds which we have made, is its oxidation in acetic or dilute mineral acid to an intense blue dyestuff by chromic acid or lead peroxide. The fact that solutions of the carbinol prepared in the cold do not give this reaction but that they give it after heating shows that the conversion of the carbinol into the styrene does not proceed readily in the cold. The cold oxidation of the carbinol to phenylacetic acid illustrates the same point.

When the identity of the product obained from toluene had been established, experiments were extended, and it was found that *p*-xylene gave a similar product with Michler's ketone, whilst tetraethyldiaminobenzophenone reacted similarly with toluene in the presence of sodium.

Reaction with Substances containing the Methylene Group.—Regarding the formation of a benzyl derivative from toluene as due to oxidation of the methyl group with simultaneous formation of benzhydrol, we considered that a substance containing a readily oxidisable methylene group should also react with the sodium

derivative of Michler's ketone. As a convenient substance with which to experiment we chose *pp'*-tetramethyldiaminodiphenylmethane. When this was heated with Michler's ketone and sodium in benzene solution, we obtained without difficulty a good yield of *octamethyltetra-aminotetraphenylethanol*,

$$(NMe_2 \cdot C_6H_4)_2C(OH) \cdot CH(C_6H_4 \cdot NMe_2)_2 \text{ (III)},$$

which by dehydration with sulphuric acid gave octamethyltetra-aminotetraphenylethylene, which has been described by Gattermann (*Ber.*, 1895, **28**, 2876) and Willstätter and Goldmann (*Ber.*, 1906, **39**, 3765). This observation confirmed our conclusions with regard to the reaction products from toluene, and suggested that the reaction might be of general application. To obtain further confirmatory evidence, carbinols were prepared from (*a*) Michler's ketone and tetraethyldiaminodiphenylmethane, and (*b*) tetraethyldiaminobenzophenone and tetramethyldiaminodiphenylmethane, and the two carbinols, $(NMe_2 \cdot C_6H_4)_2C(OH) \cdot CH(C_6H_4 \cdot NEt_2)_2$ (IV) and $(NEt_2 \cdot C_6H_4)_2C(OH) \cdot CH(C_6H_4 \cdot NMe_2)_2$ (V) were shown to give the same ethylene compound by dehydration with sulphuric acid.

Other substances of diverse character containing the methylene group, which have been found to react with the ketyl compound, are acenaphthene and fluorene. In each case, the expected compound was obtained without difficulty in benzene solution. Tetrahydronaphthalene, however, failed to react.

Decomposition Products of the Sodium Ketyl Compound and the Mechanism of its Reaction with Methyl and Methylene Groups.— To explain the ready attack of the ketyl compound on methyl and methylene groups, it is simplest to assume that the radicals $CR_2(ONa)\cdot$ (where $R = NMe_2 \cdot C_6H_4$) are the active agents. Since Michler's hydrol is always a product, the reaction, in the case of toluene, assumes the form $2CR_2(ONa)\cdot + CH_3Ph = CR_2H(ONa) + CR_2(ONa) \cdot CH_2Ph$. For this reaction, only one atom of sodium should be required per mol. of ketone, but when only one atomic proportion of sodium was heated with the ketone in toluene solution, although in the course of 2 hours the whole of the sodium had disappeared, yet no benzyl compound was formed. This observation led us to make a more careful study of the reaction.

With 0·95 atomic proportion of sodium, in two experiments, after heating in a closed vessel for 2 hours and 16 hours, respectively, identical results were obtained: no benzyl carbinol was found, about one-third of the ketone was recovered, and the products included about 0·1 mol. of Michler's hydrol, 0·2 mol. of dimethylaminobenzoic acid, and other bases, including much crystal violet. These, together with dimethylaniline, are the usual products under similar conditions.

When the sodium is increased to 1·5 atomic proportions, a maximum yield of benzylcarbinol is obtained, and sodium remains unchanged at the end; no ketone is recovered. The same result is obtained by using 2 atomic proportions of sodium. A typical experiment, with 1 mol. of Michler's ketone, gave approximately 0·37 mol. of tetramethyldiaminodiphenylbenzylcarbinol, 0·30 mol. of hydrol, 0·08 mol. of dimethylaminobenzoic acid, and 0·11 mol. of colour base.

When benzene is used as solvent, with 2 atoms of sodium, the principal product is Michler's hydrol, with a fair amount of colour base.

During the reaction, the solution gradually assumes an intensely greenish-blue colour, but if air is passed through the apparatus, no blue colour is produced, no hydrol is obtained, and most of the ketone is recovered unchanged, but some dimethylaminobenzoic acid and crystal violet are formed, together with a much redder dyestuff, probably indicating oxidation of the dimethylamino-groups of crystal violet.

If a chloro-compound is added to the reaction mixture, when only one atomic proportion of sodium or less is used, no blue colour appears, but the formation of dye base proceeds at once (*e.g.*, of malachite green, from chlorobenzene), and only traces of the above by-products are formed.

Whilst we feel that more data are required before an entirely satisfactory explanation can be given of all the above observations, we put forward the following discussion tentatively. First, with regard to the colour of the solution obtained when sodium dissolves in a solution of the ketone, it has been freely assumed by Schlenk that free radicals of the type $R_2C(ONa)\cdot$ are coloured, just as Gomberg assumes that free radicals, $R_3C\cdot$, have colour. If this assumption be accepted, then free radicals must always be present in our toluene solutions of the ketyl compound at all stages of the reaction, but the quantity of free radical present may be very small, since traces of oxygen rapidly decolorise the solution. In the presence of a chloro-compound, no colour ever appears, and since the formation of a triarylcarbinol starts at once, it is probably the monosodio-derivative of the ketone which attacks the chloro-compound, as suggested by Schlenk and Weickel to explain the action between sodiobis-diphenylyl ketone and methyl iodide (*Ber.*, 1911, **44**, 1182):

$$2R_2C(ONa)\cdot + R'Cl \begin{cases} \rightarrow R_2R'C(ONa) \xrightarrow{H_2O} R_2R'C(OH) \\ \rightarrow R_2CCl(ONa) \longrightarrow R_2CO + NaCl \end{cases}$$

It is not necessary then to assume the formation of a disodio-compound of the ketone (compare Part I).

The non-formation of benzyl compound when only one atom of sodium is used may be due to the greater tendency of a monosodio-radical to combine with another mol. of ketone than to attack a methyl group. We suggest that an intermediate compound, probably of the type $R_2C(ONa)\cdot O\cdot CR_2Na$, is formed,* combination taking place through the oxygen atom, rather than between two carbon atoms. It has been shown recently by Schorigen (*Ber.*, 1926, **59**, 2510) that when sodium acts on complex ethers the point of attack is the oxygen atom. Hence, when more than one atomic proportion of sodium is available, the intermediate compound would be attacked with formation of active free radicals which would attack the toluene :

$$\begin{array}{l} R_2C(ONa)-\!\!\!-\!\!\!-O \\ +\ C_6H_5\cdot CH_2-\!\!\!-H\ \ CR_2Na \end{array} + Na \longrightarrow \begin{array}{l} R_2C\!-\!\!-ONa \\ C_6H_5\cdot CH_2 \end{array} + \begin{array}{l} ONa \\ HCR_2 \end{array} + Na$$

It would appear that the additional sodium acts catalytically, and this agrees with the experimental results, as far as we can interpret them. Owing to side reactions, however, it has not been possible to determine how much of the sodium employed takes part in this reaction.

The observation that oxygen destroys the blue colour formed by the addition of sodium to the ketone, mainly with re-formation of the ketone, agrees with Schlenk's observations on simple aromatic ketones (*Ber.*, 1914, **47**, 487) :

$$2R_2C(ONa)\cdot + O_2 \longrightarrow R_2C(ONa)\cdot O\cdot O\cdot CR_2(ONa) \longrightarrow 2R_2C{:}O + Na_2O_2.$$

The formation of *p*-dimethylaminobenzoic acid, crystal-violet base, and dimethylaniline as by-products must be attributed to a general loosening of the bonds between the aryl radicals and the keto-carbon atom in the ketyl compound. Since these products are formed to the greatest extent when there is a deficiency of sodium, they are probably the result of internal rearrangement in a complex molecule or radical, *e.g.*, $CR_2(ONa)\cdot O\cdot CR_2\cdot \longrightarrow \cdot CR(ONa)\cdot O\cdot CR_3$ $\xrightarrow{+R_2CO}$ $R_2CNa\cdot O\cdot CR(ONa)\cdot O\cdot CR_3$. The last complex on hydrolysis should give 1 mol. each of Michler's hydrol, dimethylaminobenzoic acid, and crystal-violet base. Undoubtedly we have not yet identified all the by-products, so it is not possible to give a complete picture of the changes taking place. We do not exclude the possibility of the formation of the pinacol, $R_2C(ONa)\cdot CR_2(ONa)$, but we have as yet no evidence for it.

* This type of intermediate compound was also suggested by Beckmann and Paul (*Annalen*, 1891, **266**, 1) to explain the formation of benzophenone and benzhydrol from the monosodio-derivative of benzophenone.

EXPERIMENTAL.

The Michler's ketone used for these experiments was the technical product, purified by boiling with very dilute hydrochloric acid and recrystallising the insoluble portion from alcohol. The toluene used was the commercial product, redistilled and dried over sodium.

pp'-*Tetramethyldiaminodiphenylbenzylcarbinol* (I).—In a flask fitted with a sealed stirrer and a reflux condenser were placed 800 c.c. of toluene, 268 g. of Michler's ketone and 46 g. of sodium, and the whole was heated in a bath kept at 100—105° for 12 hours, with continuous stirring. During the heating, the colour of the solution became deep greenish-blue and remained so throughout the experiment. The blue colour is destroyed at once by air. The contents of the flask were cooled, poured off from the unchanged sodium, and treated with ice to hydrolyse the sodium compounds. The whole was then steam-distilled to remove the toluene and dimethylaniline, if any. The bases were filtered from the alkaline aqueous liquor and extracted thoroughly with ether. The residue consisted of nearly pure pp'-*tetramethyldiaminodiphenylbenzylcarbinol*, 131 g., m. p. 185°. (In those experiments in which only 0·95 mol. of sodium is used, the residue at this stage consists of nearly pure unchanged ketone, which is also almost insoluble in ether.) A similar experiment gave 36 g., m. p. 187°, from 67 g. of Michler's ketone. By recrystallisation from toluene the base is obtained in colourless, transparent needles, often pointed at one end only, m. p. 190·5° (Found: C, 79·62; H, 7·79; N, 7·72; *M*, cryoscopic in camphor, 350. $C_{24}H_{28}ON_2$ requires C, 80·00; H, 7·77; N, 7·77%; *M*, 360). The carbinol dissolves in acetic acid with a blue colour, which becomes intense on warming, then quickly fainter, and finally very pale blue.

The other products of the reaction were separated as follows: The alkaline filtrate obtained above was neutralised to precipitate the *p*-dimethylaminobenzoic acid, which was filtered, dried, and weighed. From the solid residue, consisting of carbinol and other bases, the ether had extracted the latter (see above), and this extract was freed from solvent and dissolved in dilute sulphuric acid. A strong solution of sodium hydrogen sulphite was then added, and the mixture warmed at 60°, whereby the Michler's hydrol was converted into *pp'*-tetramethyldiaminodiphenylmethane-ω-sulphonic acid. The solution was made alkaline with sodium hydroxide, filtered from the precipitated bases, and the sodium ω-sulphonate salted out (when dried, it is approx. 80% pure). The bases were extracted with dilute oxalic acid solution (which left a little ketone in those cases where there was a deficiency of sodium, see p. 2181) and the solution

yielded a considerable amount of crystal violet oxalate. Other bases (unidentified) were, however, also present.

In one experiment, the dimethylaniline in the recovered toluene was found to be 1·4 g. from 67·0 g. of ketone, and the other products, separated as described above, were 27·0 g. of the benzylcarbinol (m. p. 190°, crude), 5·0 g. of dimethylaminobenzoic acid, about 26 g. of Michler's hydrol, and 8·5 g. of crude crystal-violet base.

An experiment was carried out in which the apparatus was sealed with special care and connected to a manometer, after the required temperature had been attained. There was no evidence of any change of pressure, showing that no gaseous products are formed.

ββ-pp′-*Tetramethyldiaminodiphenylstyrene* (II).—This may be prepared from the crude *pp′*-tetramethyldiaminodiphenylbenzylcarbinol by dissolving 20 g. in 100 c.c. of 2*N*-hydrochloric acid and boiling for ½ hour; on cooling, the solution deposits 20 g. of the *dihydrochloride* of the styrene in soft, shining, colourless needles (Found in crude product: Cl, 16·0. $C_{24}H_{28}N_2Cl_2$ requires Cl, 17·1%). The basification is carried out by suspending the hydrochloride in water and gradually stirring in dilute sodium hydroxide. The *base*, recrystallised from a mixture of acetone and methyl alcohol, forms short, pale yellow prisms, m. p. 135° (Found: C, 84·66, 84·21; H, 7·90, 7·92; N, 8·17. $C_{24}H_{26}N_2$ requires C, 84·21; H, 7·60; N, 8·19%). In a quantitative experiment on the conversion of the pure benzylcarbinol into the styrene, 0·7662 g. of the former gave 0·7250 g. of the latter (theory, 0·728 g.).

Oxidation of pp′-*Tetramethyldiaminodiphenylbenzylcarbinol.*—14·4 G. of the carbinol were dissolved in 350 c.c. of cold *N*-hydrochloric acid. A thin paste of 29 g. of lead peroxide was added gradually to the stirred solution of the carbinol and oxidation was allowed to proceed for some hours at the ordinary temperature. The lead was precipitated with sodium sulphate and the filtrate basified with sodium hydroxide. The alkaline solution was extracted with ether, but the basic products of the oxidation could not be obtained sufficiently pure for identification. The solution was then acidified with dilute hydrochloric acid and again extracted with ether. After removal of the ether, an oily residue was left which solidified on standing (5·1 g.). It was recrystallised twice from hot water, giving large, glistening plates, m. p. 76—77°. This product had all the properties of phenylacetic acid, and its identity was established by comparison (mixed m. p.) with a sample prepared from benzyl cyanide.

Octamethyltetra-aminotetraphenylethanol, (III).—A mixture of 26·8 g. of Michler's ketone, 4·6 g. of sodium, 50 g. of *pp′*-tetramethyldiaminodiphenylmethane, and 100 c.c. of dry benzene was heated

at 85—90° for 16 hours with efficient stirring. The sodium was separated and the benzene removed by steam-distillation. The residual white solid was filtered off and boiled out twice with alcohol to remove Michler's hydrol and other impurities. The insoluble white residue (20 g.) was substantially pure *octamethyltetra-aminotetraphenylethanol*. It is sparingly soluble in all neutral organic solvents and is best recrystallised from toluene; colourless needles, m. p. 255° (Found: C, 77·7; H, 8·0; N, 10·7. $C_{34}H_{42}N_4O$ requires C, 78·1; H, 8·0; N, 10·7%). It dissolves in weak mineral acids or glacial acetic acid to give greenish-blue salts which become violet on addition of lead peroxide.

The same method of preparation and the same molecular proportions of materials were used in the following preparations.

αα-4 : 4′-*Tetraethyldiaminodiphenyl*-ββ-4 : 4′-*tetramethyldiaminodiphenylethan-α-ol* (V) from *pp′*-tetraethyldiaminobenzophenone and *pp′*-tetramethyldiaminodiphenylmethane: white needles from toluene or alcohol–chloroform, m. p. 228° (Found: N, 9·6. $C_{38}H_{50}N_4O$ requires N, 9·7%).

αα-4 : 4′-*Tetramethyldiaminodiphenyl*-ββ-4 : 4′-*tetraethyldiaminodiphenylethan-α-ol* (IV) from *pp′*-tetramethyldiaminobenzophenone and *pp′*-tetraethyldiaminodiphenylmethane: white needles from toluene or alcohol–chloroform, m. p. 229—230° (Found: N, 9·6. $C_{38}H_{50}N_4O$ requires N, 9·7%).

Both compounds dissolve in dilute mineral acids or glacial acetic acid, giving greenish-blue solutions which turn violet on the addition of a little lead peroxide. These ethanol derivatives were converted into the corresponding ethylene compounds by warming with concentrated sulphuric acid.

Octamethyltetra-aminotetraphenylethylene,

$$(NMe_2{\cdot}C_6H_4)_2C{:}C(C_6H_4{\cdot}NMe_2)_2.$$

—5 G. of the ethanol were dissolved in 25 c.c. of concentrated sulphuric acid and warmed for ½ hour in a boiling water-bath. The pale green solution was poured into ice water and the base precipitated by the addition of sodium hydroxide as a yellowish-white powder; yield 4·7 g. It crystallises from acetone–methyl alcohol in greenish-yellow needles, m. p. 314—316° (Gattermann, *Ber.*, 1895, **28**, 2876, gives m. p. 310—315°) (Found: N, 11·1. Calc. for $C_{34}H_{40}N_4$: N, 11·1%). It forms colourless salts when dissolved in acids, but the solutions turn violet on the addition of a little lead peroxide.

αα-4 : 4′-Tetraethyldiaminodiphenyl-ββ-4 : 4′-tetramethyldiaminodiphenylethanol and αα-4 : 4′-tetramethyldiaminodiphenyl-ββ-4 : 4′-tetraethyldiaminodiphenylethanol when warmed with concentrated sulphuric acid gave the same product, *viz.*, αα-4 : 4′-*tetraethyldiaminodiphenyl*-ββ-4 : 4′-*tetramethyldiaminodiphenylethylene*, pale

yellow needles from alcohol–chloroform, m. p. 212°. The identity was established by mixed melting-point and nitrogen determinations (Found: N, 10·0, in each case. $C_{38}H_{48}N_4$ requires N, 10·0%).

4 : 4′-*Tetramethyldiaminodiphenylacenaphthenylcarbinol*, $(NMe_2{\cdot}C_6H_4)_2C(OH){\cdot}C_{12}H_9$.—A well-agitated mixture of 26·8 g. of Michler's ketone, 4·6 g. of sodium, 30 g. of acenaphthene, and 100 c.c. of dry benzene was heated at 85—90° for 16 hours. The excess of sodium was separated and the benzene removed by steam-distillation. The residual crystalline mass was filtered off and boiled several times with alcohol to remove impurities. The white, insoluble residue (12 g.) was recrystallised from toluene; colourless needles, m. p. 232° (Found: N, 6·7. $C_{29}H_{30}ON_2$ requires N, 6·6%). It dissolves in dilute mineral acids or glacial acetic acid to reddish-blue solutions. These solutions are almost decolorised by boiling, and on the addition of a little lead peroxide the resulting solution assumes a violet colour.

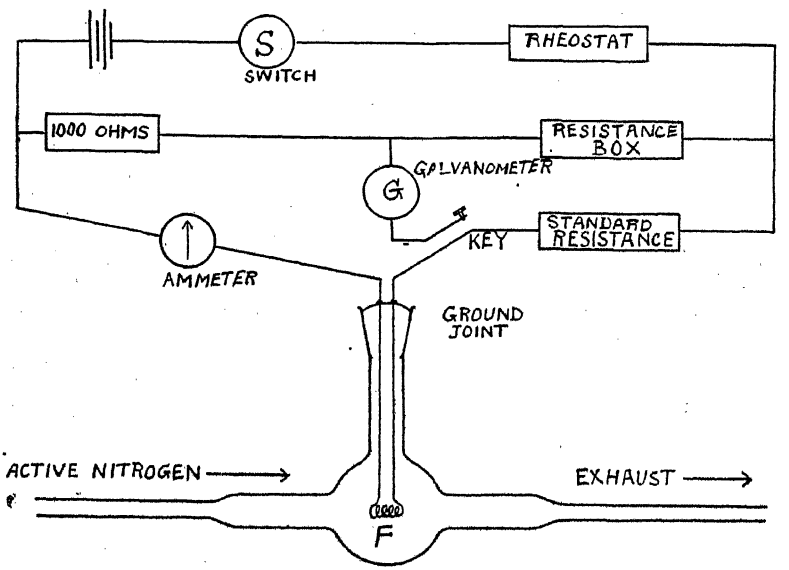
4 : 4′-*Tetramethyldiaminodiphenylmethyleneacenaphthene*, $(NMe_2{\cdot}C_6H_4)_2C{:}C_{12}H_8$.—Since concentrated sulphuric acid sulphonates the acenaphthene nucleus, in this case the ethylene derivative was prepared by boiling 5 g. of the ethanol for an hour with aqueous hydrochloric acid. On cooling, a crystalline *hydrochloride* was deposited in fine, white needles. The *base* was obtained as a greenish-yellow powder by basifying with sodium hydroxide. The dried product (4·7 g.) was recrystallised from chloroform–alcohol; pale yellow plates, m. p. 209° (Found: N, 7·0. $C_{29}H_{28}N_2$ requires N, 6·9%). It dissolves in acetic acid to a colourless solution which turns violet on addition of lead peroxide.

4 : 4′-*Tetramethyldiaminodiphenylmethylenefluorene*, $[N(CH_3)_2{\cdot}C_6H_4]_2C{:}C\begin{matrix}C_6H_4\\C_6H_4\end{matrix}$.—A mixture of 13·4 g. of Michler's ketone, 2·3 g. of sodium, 20 g. of fluorene, and 50 c.c. of dry benzene was heated with stirring at 85—90° for 16 hours. The unchanged sodium (0·5 g.) was separated and the benzene removed by steam distillation. The residual, orange, crystalline product was boiled three times with alcohol and the insoluble residue (8·5 g.) was recrystallised first from toluene and finally from chloroform–alcohol; pale yellow needles, m. p. 239—240° (Found: N, 6·7. $C_{30}H_{28}N_2$ requires N, 6·7%). It dissolves in dilute mineral acids or acetic acid to a pale yellowish-green solution which turns blue on addition of lead peroxide. In this case, dehydration of the carbinol to the ethylene derivative has occurred at some stage which has not been determined.

The analyses recorded in Parts I and II were carried out by Mr. W. H. Cliffe, whose help we gratefully acknowledge. The work was carried out in the Research Department of the British Dyestuffs Corporation, Ltd., to whom our thanks are due for permission to publish it.

BLACKLEY, MANCHESTER. [*Received, June 8th*, 1927.]

Addendum.—Since the above work was completed, a paper by Madelung and Völker has appeared (*J. pr. Chem.*, 1927, **115**, 24), in which the formation of *pp'*-tetramethyldiaminodiphenylbenzylcarbinol and of *pp'*-tetramethyldiaminodiphenylstyrene from Michler's ketone and magnesium benzyl chloride is described, the styrene being the principal product. The m. p.'s are stated to be 173° and 129°, respectively, whereas our m. p.'s are 190·5° and 135°. The above authors' compounds are evidently impure, and are most probably contaminated with unchanged ketone, since our observations have shown that with Michler's ketone the Grignard reaction only proceeds to a very limited extent. It is to be noted that earlier workers, by the action of magnesium alkyl halides on Michler's ketone, never obtained carbinols, but always the corresponding ethylene derivative. Madelung and Völker state that the carbinol and the styrene both give the same blue colour in acetic acid (*loc. cit.*, pp. 29, 41). This does not agree with our observations; we find that the former gives a very intense blue colour with cold acetic or with one equiv. of dilute mineral acid, comparable in intensity with the colour given by a true triphenylmethane-dye base, whilst the styrene gives a very weak colour. When the intensely coloured solution of the carbinol in acid is heated, the colour gradually disappears and finally approximates in intensity to that given by the styrene.



CCXCII.—*On Active Nitrogen. Part III. Active Nitrogen and the Metals.*

By ERIC JOHN BAXTER WILLEY.

WHILST metallic vapours readily combine with active nitrogen to form nitrides (Rayleigh, *Proc. Roy. Soc.*, 1913, *A*, **88**, 539; Willey, *J. Soc. Chem. Ind.*, 1924, **43**, 263), the clean, cold metals rarely exert any noticeable influence upon the afterglow. In ordinary circumstances, copper forms the only exception to this statement, but if mercury or low-melting alloys of lead be employed and the gas be bubbled through the liquid, this rapidly becomes foul and abundant nitride formation occurs, suggesting that the inactivity

of the clean and cold metals is due to the formation of a skin of nitride, which, being inactive, protects the underlying portions of the metal against attack. In view of the fundamental importance of nitride formation in the catalysts employed in the synthesis of ammonia, it was decided to investigate in some detail the effect of active nitrogen on the metals; the results obtained support the foregoing theory, and, moreover, it has been found that in several cases the metals become active catalysts in the destruction of the afterglow at the temperature of decomposition of their nitrides. The experimental data also show that the energy of active nitrogen

FIG. 1.

is *ca.* 45,000 cals./g.-mol., in excellent agreement with the value advanced in earlier communications (J., 1926, 1804; this vol., p. 669), and that the decay process is probably bimolecular with respect to the active nitrogen.

EXPERIMENTAL.

The apparatus employed is shown in Fig. 1. Active nitrogen, cooled to room temperature by passage down a thin-walled tube, flowed over the filament, F, which served both as a resistance thermometer and as a heating coil. The galvanometer and leads were enclosed in an earthed shield, and an auxiliary electrode, also earthed, was provided between F and the end of the discharge tube

order to afford protection from stray discharges; in this way, disturbance of the Wheatstone circuit was avoided. The filament was silver-soldered to heavy copper leads sealed through the ground joint as shown.

It was found that both with a bare platinum filament initially at room temperature and with filaments of other metals, as well as those obtained by electrodeposition of coatings so thin as not appreciably to alter the resistance of the original platinum, a very definite increase in temperature occurred when active nitrogen was drawn through the apparatus; this was least in the case of molybdenum and tungsten, and greatest with smooth-surface copper. No such increase in temperature was observed when the filament was replaced by a thermometer, thus showing that the heating effect is due to the decay of the endothermic active nitrogen at the surface of the metal.

With platinum, iron, silver, zinc, tungsten, and molybdenum, the relationship between the velocity of the gas stream (measured upon an arbitrary scale) and filament temperature was linear between the limits examined. The figures obtained for platinum are typical:

Flow speed	0·0	4·0	6·5	8·5	10·3	12·3
Resistance	1·302	1·313	1·320	1·325	1·330	1·335

(Owing to the limited capacity of the pump, it was not possible to work with flow speeds above 1·5 litres/hour, measured at atmospheric pressure.)

With a copper-coated filament, however, the temperature increment was much greater than that obtained previously and the glow ceased abruptly at the metallic surface; moreover, the curve obtained (Fig. 2) is different in form, the temperature rapidly increasing to a value at which it remains constant over a certain range of flow rate, and then again increasing. The existence of this flat portion, AB, is explicable on the assumption that the maximum destruction of active nitrogen at the surface is reached with a gas-velocity corresponding to the ordinate of A, but that at B the gas-velocity is high enough to set up turbulent motion round the filament, causing increased circulation of the gas and a consequent increase in the number of molecules deactivated by the metal. Support for this view was obtained in two ways. It was noticed that so long as the gas-velocity was not too high, the coating of copper remained intact and the experiments could be repeated as often as desired. Above a gas-velocity corresponding closely with B, however, the point at which the afterglow ceased (initially about 2 m. downstream in such experiments) began to recede rapidly, until after about a minute no afterglow was visible except

for localised patches round the electrodes. When the filament was dismounted, the copper coating was found to have vanished almost entirely, whilst the walls of the bulb had become reddish-brown in colour, just as if they had been " spattered " from a copper cathode. Prolonged treatment of the glass with nitric acid produced no change in its colour, and little or no copper could be detected in solution; but quantitative tests in which a long filament was first plated with copper and then cut in two, one half being used for a colorimetric determination of the copper and the other being subjected to the action of active nitrogen, showed that nearly the whole of the copper lost from the wire could be recovered from the bulb if this were powdered and fused with sodium carbonate. Even with the most rigorous protection against stray discharges, the result was the same, and hence it would appear that the disintegration is due to the evolution of heat at the copper surface owing to the decay of large amounts of active nitrogen thereat, whilst the scattered metal has so strong a catalytic effect as to " poison " the glass.

The nature of the copper surface has a great influence in this connexion. If the plating is spongy, the curve obtained shows only the merest trace of flattening, and the disintegration is rapid even at lower gas velocities than before. This " spattering " effect was still more pronounced when the coating had been prepared *in situ* by the reduction of copper oxide by means of active hydrogen in an auxiliary apparatus, whilst commercial copper wire which had been carefully cleaned did not show it at all. No other metal showed any disintegration.

It seems probable, therefore, that, in the case of other metals, the linear relation between gas-velocity and filament temperature corresponds with the portion of the curve to the left of A (Fig. 2), and that if a sufficiently high flow speed could have been attained, they would have given curves showing a similar flattening. It is possible, upon the basis of the data obtained here, to calculate (i) the relative order of catalytic efficiencies of these metals for the destruction of active nitrogen, and (ii), provided a certain assumption be made, the order of the decay process of active nitrogen.

(i) All other factors remaining constant, the increase in the temperature (ΔT) of a filament will be directly proportional to its area (A) and to the catalytic efficiency of the metal (E), and inversely proportional to its weight (W), *i.e.*, $\Delta T = kAE/W$. Now it was noticed that when a current of active nitrogen was drawn past a copper-coated filament, the glow appeared to be entirely extinguished provided that the flow speed was not too high, and hence we may assume that in these circumstances the whole of the

active nitrogen reaching the surface of the filament was transformed to the inert variety. We may thus calculate the catalytic efficiencies of the various metals employed, relative to copper as unity, as shown in Table I. The measurements were all made with filaments immersed in nitrogen flowing at the rate of 1·5 litres/hr. (measured at *N.T.P.*), the gas being at a pressure of 10 mm. Hg and containing 1·5% of active nitrogen.

TABLE I.

Metal.	100 *W*.	ΔT.	$A \times 10^4$.	*E*.
Platinum	0·85	8·0	2·2	0·24
Silver	2·1	12·5	3·9	0·26
Zinc	2·1	12·5	3·9	0·26
Iron	2·0	13·0	3·7	0·27
Copper (smooth)	1·15	36·0	2·8	1·00
Copper (spongy)	1·84	15·0	3·6	0·33
Tungsten	2·3	0·0	—	0·0
Molybdenum	0·8	0·0	—	0·0

(ii) Let us make the very probable assumption that a constant fraction of the active nitrogen present at any instant is decomposed at the filament surface; then, from the linear relation between the flow speed and the temperature increment in the filament, we see that the number of active nitrogen molecules present at any instant varies directly with the flow speed of the gas and therefore inversely as the time (t) taken for a molecule to travel from the discharge to the filament, *i.e.*,

$$[N_2'] = k'/t, \text{ or } -d[N_2']/dt = k'/t^2.$$

Hence the decay process is, upon this assumption, bimolecular with respect to the active nitrogen.

It was hoped to use the results of these experiments in conjunction with the Hertz–Knudsen equation (which provides a means of calculating the number of molecular impacts per unit area per second) to evaluate the energy of active nitrogen. Such attempts, however, did not lead to intelligible results. It was then thought that if the "blanketing" effect of the converted nitrogen round the filament could be eliminated by the use of a hot wire, data of more value might be obtained, for it is obvious that the conditions obtaining near the cold filaments are somewhat complicated. Furthermore, the metals should, *ex hypothesi*, become completely active at or about the temperatures of decomposition of their nitrides, and this view was tested in the next series of experiments.

The temperature of the wire was gradually raised by altering the adjustment of the rheostat, and its resistance was determined for each setting in a stream of inert nitrogen at 10 mm. pressure, a constant flow speed being maintained all the time; the usual

parabolic relationship between current and resistance was obtained, as shown in Figs. 3 A, B, and C. The nitrogen was then activated and the procedure repeated, with the result that in the case of

iron (Fig. 3 C), platinum, and silver (Fig. 3 A) marked "breaks" were found in the curves, at *ca.* 300°, 92°, and 30°, respectively. Moreover, at these temperatures the glow practically ceased as the

active nitrogen reached the filament, indicating that it was being destroyed by the hot wire. No departure from the calibration curve was noticed with tungsten and molybdenum filaments, but with copper (Fig. 3 B) the form of the curve shows that the section above the break has already been reached even at the ordinary temperature.

It will be noticed that, in the case of the iron-coated filament, the curves obtained for increasing and decreasing values of the current do not coincide; it is possible that this is due to sintering, in view of the temperature to which the filament was raised, for when the original deposit was replaced by a fresh one the discontinuity occurred just as before. No formation of nitride was observed in any of these experiments, but the platinum filament became coated with a dense layer of platinum-black, as observed by Beilby and Henderson (J., 1901, **79**, 1253) when this metal was heated in a current of gaseous ammonia.

Since it seemed likely that the comparative inactivity of commercially drawn copper wire as a catalyst for the decay of active nitrogen is due to surface phenomena which might be minimised when a hot filament is in contact with active nitrogen, the ordinary material was used in this case, with the result, as will now be shown, that complete activity appeared when the hot metal was used. The significance of these breaks in the curves is clearly that at the temperature concerned the filament is becoming catalytically active in the destruction of active nitrogen; energy is therefore being liberated and the rise in temperature of the filament follows. From these data we may evaluate approximately the energy of active nitrogen, as follows.

Consider two points, A and B, on a line parallel to the abscissa (in Fig. 3 A) which is drawn to cut the two curves where they have become approximately parallel. Then the energy supplied by the active nitrogen (in cals./sec.) is

$$R_T(C^2_B - C^2_A)/4{\cdot}2 \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{(i)}$$

where R_T is the ohmic resistance of the filament at the points A and B, and C_A and C_B are the currents (amps.) corresponding to A and B, respectively.

Since at this point the glow had almost entirely been lost in the gas below the filament, we may assume that all the active nitrogen passing was destroyed, and from a knowledge of the flow rate of the gas and its active-nitrogen content we can calculate n, the number of molecules undergoing conversion per second. Thus from (i) we have $R_T(C^2_B - C^2_A) = nq$, where q is the energy of a single

molecule of active nitrogen. The energy of active nitrogen per g.-mol., Q, is then given by the expression :

$$Q = R_T(C^2_B - C^2_A) \times 6{\cdot}06 \times 10^{23}/4{\cdot}2n.$$

TABLE II.

Metal.	R_T.	C_A.	C_B.	Flow speed (c.c./hr. at $N.T.P.$)	$n \times 10^{-17}$.	Q.
Platinum ...	0·530	0·45	0·54	1500	1·7	40,200
Silver	0·180	0·92	1·24	3000	3·4	52,700
Copper	0·175	0·48	0·80	2000	2·2	47,000
					Mean	46,600

It will be noticed that if evaluations of Q are made from the two curves just after activity has set in, values much higher than 46,000 cals./g.-mol. are obtained. This is probably due to the "blanketing" effect mentioned on p. 2192, and it was therefore necessary to make calculations from points on the curves corresponding to a sufficiently high temperature to ensure an adequate circulation of the gas, *i.e.*, from points at which the curves are parallel.

It now remains to discuss the probable mode of action of the metals upon active nitrogen. The existence of definite points at which they became active (and in two cases, a definite action of the active nitrogen upon the metal surface) would point to the catalytic decay process being due to the alternate formation and decomposition of the nitride, and the temperatures in question lend a certain measure of support to this view. This is most apparent in the case of iron, since the activity sets in at about 300° and the nitride commences to decompose between 300° and 400° (Baur and Voerman, *Z. physikal. Chem.*, 1905, **52**, 467; White and Kirschbraun, *J. Amer. Chem. Soc.*, 1906, **28**, 1343; Noyes and Smith, *ibid.*, 1921, **43**, 475). The temperatures of decomposition of the corresponding substituted-ammonia compounds of silver, platinum, and copper do not appear to have been determined, although the data of Beilby and Henderson (*loc. cit.*) show that they are comparatively low, and in the absence of evidence to the contrary we may regard this tentative explanation as justified.

Summary.

The catalytic activity of certain metals in the form of fine filaments in accelerating the decay of active nitrogen has been studied both at the ordinary and at higher temperatures. From the data obtained an evaluation of the energy of active nitrogen has been made which agrees well with the value already found, and it appears

that the activity of the metals in this respect probably depends upon the stability of their nitrides; of the metals employed, copper appears to be by far the most active. It has also been shown that the decay process of active nitrogen in the gas phase is bimolecular with respect to the active nitrogen.

The author's acknowledgments are due to Dr. E. K. Rideal for his interest and advice with regard to these experiments.

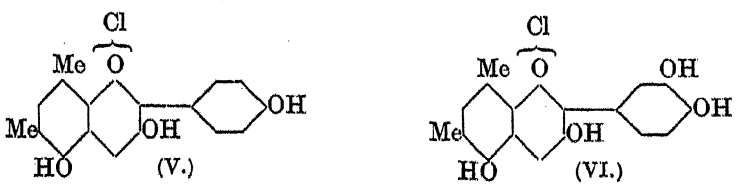
CCXCIII.—*A Synthesis of Pyrylium Salts of Anthocyanidin Type. Part XIV.*

By ALEXANDER ROBERTSON and ROBERT ROBINSON.

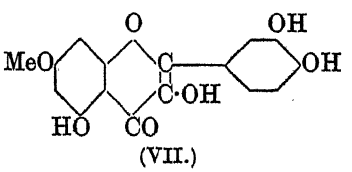


ALL the anthocyanins derived from cyanidin chloride (3 : 5 : 7 : 3′ : 4′-pentahydroxyflavylium chloride) which have been described by Willstätter and his collaborators give a strong ferric chloride reaction, and hence the attachment of the sugar residues to positions 3′ and 4′ is highly improbable. Moreover, we know that the free hydroxyl-group combination (3 : 7 : 3′ : 4′) leads to the exhibition of an alkali colour-reaction practically identical with that due to the combination (3 : 5 : 7 : 3′ : 4′), whilst, on the other hand, the combination (5 : 7 : 3′ : 4′) produces a different effect. The evidence would clearly be much more complete if the effect of the combination (3 : 5 : 3′ : 4′) could be estimated, and the present communication includes a description of flavylium salts containing free hydroxyl groups in these positions. The results may be stated as follows. The combination (3 : 5 : 3′ : 4′) is intermediate between (3 : 7 : 3′ : 4′) and (5 : 7 : 3′ : 4′), and whilst it is closer to the former in one substance, it is closer to the latter in another; thus the influences of small constitutive variations are sufficiently pronounced to diminish the value of the argument from the colour-reactions. The present results are, however, in complete agreement with the conclusions of Pratt and Robinson (J., 1925, **127**, 1131) regarding the constitution of the anthocyanins. In order to obtain 3 : 5 : 3′ : 4′-tetrahydroxyflavylium salts by the usual methods, we required 2 : 6-dihydroxybenzaldehyde or a suitable derivative. The first line of attack was through *p*-orsellinic acid, the method for the preparation of which has been greatly improved. The acid could not be reduced directly by means of sodium amalgam in the presence of boric acid and *p*-toluidine (or sodium bisulphite), although Weil

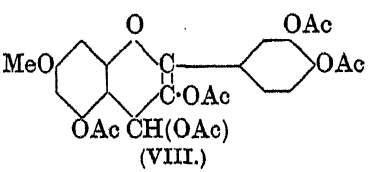
(*Ber.*, 1922, **55**, 224, 301, 2664) has applied this process with satisfactory results to the reduction of derivatives of salicylic acid. Next, 2 : 6-*dimethoxy*-4-*methylbenzoyl chloride* (I) could not be reduced directly by Rosenmund's method, neither could the *imino-chloride* derived from the related p-*toluidide* be reduced by following the conditions prescribed by Sonn in analogous cases (*Ber.*, 1919, **52**, 1927). The *nitrile* corresponding to (I) could, however, be reduced by an application of the method due to Stephen (J., 1925, **127**, 1874), although the aldehyde (II) was obtained in poor yield and was found to be useless for the special purpose in view. Finally, we succeeded in obtaining a substituted 2 : 6-dihydroxybenzaldehyde, namely, m-*xylorcylaldehyde* (III), by applying the Gattermann synthesis to *m*-xylorcin. The aldehyde is a bright yellow substance, and for this reason it may be best represented by the constitution (IV).

(I.) (II.) (III.) (IV.)

On condensation with ω : 4-dimethoxyacetophenone and ω-methoxyacetoveratrone in formic acid solution under the influence of hydrogen chloride, the *m*-xylorcylaldehyde readily yielded *flavylium* salts which, after demethylation, had the formulæ (V) and (VI), respectively.

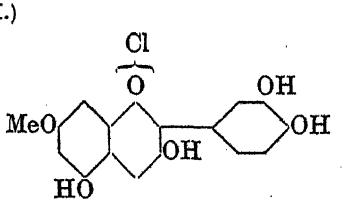


(V.) (VI.)



The reactions of (V), taken in conjunction with other similar data, suggest that pelargonin is a pelargonidin 5-diglucoside and callistephin a pelargonidin 3-glucoside, but in view of the problematic effect of the methyl groups, the 7-saccharide configuration is not definitely excluded in either case. The alkali colour-reaction of (VI) is similar to that exhibited by mecocyanin, but the methyl groups may have a reddening influence, as indeed the properties of rhamnetinidin (see below) suggest. A survey of commercial dyestuffs provides no certain guide as to the probable effect on the colour of the substitution of methyl for hydrogen. Thus new magenta is bluer than magenta, but phenosafranine is bluer than

safranine-T, and further conflicting cases could be quoted. In order to obtain a flavylium salt with free hydroxyl groups in the positions 3 : 5 : 3′ : 4′, still more closely related to a cyanidin 7-glucoside, we have reduced the flavonol rhamnetin (VII) to the related *rhamnetinidin chloride* (IX). Rhamnetin is known to be quercetin 7-methyl ether because on fission it yields phloroglucinol monomethyl ether, and on methylation quercetin 3 : 7 : 3′ 4′-tetramethyl ether, the so-called yellow quercetin tetramethyl ether. The specimen employed was derived from xanthorhamnin and was free from quercetin and rhamnazin. The reduction of quercetin to cyanidin chloride was accomplished by Willstätter and Mallison (*Sitzungsber. K. Akad. Wiss. Berlin*, 1914, 769), who employed magnesium as the reducing agent in methyl-alcoholic hydrogen chloride solution; the yield was poor and the product was difficult to isolate. We made many unsuccessful experiments with the object of improving the direct method, and therefore had to resort to an indirect process.



Rhamnetin was acetylated and reduced by zinc dust in boiling acetic anhydride solution (Herzig's acetylating reduction). The product [probably containing (VIII)] was then hydrolysed by means of aqueous-alcoholic hydrochloric acid with formation of rhamnetinidin chloride and other substances. This method constitutes an advance, although the yield of pure product remains unsatisfactory. The insoluble by-products probably arise from a pinacol

(VII.)

(VIII.)

(IX.)

formed in the reduction, and the optimum conditions for the process are being studied in detail in connexion with the reduction of quercetin and kaempferol. The alkali colour-reaction of rhamnetinidin is much closer to that of cyanidin and cyanin than to that of mecocyanin. This is the most definite evidence at our disposal, and it points clearly to the conclusion that mecocyanin, chrysanthenin, asterin, idaein, keracyanin, and prunicyanin are cyanidin 3-saccharides. Similarly, cyanin is indicated as a cyanidin 5-diglucoside,

but we are on less safe ground here, since it is the general experience that purification of an anthocyanidin makes the alkali colour-reaction become bluer and never redder. Whilst, therefore, the fact that rhamnetinidin surpasses mecocyanin in the purity (absence of red) of the blue colour of its alkaline solutions could hardly be explained away as due to impurity of the rhamnetinidin (the presence of cyanidin in significant amount being excluded by the determination of methoxyl content and by the ascertained absence of quercetin in the rhamnetin employed), yet we could not, in view of the circumstances, be sure that further purification would not yield a rhamnetinidin having reactions identical with those of cyanin and cyanidin.

EXPERIMENTAL.

p-Orsellinic Acid and some Derivatives.—The method adopted for the preparation of the acid is based on that by means of which Brunner (*Annalen*, 1907, **357**, 321) obtained γ-resorcylic acid in 40% yield from resorcinol. A mixture of orcinol (20 g.), potassium bicarbonate (40 g.), and glycerol (40 g.) was heated (oil-bath at 115—120°) for 6 hours in an atmosphere of carbon dioxide. The *p*-orsellinic acid (16 g.) isolated from the reaction product is almost pure and, after crystallisation from boiling water (some decomposition to orcinol) and drying at 100°, had m. p. 165—166° (decomp.). The methyl ester has previously been obtained by Herzig (*Monatsh.*, 1903, **24**, 894) by the action of diazomethane on the acid. We have prepared the substance by the action of methyl iodide on silver *p*-orsellinate in boiling benzene solution. It crystallises from light petroleum in elongated, flat prisms, m. p. 93—94° (Herzig gives m. p. 98—99°) (Found: C, 59·4; H, 5·7. Calc. for $C_9H_{10}O_4$: C, 59·4; H, 5·5%). The m. p. could not be raised by repeated crystallisation. The ethyl ester has previously been obtained by Lipp and Schiller (*Ber.*, 1909, **42**, 1967) as a by-product from the condensation of ethyl sodioacetoacetate and propylene dibromide. These authors quote the m. p. 61°; we applied the silver-salt method and our ester crystallised from 60% alcohol in prismatic needles, m. p. 62°. These esters, like *p*-orsellinic acid, give a blue coloration with ferric chloride. [The publication of Wagenhofer on the complete methylation of *p*-orsellinic acid (*Monatsh.*, 1924, **45**, 223) appeared in the course of our work.] The acid (15 g.) was methylated by means of methyl sulphate (58 g.) and aqueous sodium hydroxide, giving methyl *p*-orsellinate dimethyl ether (12 g.). This ester has m. p. 86°, and on hydrolysis yields the acid, m. p. 180—182° (decomp.) (Found: C, 61·5; H, 6·3. Calc. for $C_{10}H_{12}O_4$: C, 61·3; H, 6·1%) (Herzig, *loc. cit.*, gives m. p. 178°).

2 : 4-*Dimethoxy*-6-*methylbenzaldehyde* (*Orcylaldehyde Dimethyl Ether*).—This substance, stated to melt at 62°, has been prepared by Gattermann by nuclear synthesis from orcinol dimethyl ether (*Annalen*, 1907, **357**, 372). We prepared the compound from orcylaldehyde in order to carry out certain confirmations of orientation, and because we were attempting the synthesis of the isomeric *p*-orcylaldehyde dimethyl ether. The methylation of the aldehyde (1 mol.) was effected by means of methyl sulphate (1·5 mol.) and aqueous sodium hydroxide (2 mol.). The alkali-insoluble product crystallised from light petroleum in small, colourless needles, m. p. 64—65°. On oxidation with potassium permanganate, orsellinic acid dimethyl ether was obtained in good yield. This crystallised from 20% acetic acid in glistening prisms, m. p. 143—144° (decomp.) (Found : C, 61·2; H, 6·2. Calc. for $C_{10}H_{12}O_4$: C, 61·3; H, 6·1%). The acid (m. p. given as 140°) has been previously obtained by Herzig (*loc. cit.*) by hydrolysis of the product of methylation of orsellinic acid by diazomethane. A mixture of the dimethyl ethers of orsellinic acid and *p*-orsellinic acid began to melt at 130°.

2 : 6-*Dimethoxy*-4-*methylbenz*-p-*toluidide*.—Phosphorus pentachloride (9 g.) was added to a mixture of *p*-orsellinic acid methyl ether (8 g.) and carbon tetrachloride (or benzene) (50 c.c.), and the reaction completed at 50°. The residue, left after the removal of the solvent and phosphoryl chloride under diminished pressure, was redissolved in benzene (100 c.c.) which was distilled away as before, leaving the 2 : 6-*dimethoxy*-4-*methylbenzoyl chloride* (I) as a mass of colourless needles, m. p. 84—85° (for the purest specimen obtained). The p-*toluidide* was obtained by the action of an excess of *p*-toluidine on a solution of the acid chloride in benzene. It crystallised from benzene, followed by light petroleum, in colourless needles, m. p. 168—169° (Found, in material heated at 100° for 6 hours with loss of benzene : C, 71·7; H, 6·8. $C_{17}H_{19}O_3N$ requires C, 71·6; H, 6·6%). This *p*-toluidide is moderately readily soluble in methyl or ethyl alcohol, and sparingly soluble in benzene or light petroleum. From a suspension of it in benzene (6 g. in 50 c.c.) the corresponding *imino-chloride* was prepared by the action of phosphorus pentachloride (5 g.) for 10 minutes on the steam-bath. After removal of the benzene and phosphoryl chloride, a colourless solid was obtained. On exposure to moist air, this was quickly converted into the original *p*-toluidide, m. p. 168—169°.

2 : 6-*Dimethoxy*-4-*methylbenzamide*, $(MeO)_2C_6H_2Me{\cdot}CO{\cdot}NH_2$.—A stream of ammonia was led through a solution of 2 : 6-dimethoxy-4-methylbenzoyl chloride (10 g.) in benzene (150 c.c.), and the solid which separated was collected, washed with water, and crystallised

from benzene; slender needles, m. p. 199° (yield, 7 g.) (Found: C, 61·5; H, 6·8. $C_{10}H_{13}O_3N$ requires C, 61·5; H, 6·7%). Its solubilities resemble those of the *p*-toluidide.

2 : 6-*Dimethoxy*-4-*methylbenzonitrile*.—A solution of the foregoing amide in pure thionyl chloride was boiled for 5 minutes, and the thionyl chloride then distilled under diminished pressure; the last traces were eliminated by the addition of benzene and redistillation. The *nitrile* (yield, 65—70%) crystallises from benzene–light petroleum in prismatic rods, m. p. 138—139° (Found: C, 68·0; H, 6·5. $C_{10}H_{11}O_2N$ requires C, 67·8; H, 6·2%). The substance may also be crystallised from 60% alcohol in large, squat prisms.

2 : 6-*Dimethoxy*-4-*methylbenzaldehyde* (II).—Hydrogen chloride was led into a mixture of powdered anhydrous stannous chloride (15 g.) and ether (150 c.c.) until a homogeneous solution was obtained. 2 : 6-Dimethoxy-4-methylbenzonitrile (6 g.), dissolved in a little chloroform, was then added, and the passage of hydrogen chloride continued until the liquid was saturated. Crystals separated after 12 hours; after 14 days, the separated solid weighed 8 g. and ultimately about 1 g. more was obtained. This double tin salt crystallised in needles and was very difficult to hydrolyse. The best results were obtained by dissolution in water at 40—50°, addition of an excess of sodium acetate, and heating on the steam-bath for 3 minutes. The *aldehyde* (1·5 g.) was isolated by means of ether, and crystallised from light petroleum in long, colourless, prismatic needles, m. p. 90—91° (mixed m. p. with orcylaldehyde dimethyl ether, 50—55°) (Found: C, 66·7; H, 6·7. $C_{10}H_{12}O_3$ requires C, 66·7; H, 6·7%). This substance is readily soluble in ether and the simple alcohols, moderately readily soluble in benzene, and slightly soluble in hot water. It yields a yellow, sparingly soluble p-*nitrophenylhydrazone* and reduces an ammoniacal silver solution. All attempts to condense it with ω-methoxyacetoveratrone were fruitless, and, no doubt as the result of steric hindrance, it does not appear to form a Schiff's base by condensation with aniline.

4-*Nitro*-6-*hydroxy*-m-*xylene*.—The nitration of *m*-xylidine (100 g.) by the method of Nöelting and Collins (*Ber.*, 1884, **17**, 265) gave 4-nitro-6-amino-*m*-xylene (80 g.), and this was converted into the corresponding phenol by the following method (compare D.R.-PP. 95,339 and 97,012) which is superior to that described by Pfaff (*Ber.*, 1883, **16**, 616). A diazonium salt solution, prepared at below 0° from the nitro-amine (16·6 g.), sulphuric acid (50 g.), crushed ice and water (300—350 g.), and sodium nitrite (7 g.), was filtered and gradually added to boiling 55% sulphuric acid (350 c.c.). On cooling, the nitroxylenol separated in light brown crystals (12—

14 g.), which could be employed for the next stage. The substance crystallised from hydrochloric acid in very slender needles, m. p. 95°. The reduction to 4-amino-6-hydroxy-*m*-xylene (Pfaff, *Ber.*, 1883, **16**, 1137) was conveniently effected by means of iron in alcoholic solution (compare West, J., 1925, **127**, 494). Iron powder (80 g.) was added in portions of about 10 g. at intervals of 3 minutes to a boiling solution of the nitro-*m*-xylenol (55 g.) in alcohol (300 c.c.) and concentrated hydrochloric acid (20 c.c.), and the mixture was boiled for 5 hours, a test then showing that reduction was complete. The filtered solution was concentrated to 100 c.c., cooled, and saturated with hydrogen chloride. After keeping in an ice-chest for some hours, the hydrochloride was collected, and a further quantity could be isolated from the mother-liquor by concentration to 50 c.c. and renewed saturation with hydrogen chloride. The salt crystallised in glistening plates; total yield of practically pure substance, 45 g.

m-*Xylorcin*.—The method of Pfaff (*loc. cit.*) for the preparation of this phenol gave unsatisfactory results, and we adopted the following procedure: 4-Amino-6-hydroxy-*m*-xylene hydrochloride (16 g.) was dissolved in 10% sulphuric acid (200 c.c.) by heating, and crushed ice (200 g.) was added after sudden cooling and shaking to ensure the separation of small crystals. Sodium nitrite (6·4 g.), dissolved in a little water, was then introduced, and the mixture stirred until the sulphate had disappeared. A little charcoal was added, and the diazo-solution filtered and gradually added to 600 c.c. of boiling 10% sulphuric acid. Very little tarry matter was produced, and the filtered solution (charcoal), which was almost colourless, was saturated with ammonium sulphate. Part of the xylorcin crystallised and was collected; the remainder was isolated by six extractions with ether. The product crystallised from benzene in colourless, hexagonal plates, m. p. 124—125° (yield, 8—10 g.). The substance has the properties attributed to it by Pfaff.

m-*Xylorcylaldehyde* (III).—A mixture of *m*-xylorcin (10 g.), anhydrous hydrogen cyanide (15 c.c.), and ether (150 c.c.) was saturated with hydrogen chloride, and the aldimine-hydrochloride separated in almost colourless, prismatic needles in 1 hour. After keeping over-night, the salt was collected, washed with ether, dried, and dissolved in cold water (200 c.c.). The solution was heated at 80—90° for 15 minutes, and a part of the *aldehyde* crystallised, the remainder separating in long, yellow needles on cooling. The substance was recrystallised from 40% ethyl alcohol (charcoal); bright yellow, prismatic needles, m. p. 155—156° (Found: C, 64·8; H, 6·0. $C_9H_{10}O_3$ requires C, 65·1; H, 6·0%). So far as we are able to judge, the striking colour of this substance is not due to

impurity, and Gattermann has noted the yellow colour of 4 : 8- and 2 : 7-dihydroxynaphthaldehyde (Annalen, 1907, **357**, 341).

3 : 4′-*Dimethoxyflavylium Chloride*.—Bright scarlet needles (changing to orange-red on contact with air) separated when hydrogen chloride was passed into a solution of salicylaldehyde (2·2 g.) and ω : 4-dimethoxyacetophenone (3·4 g.) in ether (80 c.c.). The *chloride* recrystallised from 8% hydrochloric acid in glistening, red, prismatic needles (yield, 5·7 g.) (Found, in material dried over sulphuric acid in a high vacuum for 12 hours : C, 60·0; H, 5·7. $C_{17}H_{15}O_3Cl,2H_2O$ requires C, 60·3; H, 5·6%). The substance is sparingly soluble in cold dilute hydrochloric acid, but easily soluble in the hot solvent. The ferrichloride crystallised from acetic acid in small, dull orange, prismatic needles, m. p. 151—152°. Pratt and Robinson described (J., 1923, **123**, 751) hair-fine, orange-red needles, m. p. 135°, so that it is possible that this substance exists in two modifications. The crystalline form, colour, and melting point are different, and in repeating the preparation through the unsaturated ketone we obtained the salt, m. p. 151—152°.

3 : 4′-*Dihydroxyflavylium Chloride*.—This salt is of interest inasmuch as it contains hydroxyl groups in the two positions considered to have the greatest effect on the alkali colour-reactions of the anthocyanidins. Thus, a comparison of the colour of alkaline solutions of this salt and of 7 : 3′ : 4′-trihydroxyflavylium chloride and the representative of the 5 : 3′ : 4′-hydroxylated series described below demonstrates the relatively feeble hypsochromic character of the hydroxyl groups in positions 7 and 5. A mixture of 3 : 4′-dimethoxyflavylium chloride (2·5 g.), phenol (10 g.), and hydriodic acid (60 c.c.; *d* 1·7) was boiled for 30 minutes in an atmosphere of carbon dioxide. After cooling, the phenolic layer was separated, and the demethylated *iodide* was obtained in slender, bright red needles by the addition of ether (yield, 0·7 g.). The *chloride*, obtained in the usual manner by means of silver chloride in methyl-alcoholic solution, was precipitated, after concentration, by dilute hydrochloric acid as a mass of bright red plates, and crystallised from 5—6% hydrochloric acid in red plates exhibiting a golden reflex. Rapid cooling causes the separation of needles (Found, in material dried over soda-lime for 12 hours : C, 59·6; H, 5·1.

$$C_{15}H_{11}O_3Cl,1{\cdot}5H_2O$$

requires C, 59·7; H, 4·7%). The salt crystallises from ethyl-alcoholic hydrogen chloride in flat, pointed prisms. It is moderately soluble in 4—6% hydrochloric acid and very readily soluble in hot dilute or concentrated hydrochloric acid, giving orange to orange-red solutions. When it is treated with much water, a colourless solution of the pseudo-base is obtained, addition of acids

restoring the orange-yellow colour of the flavylium salt. Aqueous or aqueous-alcoholic sodium carbonate dissolves the salt to a red solution, tinged with violet.

5-*Hydroxy*-3 : 4′-*dimethoxy*-6 : 8-*dimethylflavylium Chloride*.—A solution of *m*-xylorcylaldehyde (2 g.) and ω : 4-dimethoxyacetophenone (3 g.) in formic acid (25 c.c.) was saturated with hydrogen chloride, kept for 48 hours, and mixed with an excess of dry ether. The precipitated dark brown, prismatic needles were collected and crystallised from 8% hydrochloric acid as a dark brown, matted mass of slender, woolly needles (3 g.) (Found, in material dried over soda-lime for 12 hours : C, 57·1 ; H, 6·2. $C_{19}H_{19}O_4Cl,H_2O$ requires C, 57·4 ; H, 6·3%).

The *ferrichloride* crystallised from acetic acid in spherical aggregates of brown, prismatic needles, m. p. 211—212° after darkening at 190°.

3 : 5 : 4′-*Trihydroxy*-6 : 8-*dimethylflavylium Chloride* (V).—The foregoing dimethyl ether (2 g.) was demethylated by boiling hydriodic acid (60 c.c. ; *d* 1·7) and phenol (20 g.) in 40 minutes (passage of carbon dioxide). The iodide was precipitated from the separated phenolic layer by means of ether in purple rods (1 g.), and converted into the *chloride* in the usual way. This salt separated from its concentrated aqueous methyl-alcoholic hydrochloric acid solution in violet, prismatic needles, and was recrystallised from 8% hydrochloric acid ; glistening, violet needles (Found, in material dried in a high vacuum over sulphuric acid for 24 hours : C, 63·9 ; H, 5·1. $C_{17}H_{15}O_4Cl$ requires C, 64·1 ; H, 4·7%). This salt is very sparingly soluble in cold dilute hydrochloric acid but dissolves freely in the hot solvent to a reddish-brown solution. Unlike most flavylium salts, the anhydrous material is not hygroscopic and, as the crystals suffered no change in appearance on drying, it would appear that they separated in the anhydrous condition. The alcoholic solutions are not fluorescent, and on dilution with water give almost colourless solutions of the pseudo-base. The colour of the solution in aqueous sodium carbonate is reddish-violet, and in aqueous-alcoholic sodium carbonate, bluish-violet.

5-*Hydroxy*-3 : 3′ : 4′-*trimethoxy*-6 : 8-*dimethylflavylium Chloride*.—The condensation of *m*-xylorcylaldehyde and ω-methoxyacetoveratrone was carried out as in the analogous case (above) and the yield was almost quantitative. A hot solution of the crude salt in 0·5% hydrochloric acid was filtered, and the acid concentration increased to 8%. The dark red, woolly needles which separated were collected, and when dried exhibited a green reflex. The solutions in hot 7—8% hydrochloric acid are deep crimson, and on cooling, the separation of the salt is almost complete. The *ferri-*

chloride crystallised from acetic acid in reddish-brown, elongated, rhombic plates, exhibiting a bluish-green reflex; m. p. 200—203° (Found: C, 44·6; H, 3·9. $C_{20}H_{23}O_5Cl_4Fe$ requires C, 44·5; H, 3·9%). This derivative is readily soluble in hot acetic acid, and separates almost completely on cooling the solution.

3 : 5 : 3′ : 4′-*Tetrahydroxy*-6 : 8-*dimethylflavylium Chloride* (VI).—The chloride (1·5 g.) last described was demethylated under the usual conditions by hydriodic acid (80 c.c.; *d* 1·7) in presence of phenol (15 g.) in 30 minutes. Water (30 c.c.) was added, the phenolic layer separated, and the *iodide* precipitated by the addition of ether. The slender, red needles were collected and converted into the *chloride* by means of silver chloride in hot dilute hydrochloric acid solution. On standing, the cooled solution deposited dark red, microscopic, slender needles, and these were recrystallised from 10% hydrochloric acid (Found, in material dried in a high vacuum over sulphuric acid for 24 hours: C, 58·1; H, 5·1. $C_{17}H_{15}O_5Cl,H_2O$ requires C, 57·9; H, 4·8%). The salt is readily soluble in hot dilute hydrochloric acid, giving deep red solutions that deposit crystals but slowly on cooling. It dissolves in aqueous sodium carbonate to a bluish-violet solution, unchanged, in the absence of oxygen, by the addition of sodium hydroxide. In alcoholic solution, the sodium carbonate reaction is also violet, but this becomes blue on the addition of sodium hydroxide. The ferric chloride reaction in alcoholic solution is intense violet.

Rhamnetinidin Chloride (IX).—The crude rhamnetin obtained by hydrolysis of xanthorhamnin from Persian berries, was thoroughly extracted with boiling alcohol to remove quercetin, and then with hot acetic acid to remove rhamnazin. Finally it was purified through its monopotassium salt (Perkin and Wilson, J., 1903, **83**, 136). The light yellow product was dried at 140° (Found: MeO, 9·7. Calc.: MeO, 9·8%). A mixture of rhamnetin (4·6 g.), potassium acetate (5 g.), and acetic anhydride (80 c.c.) was boiled for 2—3 minutes (acetylation cannot be complete at this stage), and a large excess of zinc dust added in small portions in rapid succession. When further additions produced no change in the appearance of the solution (about 5 mins.), the liquid was boiled for 5 minutes longer, then cooled, decanted, and added to 500 c.c. of water containing concentrated hydrochloric acid (25 c.c.). The zinc was washed with a little acetic acid. The ochreous, sticky product was collected on a glass rod and on the sides of the container, washed with water, dissolved in alcohol (100 c.c.) and hydrochloric acid (30 c.c.), and the solution boiled for 20 minutes, the red colour of the flavylium salt appearing during this process. The crimson solution was concentrated in a vacuum, a little water being added

from time to time. When most of the colouring matter had been precipitated, the substance was collected, thoroughly extracted with a large volume of ether, and the residue with boiling 0·5% hydrochloric acid. The salt was precipitated from the filtrates, after concentration, by concentrated hydrochloric acid, and this operation was repeated. The product was then fractionally crystallised by slow evaporation of an alcoholic solution containing 10% hydrochloric acid; some tarry matter was first eliminated and then definite prismatic crystals separated. These were collected, twice recrystallised in the same way, and air-dried (Found: C, 51·9; H, 4·7; MeO, 8·3. $C_{16}H_{13}O_6Cl,2H_2O$ requires 51·6; H, 4·6; MeO, 8·6%). After this had been exposed to a vacuum for 12 hours, the analytical results indicated a monohydrate, but were not sufficiently sharp. *Rhamnetinidin chloride* is very sparingly soluble in cold 0·5% hydrochloric acid, readily soluble in the hot solvent to a brownish-red solution; the alcoholic solutions are bluish-red. The salt crystallises from aqueous-alcoholic hydrochloric acid in clusters of elongated prisms, orange-red by transmitted light, and forming a dark purplish-brown mass exhibiting an intense green reflex. On the addition of aqueous sodium carbonate to the solid salt, a blue solution is obtained. This is bluer than that of mecocyanin and redder than that of cyanidin, cyanin, or fisetinidin under the same conditions. Thick layers are violet-red, and this dichroism is the chief distinction from fisetinidin. On progressive dilution the colour becomes violet and finally blue. In alcoholic solution, the distinction from mecocyanin is much more pronounced, since with sodium carbonate under similar conditions, rhamnetinidin gives a blue solution (on the red side by comparison with cyanidin), whereas mecocyanin gives a violet solution. On the addition of sodium hydroxide to the alcoholic solution, mecocyanin and rhamnetinidin give identical pure blue colorations. The ferric chloride reaction of rhamnetinidin is blue in alcoholic solution and violet in aqueous solution.

We desire to thank the Royal Society for a grant which has defrayed a part of the cost of the work, and we are grateful to the International Education Board of New York for a Fellowship that enabled one of us to take part in the investigation.

THE UNIVERSITY, MANCHESTER. [*Received, July 11th*, 1927.]

CCXCIV.—*A New Method of (Absolute) Potentiometric Titration.*

By BERNARD CAVANAGH.

THE following is an account of a new method of titration which combines great simplicity with the highest precision and with other special advantages. No potentiometer or standard cell is required, no normal electrode or reference "half-cell" and no mechanical stirrer, neither is any sort of liquid junction involved. Small quantities of solution can be rapidly titrated in an ordinary flask, with the aid only of a rheostat or resistance, a key, and a pointer-galvanometer. Yet the sensitivity and precision are the highest attainable by electrometric methods, and, in addition to its convenience for ordinary titrations, the method is especially suited for the titration of (*a*) very dilute solutions and (*b*) very small volumes (micro-titration).

This paper deals with the titration of the following ions: $H^{\cdot}$, $Ag^{\cdot}$, OH', Cl', Br', I'. The underlying principles will first be discussed.

1. The fundamental idea consists in the application to electrometric titration of the long-known principle of the Helmholtz cell, or cell without liquid junction. A familiar example of this type of cell is that consisting of a hydrogen electrode and either a calomel or a silver chloride electrode in one and the same solution of hydrochloric acid. The *E.M.F.* of this cell at the temperature T is given by

$$E = E_0 + 2RT/F \,.\, \log_e C\gamma,$$

where E_0 is a constant and C is the concentration of hydrochloric acid; or, if for the present we ignore the correction factor γ, *i.e.*, the "activity coefficient," and consider a particular temperature, *e.g.*, 16°, we may write

$$E = E_0 + 0{\cdot}1147 \log_{10} C \quad . \quad . \quad . \quad . \quad (1)$$

More generally, if for pure hydrochloric acid we substitute a mixed electrolyte containing hydrogen ions and chlorine ions at different concentrations, C_H and C_{Cl}, then the *E.M.F.* of the cell will be

$$E = E_0 + 0{\cdot}05735 \log (C_H \times C_{Cl}) \quad . \quad . \quad . \quad (2)$$

It is plain, therefore, that if we know E_0 and *one* of the factors C_H or C_{Cl}, we can determine the other by measuring E. This would be an example of what is commonly called a "physical" method of analysis.

Alternatively, we may gradually remove one of the ions from the solution by means of a standard reagent, the *residual* concentration

of the ion being, at each stage, indicated by the value of E, until that residual concentration either (*a*) can be neglected or (*b*) (for refined titration) reaches a certain value known to characterise the exact end-point of the titration. For instance, at the end-point in the titration of a chloride against silver, the value of C_{Cl} is equal to the solubility, S_{AgCl}, of silver chloride. The *E.M.F.* at the end-point would therefore be, in accordance with equation (2):

$$E = (E_0 + 0{\cdot}05735 \log S_{AgCl}) + 0{\cdot}05735 \log C_H \quad . \quad . \quad (3)$$

the bracketed expression being a known constant, so that the end-point *E.M.F.* depends on C_H, the acidity of the solution. A rough knowledge of C_H, however, is sufficient to permit high precision in the titration. Thus, even if C_H were estimated at *twice* its true value, the error produced in the end-point would be only $1{\cdot}5 \times 10^{-7}$ g.-equiv. per 10 c.c. of solution, which is only 1·5% in the titration of $N/1000$-solution, so that only when high precision in the most dilute solutions is required, will C_H have to be known more accurately.

Similarly, at the end-point in the titration of a strong acid by a strong base the value of C_H is equal to the acidity, h, of distilled water under the conditions prevailing. (The value of h depends ordinarily on the amount of carbon dioxide in the air and may be between 2×10^{-6} and 3×10^{-6}.) We obtain therefore a formula for the end-point potential of the same type as (3), *viz.*,

$$E = (E_0 + 0{\cdot}05735 \log h) + 0{\cdot}05735 \log C_{Cl} \quad . \quad . \quad (4)$$

so that in this case we need a rough knowledge of C_{Cl}.

It is plain that we have here a means of absolute * potentiometric titration in a single vessel without a liquid junction, and it may be observed that the resistance can thus easily be kept low, so that the method is peculiarly useful for the titration of dilute solutions without the employment of a refined galvanometer. It seems probable that the principle may be widely applicable.

2. *Elimination of the Potentiometer.*—The use of a potentiometer has been implied since we have to determine when the potential between the two electrodes reaches a certain end-point value. The instrument, it is true, need be only of simple pattern, and may be set for the end-point *E.M.F.*, so that the end of the titration is shown in practice by the reversal of the galvanometer deflexion; but we can eliminate the necessity for a potentiometer if we can

* The end-point is marked by the *E.M.F.* attaining a particular absolute value. This is the case also in the methods of Treadwell and of Müller. In all other methods, the end-point is marked by the attainment of a maximum value by the differential dE/dx, the rate of change of potential. It can be shown that the intrinsic sensitivity of the "absolute" methods is the higher.

construct a cell that will develop the required end-point *E.M.F.*, which might be done by imitating the composition which the titrated cell should have at the end-point. For instance, for the titration of a chloride, we might take a solution having the same acidity as the titrated solution, and shake it with some well-washed, precipitated silver chloride. A hydrogen electrode and a silver chloride electrode dipping into such a solution should develop the required end-point *E.M.F.* This procedure would bear the same relation to the (alternative) use of the potentiometer as the method of Treadwell bears to that of Müller.

A much simpler and more trustworthy procedure is available, however, for comparison of (1) and (3) shows that they become identical when $C^2 = S_{AgCl} \times C_H$; and it follows that if we take some hydrochloric acid of approximately the concentration C, where

$$C = \sqrt{S_{AgCl} \times C_H} = 0{\cdot}0031\sqrt{C_H} \quad . \quad . \quad . \quad (5)$$

(C_H being, as before, the acidity of the *titrated* solution), then a hydrogen and a silver chloride electrode dipped into this solution will develop the end-point *E.M.F.* This is more trustworthy than the other form of end-point cell because, the concentrations of both ions being considerable, there is less liability to polarisation during the titration. It follows from the relation (5) that, just as C_H need not be accurately known (see p. 2208), so C, the concentration of the hydrochloric acid in the end-point cell, does not require accurate adjustment.

In just the same way, for the titration of a strong acid by a strong base we obtain from (1) and (4) the relation $C^2 = hC_{Cl}$, and adopting $2{\cdot}5 \times 10^{-6}$ as a mean value for h (see p. 2208), we have

$$C = 0{\cdot}0016\sqrt{C_{Cl}} \quad . \quad . \quad . \quad . \quad . \quad (6)$$

as the strength of the hydrochloric acid solution required, in terms of the chloride concentration. (In the total absence of carbon dioxide, the numerical coefficient would be 0·0003.)

3. *The Silver Chloride–Quinhydrone Cell.*—Of late, the hydrogen electrode has been superseded for many purposes by the more convenient " quinhydrone electrode," since Biilmann showed that, for solutions not distinctly alkaline, the presence of a trace of quinhydrone in solution caused a smooth platinum electrode to behave as a reversible hydrogen electrode.

It appeared possible that an exceedingly simple form of the Helmholtz cell might be obtained by merely dipping a smooth platinum electrode and a silver chloride electrode into a solution containing hydrogen ions, chlorine ions, and a little quinhydrone, providing always that the electrodes did not interfere with one another.

In the first experiments, a plain silver wire was used, in the presence of a visible precipitate of silver chloride, but the results were unsatisfactory owing possibly to some slight catalysis of the quinhydrone reaction on the metallic surface. When, however, the silver was coated electrolytically with silver chloride, excellent and quickly reproducible results were obtained.

Many measurements were made with cells containing various proportions and concentrations of the two ions, and the results, substituted in the more exact form of equation (2), *viz.*,

$$E = E_0 + 0{\cdot}05735 \log a_{\mathrm{H}} a_{\mathrm{Cl}} \quad . \quad . \quad . \quad . \quad (7)$$

(a_{H} and a_{Cl} being "corrected concentrations" or activities) gave the mean value 0·4740 for E_0. The measurements covered the whole range of the titrations of both ions, up to and beyond the end-points, leaving no doubt as to the practicability of using this very simple form of cell. In fact, the results were so uniformly good as to prompt an investigation, now in progress, of the suitability of this type of cell as a means of "physical" analysis.

4. *The Silver–Quinhydrone Cell and the Solubility of Silver Chloride.*—It is of interest that, *beyond* the end-point in the chloride titration, we have in effect the rather remarkable one-solution cell, Ag | Ag^+, H^+ (quinhydrone) | Pt, or, if we regard the quinhydrone electrode as a hydrogen electrode, Ag | Ag^+, H^+ | H_2, of which the *E.M.F.* is given by

$$E = E'_0 + RT/F \,.\, \log a_{\mathrm{Ag}}/a_{\mathrm{H}} \quad . \quad . \quad . \quad . \quad (8)$$

and is thus practically unaffected by the addition of water.

The results in this region were very good and yielded the value 0·1009 for E'_0. Now the activity-product of silver chloride, and hence its true solubility in pure water, S_{AgCl}, is readily obtained from E_0 and E'_0, for

$$-2RT/F \,.\, \log S_{\mathrm{AgCl}} = E_0 + E'_0 = 0{\cdot}5749 \text{ (at } 16°),$$

whence $S_{\mathrm{AgCl}} = 0{\cdot}97 \times 10^{-5}$ at 16°, with a probable accuracy of $\pm 2\%$.

5. *Final Simplification: Elimination of the End-point Cell.*—It is evident, therefore, that the method of titration outlined in Sections 1 and 2 is fully applicable with the more convenient silver chloride–quinhydrone cell. A final simplification of apparatus and procedure, however, now becomes possible, arising out of the value of E_0, given above.* Substituting 0·4740 for E_0 and $0{\cdot}97 \times 10^{-5}$ for

* This simplification is *not* available if the hydrogen electrode is used, because of the *negative* value of E_0 in that case.

S_{AgCl} in equation (3), we have, for the end-point potential in the titration of a chloride,

$$E_{Cl} = 0{\cdot}1866 + 0{\cdot}05735 \log C_H \quad . \quad . \quad . \quad . \quad (9)$$

this being the formula required when a potentiometer is used (see Section 12). Now calculation shows that E_{Cl} vanishes when $C_H = 5{\cdot}6 \times 10^{-4}$, *i.e.*, if the acidity of the solution is roughly $N/1800$, the end-point potential will be zero, and we require neither a potentiometer nor a second pair of electrodes to balance it. One pair of electrodes and a galvanometer is then all the physical apparatus required for the titration.

Similarly, for the acid–alkali titration, substituting for E_0 and for h in equation (4), we obtain for the end-point potential

$$E_H = 0{\cdot}153 + 0{\cdot}05735 \log C_{Cl} \quad . \quad . \quad . \quad . \quad (10)$$

which vanishes when $C_{Cl} = 2{\cdot}2 \times 10^{-3}$ (or $N/450$).

6. *The Bromide and the Iodide Cells.*—From similar series of measurements with the corresponding silver bromide (or iodide)–quinhydrone cells, the values 0·6235 and 0·8460, respectively, have been obtained for E_0, and $5{\cdot}6 \times 10^{-7}$ and $6{\cdot}5 \times 10^{-9}$ for the solubilities of the bromide and iodide. Hence we obtain for the end-point potentials:

$$E_{Br} = 0{\cdot}261 + 0{\cdot}05735 \log C_H \quad . \quad . \quad . \quad . \quad (11)$$
$$E_I = 0{\cdot}3725 + 0{\cdot}05735 \log C_H \quad . \quad . \quad . \quad (12)$$

which vanish, respectively, when $C_H = 2{\cdot}8 \times 10^{-5}$ or $3{\cdot}2 \times 10^{-7}$.

When the end-point cells are required in the titration of bromide and iodide, it is convenient still to use the hydrochloric acid cell, of which the *E.M.F.* is

$$E_{HCl} = 0{\cdot}4740 + 0{\cdot}1147 \log C \quad . \quad . \quad . \quad . \quad (13)$$

C being the concentration of the acid. Equating this in turn to E_{Br} and E_I, we obtain for the bromide $C = 0{\cdot}013\sqrt{C_H}$ (14), and for the iodide $C = 0{\cdot}12\sqrt{C_H}$ (15).

Two points must be mentioned with regard to the iodide cells, *viz.*, first, that the acidity must be kept very low—below $N/100$—because at higher concentrations the hydriodic acid reacts with the quinhydrone producing free iodine; and, secondly, that in the immediate neighbourhood of the end-point, equilibrium (and hence a reproducible potential) is only obtained after standing for ¼—½ hour with occasional shaking. Thus when high precision is required the titration of an iodide cannot be very expeditious.

7. "*Corrected Concentrations*": *Activities.*—For the sake of simplicity, the correction factors or activity coefficients, by which the concentrations are multiplied in the exact forms of the equations

given, have been ignored up to this point. It is, in fact, only when high precision is aimed at, and the most dilute solutions are titrated, that these factors need be considered; in such cases every symbol C, with or without subscript, representing a concentration (but not the symbols h, S_{AgCl}, S_{AgBr}, etc., which already represent activities), is to be multiplied by the appropriate activity coefficient, to make the formulæ exact.

EXPERIMENTAL.

8. *The Electrodes.*—The simpler the form of the electrodes the more easily is the surface layer of solution kept uniform with the rest by shaking.

The platinum electrodes are best free from glass so that they may the more easily be cleaned occasionally in hot sulphuric–chromic acid, and "blanked" by heating to redness for a minute or two in an alcohol flame. A form which has been found effective consists of a strip of thin foil, bent along its length to give a little rigidity, and fixed in a binding screw.

The silver halide electrodes have been made from pieces of stout silver wire about 15 cm. long by coating them, along a length of, say, 5 cm. from one end, with the appropriate halide. The wire is made the anode in the electrolysis of a dilute solution of the sodium or potassium salt, and a current of 2—3 milliamps. per sq. cm. is passed for about an hour. The wire should be turned once or twice to secure an even coating. Several electrodes can be prepared at one time, and they may be preserved in the dark for a week or more in corked tubes full of distilled water. In use, a silver halide electrode is fixed in a binding screw, and mounted in an ordinary clamp, vertically alongside and close to a platinum electrode, so that the pair will easily pass through the neck of a conical flask. We may speak of a "chloride-pair" of electrodes or a bromide- or iodide-pair, according to the nature of the silver halide electrode.

9. *The Reference Ion.*—We have seen that the potentials with which we have to deal in this method depend always on two ions, and the essential principle is that if we know the concentration of one of these ions roughly, we can titrate the other exactly. It will be convenient to speak of the ion of which the concentration must be roughly known as "the reference ion." Thus, in the titrations of the three halides the reference ion is the hydrogen ion, whilst in the titration of hydrogen ions (acids) it might be any of the three halides, but most commonly the chloride. Now in most cases, so long as the solution to be titrated is not weaker than about $N/100$ —the limit is lower in the case of bromide or iodide—*only the order of magnitude of the reference-ion concentration need be known* (see p. 2208). If, however, we are aiming at the highest precision in the

end-point, as in titrating extremely dilute solutions, we may need to know the reference-ion concentration to within a few units %, and a rough titration may be necessary to determine this.

If the reference ion is absent or nearly so, then we can easily introduce it in whatever concentration we require, by adding a little of a standard solution of sodium chloride (for Cl′) or of nitric or sulphuric acid (for H·).

It should be observed that, strictly speaking, it is the concentration at the end-point that has to be known or adjusted, and when the highest precision is required some allowance must be made for the dilution caused by the volume of reagent to be added; this can easily be done after a rough preliminary titration.

10. *The Method in its Simplest Form.*—The simplest form of procedure is applicable when the reference-ion concentration approximates to (see p. 2212), or can be adjusted roughly to, the values calculated from equations (9)—(12). All the physical apparatus required is a sturdy pointer-galvanometer (which will just detect, say, 10^{-7} amp.) in series with a rheostat, a tapping-key or plug, and one appropriate pair of electrodes, *viz.*, a chloride-pair for the titration of chloride or acid, a bromide- or an iodide-pair for the corresponding halide titrations. The deflexions of the galvanometer should be minimised by means of the rheostat so as to avoid any tendency to polarise the electrodes.

To the solution to be titrated, contained in a conical flask, a trace of quinhydrone is added (not more than 1 mg. per c.c. of solution), and most of it dissolved by gentle shaking. On raising the flask so that the pair of electrodes dips into the liquid, shaking gently, and then depressing the key, a marked deflexion of the galvanometer pointer is obtained with a high resistance in circuit, indicating a high *E.M.F.* (of the order of 0·2—0·3 volt). Some of the standard reagent is now added, and the observation of the *E.M.F.* then repeated, and so on, until eventually the *direction* of the pointer deflexion is reversed, the *E.M.F.* having reached and passed zero. This marks the end of the titration.

The indication is very sharp and sensitive. Thus the change from a deflexion representing an *E.M.F.* of 5 millivolts to the same deflexion in the reverse direction is produced, in 10 c.c. of solution, by the following quantities of reagent:

In titration of acid	3×10^{-8} g.-equiv.
„ „ „ chloride (or silver)	1×10^{-7} „
„ „ „ bromide (or silver)	6×10^{-9} „
„ „ „ iodide (slowly, see p. 2211) ...	$6{\cdot}5 \times 10^{-11}$ „

11. *The Use of the End-point Cell.*—When the concentration of the reference ion cannot conveniently be adjusted to the appropriate

value given above, it becomes necessary to add to the apparatus *either* a simple potentiometer *or* a second pair of electrodes—a chloride-pair—connected in opposition (platinum to platinum) to the first pair. In the latter case the end-point cell is completed by diluting some roughly standard hydrochloric acid approximately to the concentration C given in equation (5), (6), (14), or (15), dissolving a little quinhydrone in this solution contained in a flask or beaker, and raising the vessel on a support so that the second pair of electrodes dips into the solution. The vessel should be gently shaken occasionally during the titration.

Otherwise the titration proceeds exactly as described in Section 10, the end-point being indicated by the reversal of direction of the galvanometer deflexion, and the sensitivity being of the same order. The end-point cell can be used repeatedly for the same type of titration so long as the reference-ion concentration (C_{Cl} or C_H) in the titrated solutions remains the same.

12. *Alternative Use of a Potentiometer.*—If it is preferred to use a simple form of potentiometer to produce the end-point potential, instead of the end-point cell, it will be convenient, by means of equations (9), (10), (11), and (12), to construct tables after the following manner, giving the end-point potential for various values of the reference-ion concentration.

End-point Potential in Titration of Chloride (or Silver).

Acidity, C_H ...	1	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}
End-pt. *E.M.F.*	0·1866	0·1292	0·0719	0·0145	−0·0428	−0·1002

For intermediate values:

To {multiply / divide} C_H by.....	1·25	1·6	2	2·5	3·2
Add to / Subtract from E the value ...	0·0055	0·0117	0·0173	0·0228	0·0290

These two tables, in conjunction with ordinary proportional interpolation, cover all probable values of C_H and E and similar tables are readily constructed for the other titrations. It would appear, however, that the second pair of electrodes, combined with a standard solution of hydrochloric acid and a measuring cylinder, constitutes a sort of "chemical potentiometer" which possesses advantages as regards bulk, cost, and immediate readiness for use over the simplest of physical instruments.

Results.

It would be superfluous to quote the results obtained in the more concentrated solutions, where the precision of the indication is greater than that of the volumetric apparatus. The results in

Table I, obtained with the more dilute solutions, indicate the limits of precision, and the order of accuracy attained requires no comment.

In order to provide a check on the *correctness* as well as the concordance of the results, the very dilute solutions were prepared by the precise dilution of carefully compared strong solutions. These gave the " calculated " results in the sixth column, from which the percentage deviations are given in the seventh column. $N/5$-Solutions of silver nitrate and the halides of potassium were compared by Volhard's method, and very good distilled water was used for the subsequent dilutions. The acid and alkali were compared at $N/2$-strength, and for the dilution of the baryta, conductivity water was used with a special arrangement to exclude atmospheric carbon dioxide.

		0·09	0·00045	10·37		+0·1
		0·0022	None	10·45		+0·9

In the titrations a cheap pointer galvanometer was used throughout. The resistance of the titrated solutions was diminished by the addition of small quantities of a 10% potassium nitrate solution, prepared from Kahlbaum's " for analysis " product, twice recrystallised.

The activity coefficients depended largely on the added potassium nitrate. They were derived mainly by the use of Lewis and Randall's data (" Thermodynamics," McGraw Hill, New York, p. 382). In the third column are given the " corrected concentrations " or *activities* of the reference ion (*R.I.A.*) which were adjusted to some representative rounded values, while in the fourth column are given the activities of the hydrochloric acid in the end-point cells (*E.P.C.*), except where none was required.

Finally, it may be observed that the possibility of using a pair of very simple electrodes fixed close together and a single simple vessel for titration is not only a convenience, but also a simplification which permits the application of this method in several special ways (*e.g.*, microtitration), whilst the closeness of the electrodes and absence of liquid junction make it comparatively easy to keep the electrical resistance within bounds even at the lowest concentrations. Moreover, the elimination of the uncertainty attaching to liquid-junction potentials must facilitate greater precision.

The author's thanks are due to the trustees of the Brunner Mond Research Fund, out of which the cost of apparatus used in this research has been defrayed.

THE UNIVERSITY OF MANCHESTER. [*Received, May 18th,* 1927.]

CCXCV.—*Nitrosation of Phenols. Part IV.* 3 : 5-*Dichlorophenol.*

By HERBERT HENRY HODGSON and JOHN SAMUEL WIGNALL.

THE object of this investigation was to extend the work of Hodgson and Moore (J., 1923, **123**, 2499) on the nitrosation of 3-chlorophenol to the case of 3 : 5-dichlorophenol.

Blanksma (*Rec. trav. chim.*, 1908, **27**, 25) claimed to have obtained 3 : 5-dichloro-4-nitrosophenol as a by-product in the conversion of 3 : 5-dichloroaniline to the phenol, and Willstätter and Schudel (*Ber.*, 1918, **51**, 782) stated that it was obtained by the addition of sulphuric acid to an aqueous solution of the sodium salt of 3 : 5-dichlorophenol and sodium nitrite. These products, however, gave

no Liebermann nitrosoamine reaction and proved to be identical with 3 : 5-*dichloro*-4-*nitrophenol*, prepared by direct nitration of 3 : 5-dichlorophenol. Willstätter and Schudel gave no analysis for chlorine, but recorded N, 6·95%, whereas the nitro- and nitroso-compounds require N, 6·7 and 7·3%, respectively.

After numerous unsuccessful attempts, both direct and indirect, to nitrosate 3 : 5-dichlorophenol, the required substance was obtained by the oxidation of 3 : 5-*dichloro*-4-*aminoanisole* with Caro's acid and subsequent hydrolysis of the 3 : 5-*dichloro*-4-*nitrosoanisole* by concentrated sulphuric acid.

3 : 5-Dichloro-4-nitrosoanisole is colourless, and, since 4-nitroso-anisole was described by Baeyer and Knorr (*Ber.*, 1902, **35**, 3035) as bluish-green, whilst 3-chloro-4-nitrosoanisole is now shown to be deep green, the suppression of colour may be ascribed to the chlorine atom in the 5-position.

A similar explanation would apply to the colourless 3 : 5-*dichloro*-4-*nitrosophenol*, which resembles the almost colourless 3-chloro-benzoquinone-4-oxime (Hodgson and Moore, *loc. cit.*), and may better be formulated as 3 : 5-dichlorobenzoquinone-4-oxime. Kehrmann's 2 : 6-dichlorobenzoquinone-4-oxime (*Ber.*, 1888, **21**, 3318) is light yellow and decomposes at 140°, whereas its colourless 3 : 5-isomeride decomposes at 165°.

Since 3-iodophenol on nitrosation behaves differently from 3-chloro- and 3-bromo-phenols (Hodgson and Moore, 1925, **127**, 2260), the direct nitrosation of 3-chloro-5-iodophenol was attempted, but without success.

During the attempts at nitrosation, it was found that nitrous acid nitrated 3 : 5-dichlorodimethylaniline in formic acid solution (the usual procedure was fruitless); the 3 : 5-dichloro-grouping has, therefore, the same effect as in 3 : 5-dichlorophenol, which is also nitrated by nitrous acid.

EXPERIMENTAL.

The initial material, 3 : 5-dichlorophenol, was prepared from trinitrobenzene (Hodgson and Wignall, J., 1926, 2077) and also by the following modification of Willstätter and Schudel's method (*loc. cit.*): 3 : 5-Dichloroaniline (26 g.) was dissolved in 220 c.c. of hot dilute sulphuric acid (2 : 9 by vol.), the mixture cooled, and diazotised at room temperature. Excess of nitrous acid was removed by carbamide (otherwise 3 : 5-dichloro-4-nitrophenol may be formed), and the mixture added gradually to a boiling solution of sulphuric acid (100 g.) in water (140 c.c.) through which steam was passing. The aqueous distillate was made alkaline, evaporated to very small bulk, cooled, and the 3 : 5-dichlorophenol (19·5 g.)

precipitated by careful addition of 30% sulphuric acid with vigorous stirring.

3 : 5-Dichlorophenol (16 g.) was nitrated in a solution of sodium nitrate (12 g.) in water (180 c.c.) at 90—100° by the gradual addition of 48 c.c. of dilute sulphuric acid (1 : 5) during 1 hour; the mixture was then heated on the water-bath for 2 hours and steam-distilled, 3 : 5-*dichloro*-2-*nitrophenol* (5 g.) passing over, and 3 : 5-*dichloro*-4-*nitrophenol* (6 g.) being obtained from the tarry residue by repeated extraction with hot dilute hydrochloric acid.

3 : 5-Dichloro-2-nitrophenol is moderately soluble in water and readily soluble in the usual organic solvents except light petroleum, from which it crystallises in lemon-yellow needles, m. p. 51° (Found : N, 6·5; Cl, 34·0. $C_6H_3O_3NCl_2$ requires N, 6·7; Cl, 34·1%); it does not form a hydrate (compare 3-chloro-2-nitrophenol, Hodgson and Moore, J., 1926, 155), and remains unchanged when kept for 2 hours at 110°. A solid acetate could not be obtained.

3 : 5-Dichloro-4-nitrophenol is readily soluble in the usual organic solvents except light petroleum, and crystallises from water in very pale yellow needles, m. p. 150° (Found : N, 6·7; Cl, 34·1%). The *acetate*, formed when a solution of the phenol in glacial acetic acid is warmed with acetyl chloride, crystallises from dilute alcohol in colourless needles, m. p. 99° (Found : Cl, 28·2. $C_8H_5O_4NCl_2$ requires Cl, 28·4%).

Action of Nitrous Acid on 3 : 5-*Dichlorophenol.*—This was carried out according to the directions both of Blanksma (*loc. cit.*) and of Willstätter and Schudel (*loc. cit.*). In each case a product of m. p. 150° [Found : N, (i) 6·8, (ii) 6·7; Cl, (i) 34·1, (ii) 34·2. Calc. for $C_6H_3O_3NCl_2$: N, 6·7; Cl, 34·3; calc. for $C_6H_3O_2NCl_2$: N, 7·3; Cl, 37·0%] was obtained, which was identical (mixed m. p. determination) with the 3 : 5-dichloro-4-nitrophenol above; the corresponding acetates were similarly shown to be identical.

Reduction of the 3 : 5-*Dichloro*-2- *and* -4-*nitrophenols.*—3 : 5-Dichloro-2- and -4-nitrophenols are reduced to the corresponding amino-phenols by dissolving them in 12 times their weight of water containing the theoretical amount of sodium carbonate and warming the solution on the water-bath with solid sodium hyposulphite until colourless. 3 : 5-*Dichloro*-2-*aminophenol* separates from the hot solution, but in the case of the 4-*amino*-isomeride the solution has to be cooled. 3 : 5-Dichloro-2-aminophenol is readily soluble in the usual organic solvents, except light petroleum, and crystallises from water in colourless needles, m. p. 132° (Found : Cl, 39·7. $C_6H_5ONCl_2$ requires Cl, 39·9%), which darken somewhat on keeping. Its aqueous solutions give a reddish-brown precipitate with ferric chloride. 3 : 5-Dichloro-4-aminophenol is less soluble in chloroform,

carbon tetrachloride, and carbon disulphide than its 2-amino-isomeride, but more soluble in water, from which it crystallises in colourless needles, m. p. 154° (Found : Cl, 39·8%). Its aqueous solutions give a violet coloration with ferric chloride.

3 : 5-*Dichloro*-2- and -4-*nitroanisoles* are prepared by boiling for 6 hours a mixture of the appropriate nitrophenol (6 g.) with xylene (60 c.c.) and potassium carbonate (12 g.) to which methyl sulphate (12 c.c.) is gradually added. After removal of the xylene, the anisoles can be obtained pure by steam-distillation. Yield, 70% in each case. 3 : 5-Dichloro-2-nitroanisole is much more volatile in steam than its 4-nitro-isomeride, and crystallises from methyl alcohol in colourless needles, m. p. 75° (Found : Cl, 31·7. $C_7H_5O_3NCl_2$ requires Cl, 32·0%). 3 : 5-Dichloro-4-nitroanisole crystallises from methyl alcohol in colourless needles, m. p. 70° (Found : Cl, 31·9%).

3 : 5-*Dichloro*-4-*aminoanisole* is prepared by reduction of the nitro-anisole (4·2 g.) with tin (3·5 g.) and concentrated hydrochloric acid (40 c.c.), and is finally removed by steam-distillation, being much more volatile than the parent nitro-anisole. It is very soluble in methyl alcohol and carbon tetrachloride, moderately soluble in light petroleum, and only slightly soluble in water or dilute acids; it crystallises from dilute methyl alcohol in colourless needles, m. p. 71° (Found : Cl, 36·7. $C_7H_7ONCl_2$ requires Cl, 37·0%).

3 : 5-*Dichloro*-4-*nitrosoanisole* was obtained by oxidation of the amino-anisole with Caro's acid as follows : Potassium persulphate (16 g.) was stirred into concentrated sulphuric acid (32 g.), kept at room temperature for 1 hour, then poured on ice and neutralised with potassium carbonate, the final volume being about 250 c.c. The mixture was rendered faintly acidic with acetic acid, added with stirring to a cold suspension of finely-divided 3 : 5-dichloro-4-amino-anisole (2·5 g.) in 200 c.c. of water, and kept for 24 hours, the stirring being maintained for the first 6 hours; the solid product was filtered off, and unchanged amine removed from it by extraction with warm very dilute hydrochloric acid. The crude product (1·5 g.; m. p. 122°) was crystallised from carbon tetrachloride and then from methyl alcohol; colourless needles, m. p. 125° (Found : Cl, 34·23. $C_7H_5O_2NCl_2$ requires Cl, 34·46%). The nitroso-anisole turns green on melting but becomes colourless again on solidifying, and is readily soluble in chloroform and acetone, but more sparingly soluble in carbon tetrachloride, benzene, and methyl alcohol, forming green solutions; it is insoluble in light petroleum and gives the Liebermann nitrosoamine reaction.

3 : 5-*Dichloro*-4-*nitrosophenol* [-*quinone*-4-*oxime*(?)] is obtained by heating 3 : 5-dichloro-4-nitrosoanisole (1 g.) with concentrated

sulphuric acid (10 c.c.) on the water-bath for ½ hour—longer periods produce charring. An odour of quinone is noticeable during the hydrolysis. On pouring the mixture on ice, a colourless solid separates, which completely dissolves in alkalis to a green solution. The product gives the Liebermann nitrosoamine reaction, is soluble in methyl alcohol, ether, acetone, and glacial acetic acid, sparingly soluble in water, benzene, nitrobenzene, and chloroform, and insoluble in light petroleum and carbon disulphide. It separates from dilute acetic acid in colourless leaflets, which turn light brown on exposure and decompose at 165° (Found: N, 7·4; Cl, 36·9. $C_6H_3O_2NCl_2$ requires N, 7·3; Cl, 37·0%). No change appears to be effected by alkalis but decomposition takes place with boiling acids.

Among the unsuccessful attempts to prepare the foregoing nitrosophenol may be mentioned the use of: (1) Aqueous solutions of the sodium salt of 3 : 5-dichlorophenol and sodium nitrite, which gave only the 4-nitrophenol on acidification under a variety of conditions; (2) formic and acetic acid solutions; (3) amyl nitrite (compare Henrich and Rodins, *Ber.*, 1902, **35**, 4192); (4) nitrosylsulphuric acid; (5) nitrous gases and an ethereal solution of 3 : 5-dichlorophenol. The materials used as the starting-point of indirect methods included (1) 3 : 5-dichlorodimethylaniline; (2) 3 : 5-dichloro-4-aminophenol (oxidation by Caro's acid; also diazotisation, followed by oxidation with ferricyanide).

An Example of Simultaneous Reduction and Chlorination.—Reduction of 3-chloro-4-nitroanisole (6 g.) with tin (6 g.) and concentrated hydrochloric acid (50 c.c.) gave 2·5 g. of 3 : 5-dichloro-4-aminoanisole. Iron and acetic acid, or tin and dilute hydrochloric acid, however, effected normal reduction to 3-chloro-4-aminoanisole (compare Hodgson and Handley, J., 1926, 542).

3-*Chloro*-4-*nitrosoanisole* is obtained when 3-chloro-4-aminoanisole hydrochloride (3·5 g.), dissolved in water (300 c.c.), is treated with sodium hydroxide (0·7 g.) then rendered faintly acidic with acetic acid, and oxidised by potassium persulphate (20 g.) as above. The product is almost insoluble in light petroleum, but readily dissolves in the usual organic solvents, forming green solutions; from methyl alcohol it crystallises in deep green needles, m. p. 59° (Found: Cl, 20·4. $C_7H_6O_2NCl$ requires Cl, 20·7%), which give the Liebermann nitrosoamine reaction.

Action of Nitrous Acid on 3 : 5-*Dichlorodimethylaniline.*—3 : 5-Dichlorodimethylaniline was best prepared by heating 3 : 5-dichloroaniline (8 g.), methyl sulphate (12 c.c.), and methyl alcohol (15 c.c.) for 5 hours in a sealed tube at 165—170° (great pressure is developed). The viscous red product was poured into water (100 c.c.) and kept

for 1 hour until solid. Yield 4 g. It crystallises from dilute methyl alcohol (charcoal) in colourless, rhombic plates, m. p. 55° (Found : Cl, 37·3. Calc. : Cl, 37·4%), which are readily soluble in the usual organic solvents.

Attempts to nitrosate this compound by the usual methods having proved fruitless, the following method was attempted : 3 : 5-Dichlorodimethylaniline (3·8 g.), dissolved in formic acid (15 c.c.), was treated at 0° with finely powdered sodium nitrite (1·4 g.). The brown needles which first formed rapidly became resinous, and, after separation, the product was extracted with a mixture of equal parts of alcohol and acetic acid and then recrystallised from methyl alcohol; golden needles, m. p. 142° (Found : Cl, 30·1. $C_6H_2NMe_2Cl_2 \cdot NO_2$ requires Cl, 30·2; $C_6H_2NMe_2Cl_2 \cdot NO$ requires Cl, 32·4%). This product is readily soluble in acetic acid but sparingly soluble in methyl alcohol.

Nitration of 3 : 5-*Dichlorodimethylaniline.*—To 3 g. of the dichlorodimethylaniline in concentrated sulphuric acid (12 c.c.) at 0°, nitric acid (1 c.c.; 91%) was gradually added during 1 hour. The mixture was kept for a further hour at 0°, then poured on ice, and the resulting solid was filtered off, washed with cold alcohol, and crystallised from methyl alcohol; golden needles, m. p. 142° (Found : Cl, 30·3%). This product, 3 : 5-*dichloro*-4-*nitrodimethylaniline*, was identical with the preceding substance (mixed m. p. determination), thereby establishing the fact that 3 : 5-dichlorodimethylaniline is nitrated by nitrous acid in formic acid solution.

3 : 5-Dichloro-4-nitro-dimethylaniline is not decomposed on boiling with aqueous alkaline hydroxides.

The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD. [*Received, August 5th,* 1927.]

CCXCVI.—*The Abnormal Reaction of Certain Aromatic Aldehydes with Schiff's Reagent.*

By JOHN BALDWIN SHOESMITH, CHARLES EDWIN SOSSON, and ARTHUR CLEMENT HETHERINGTON.

WIELAND and SCHEUING (*Ber.*, 1921, **54**, 2527) have recently carried out an investigation on the nature of Schiff's reagent and the colour obtained in its reaction with aldehydes, and conclude that

the essental constituent of the reagent is an *N*-sulphinic acid of pararosaniline-*C*-leucosulphonic acid,

$$SO_3H\cdot C(C_6H_4\cdot NH_2)_2\cdot C_6H_4\cdot NH\cdot SO_2H.$$

To the soluble violet dyestuff produced on the admixture of the reagent with acetaldehyde they ascribe the formula

$$NH{:}C_6H_4{:}C[C_6H_4\cdot NH\cdot SO\cdot O\cdot CH(OH)\cdot CH_3]_2.$$

There are several references to abnormalities in the Schiff aldehyde reaction in the literature (compare Lorenz, *Ber.*, 1881, **14**, 789; Schmidt, *ibid.*, p. 1840; Bela von Bitto, *Z. anal. Chem.*, 1897, **36**, 369; Paula and von Buttlar, *Annalen*, 1911, **383**, 230), and one of us has remarked on the behaviour of salicylaldehyde (J., 1923, **123**, 2700) and β-resorcylaldehyde (*ibid.*, p. 2705) in giving yellow colorations and precipitates, in place of the usual soluble dyestuff, under certain conditions.

Investigations have been carried out with a view to discovering (1) the class of aldehyde which gives these abnormal yellow precipitates with Schiff's reagent; (2) the conditions under which these precipitates are formed—because it was afterwards discovered that red colorations and precipitates are produced under other conditions; and (3) the nature of this abnormal reaction and the composition of the precipitates.

Of the large number of aldehydes examined ortho-hydroxy-aromatic aldehydes most readily give yellow precipitates; indole-aldehyde behaves similarly. The reaction product is chiefly dependent on the quantity of sulphur dioxide capable of neutralising iodine (afterwards referred to as "free" sulphur dioxide) present in the reagent, as is seen from the Table, in which Y = yellow, O = orange, R = red, P = purple, B = brown, subscript p = precipitate, subscript c = coloration, and g. = g. of "free" sulphur dioxide per 100 c.c. of reagent.

The following aldehydes, chosen as representatives of other classes, behave normally, in that red or purple solutions are obtained under all the above conditions: Benzaldehyde, *m*-hydroxy-, and *o*-, *m*-, and *p*-methoxy-benzaldehydes; *o*-, *m*-, and *p*-nitro-, *o*-chloro-, *o*- and *m*-fluoro-, *m*- and *p*-bromo-, *p*-methyl-, 2-nitro-4-methoxy-,* 3-nitro-4-methoxy-benzaldehydes; 3 : 4-methylenedioxybenzaldehyde ($P_p + V_c$); *iso*propyl- and 2-carboxy-3 : 4-methylenedioxybenzaldehydes; α-naphthaldehyde, and its 3-* and 5-methoxy- and 5-bromo-derivatives; 5-bromo-2-naphthaldehyde; acrolein (deep blue), *iso*butyric aldehyde, glycollaldehyde, and glyoxal. It is noteworthy that 2 : 4-dimethoxybenzaldehyde, 2-methoxy-1-naphthaldehyde,† and thioacetaldehyde were neutral towards the reagent, and that resacetophenone and 2 : 4 : 2′ : 4′-tetrahydroxybenzophenone gave a violet coloration very slowly—in sharp contrast to β-resorcylaldehyde, which reacts rapidly.

In general, *o*-hydroxy-aromatic aldehydes give the yellow precipitates most readily, but exceptions to the rule are afforded by *p*-hydroxybenzaldehyde, which gives the yellow reaction when only a trace of "free" sulphur dioxide is present, by vanillin, by cinnamaldehyde and indole-aldehyde.

In order to ascertain the composition of the precipitates, that obtained from β-resorcylaldehyde was examined in detail. They cannot be separated as pure compounds owing to their insolubility in organic solvents or water, and to their instability towards acids and alkali. Analytical results were therefore only approximate, but a satisfactory clue to the constitution of the precipitate in each case was obtained from the interaction of the aldehyde with reagents in which the base employed was analogous to pararosaniline.

Neither the yellow nor the red *precipitates* have a constitution approximating to that proposed by Wieland and Scheuing for the dyestuff. The two classes of precipitates have very nearly, but not quite, the same constitution. When they are first formed their behaviour corresponds with that which would be expected of sulphites of hydrated Schiff's bases formed from the aldehyde and pararosaniline-*C*-leucosulphonic acid, $SO_3H{\cdot}C(C_6H_4{\cdot}NH_2)_3$—the basic constituent of Schiff's reagent. These sulphites, on drying over calcium chloride or potassium hydroxide, slowly lose sulphur dioxide; and after complete removal of the "sulphite" sulphur dioxide by dilute aqueous sodium bicarbonate, the final dried

* These aldehydes have not been described in the literature and were prepared in connexion with other investigations, an account of which, it is hoped, will be published shortly.

† This is probably due to steric hindrance, because in another investigation it was found impossible to convert the aldehyde to the alcohol by the well-known methods which readily served in other cases.

substance has properties that would be associated with, and a composition approximating to that of, a hydrated Schiff's base of formula $SO_3H\cdot C[C_6H_4\cdot NH\cdot CH(OH)\cdot C_6H_3(OH)_2]_3$. On careful hydrolysis with 10% aqueous sodium hydroxide, in which the precipitates are soluble, it was possible to recover the aldehyde in a quantity corresponding to that expected from the above formula, but the recovered pararosaniline could not be estimated. Hence we regard the reaction with this type of aldehyde as being $SO_3H\cdot C(C_6H_4\cdot NH_2)_3 + 3R\cdot CHO + xH_2SO_3 \longrightarrow SO_3H\cdot C[C_6H_4\cdot NH\cdot CH(OH)R]_3(H_2SO_3)_x$, the sulphurous acid acting as a catalyst in the formation of the "Schiff's base."

This suggestion is substantiated by the production of the yellow precipitates from pure pararosaniline-*C*-leucosulphonic acid and β-resorcylaldehyde in sulphurous acid solution, and also of precipitates, which are analogous in appearance, constitution, and general properties, from the aldehyde and the following: (*a*) the leucosulphonic acid in hydrochloric acid solution, this acid taking the place of sulphurous acid as a catalyst, and the resulting precipitate being a hydrochloride, and not a sulphite; (*b*) sulphurous acid solutions of *p'p''p'''*-triaminotriphenylmethane; (*c*) *p'p''*-diaminotriphenylcarbinol; (*d*) *p'p''*-diaminotriphenylmethane; or (*e*) *p*-aminotriphenylmethane. It was not possible to obtain the simplest analogue of Schiff's reagent, *i.e.*, a sulphurous acid solution of *p*-aminotriphenylcarbinol.

The reaction of Schiff's reagent in the normal case is considered by Wieland and Scheuing to involve the production of a compound in which carbon and nitrogen are indirectly united through sulphur dioxide, *i.e.*, the formation of an aldehyde-bisulphite type, whilst in the abnormal cases the C–N union is direct, *i.e.*, of the Schiff's base or anil type. The presence of large quantities of sulphur dioxide in the reagent favours the bisulphite reaction and also retards the Schiff's base reaction, and thus in some of the cases examined, *e.g.*, salicylaldehyde, a small quantity of the red dyestuff is produced with Schiff's reagent saturated with sulphur dioxide. The red precipitates are therefore really yellow ones which have adsorbed a little of the red dyestuff, but not sufficient to make the analytical results for the two classes markedly different.

It is not yet understood why the aldehydes given above should behave in this abnormal manner towards Schiff's reagent.

EXPERIMENTAL.

Reaction of β-Resorcylaldehyde towards Schiff's Reagent.

The reagent was prepared by allowing 10 g. of pure pararosaniline (Kahlbaum) to stand at the ordinary temperature in 500 c.c. of

saturated aqueous sulphur dioxide; when the solution became colourless 200 c.c. were added to a (saturated) solution of 8 g. of β-resorcylaldehyde in 1000 c.c. of water at 20°. The freshly prepared reagent produced a red coloration followed by a red precipitate; a yellow precipitate then formed slowly under ordinary conditions, but very rapidly if sulphur dioxide was removed from the solution under diminished pressure. From a separate portion of the reagent, the sulphur dioxide was removed, and samples were used at various concentrations of "free" sulphur dioxide (1) to estimate the amount of sulphur dioxide present, by titration with iodine, and (2) to investigate the effect of loss of sulphur dioxide from the reagent on the nature of the reaction. The results are summarised on p. 2222.

The solids were filtered and they then dissolved in aqueous alkali—the yellow with an orange colour, the red with a purple colour—and from these solutions the original solid could be immediately reprecipitated by the addition of acid. If allowed to stand in such a solution, the solids were hydrolysed (very rapidly if the solutions were heated) and a purple solid, pararosaniline, was precipitated along with a little tar. After this was filtered off, acidification of the alkaline solution produced a strong odour of sulphur dioxide, and β-resorcylaldehyde could be extracted from the acid liquid with ether, thus showing the essential constitution of the solids to be: aldehyde, pararosaniline, and sulphur dioxide.

For analysis, the solids were filtered and dried in a desiccator. The red remained unchanged in colour, but the yellow slowly lost sulphur dioxide and water, becoming dark green, and only became yellow again on the addition of *sulphurous acid*, and not on the addition of either water or sulphur dioxide alone. The loss of sulphur dioxide and the concomitant colour change were continuous as shown by sulphur estimations (see below) at intervals. The last trace of sulphur remaining in the solids as sulphite (but not that on the central carbon atoms of the rosaniline) was removed by dilute aqueous sodium bicarbonate, which caused the sample which was originally yellow to become deep green, but did not affect the colour of the red sample.

Sulphur estimations (*Carius*). Yellow solid: 2 days, 7·16; 1 week, 5·6; 2 months, 4·0; after washing with $NaHCO_3$, 2·8%. (Last sample had N, 4·4%.) Red solid: 1 week, 6·0; 2 months, 4·3; after washing with $NaHCO_3$, 3·2%. (Last sample had N, 5·1%.) The last sample from the yellow compound, which had been thoroughly dried over calcium chloride, was further dried over concentrated sulphuric acid in a vacuum. The last treatment caused a loss of 7·2%, which is ascribed to loss of water from any

–NH·CH(OH)– groups present (compare Dimroth and Zoeppritz, *Ber.*, 1902, **35**, 996).

In order to demonstrate the catalytic action of the sulphurous acid, pararosaniline-*C*-leucosulphonic acid (Wieland and Scheuing, *loc. cit.*) was dissolved in (*a*) sulphurous acid and (*b*) dilute hydrochloric acid, and on the addition of an aqueous solution of β-resorcylaldehyde to these solutions, a yellow precipitate {Found: N, 4·4; S, 2·9. $SO_3H·C[C_6H_4·NH·CH(OH)·C_6H_3(OH)_2]_3$ requires N, 5·4; S, 4·1%} was produced in the former case, identical in all respects with that from the aldehyde and Schiff's reagent, and a greenish-yellow precipitate {Found: N, 4·4; Cl, 8·5; S, 2·75. $SO_3H·C[C_6H_4·NH·CH(OH)·C_6H_3(OH)_2,HCl]_3$ requires N, 4·7; Cl, 11·8; S, 3·5%} in the latter case; this differed from the yellow precipitate in containing hydrolysable chlorine, *i.e.*, it was the hydrochloride instead of the sulphite. Since it was impossible to recrystallise either of the solids, the analytical results only approximate to those of pure compounds, and it appears as if some of the nitrogen atoms combined with two aldehyde residues, causing the low results for S, N, and Cl.

The quantity of aldehyde present in the precipitate was determined as follows, the method being trustworthy to within ± 2%: A weighed quantity of the solid was hydrolysed with boiling 8% aqueous sodium hydroxide, the solution cooled, filtered from pararosaniline, almost neutralised with dilute hydrochloric acid, and made up to 50 c.c. Phenolphthalein was added, followed by hydrochloric acid drop by drop until the solution was just colourless; methyl-orange was then added and the solution titrated with standard acid. This was a measure of the aldehyde in the original compound, since β-resorcylaldehyde is acid to phenolphthalein,* but does not affect methyl-orange. An addition of 0·1 c.c. of the acid was required to correct for the change from p_H 7—9 (sensitivity to phenolphthalein) to p_H 3—5 (sensitivity to methyl-orange). The yellow solid contained 56% of aldehyde, and the red 50%; $SO_3H·C[C_6H_4·NH·CH(OH)·C_6H_3(OH)_2]_3$ requires 52%. The aldehyde content should be higher than that given by the titration method but the tar probably contained a little aldehyde which resisted aqueous extraction.

Influence of Sulphurous and Hydrochloric Acids on the Rate of Precipitation of Schiff's Base.—A standard solution of each acid

* Although β-resorcylaldehyde behaves as a monobasic acid towards alkali in presence of phenolphthalein (compare *Annalen*, 1911, **383**, 288), 4 : 6-dihydroxy*iso*phthalaldehyde behaves partly as a mono- and partly as a di-basic acid, and cannot be estimated in the same manner.

was in turn added to a dilute aqueous solution of aniline (3%), which was then immediately added to a 5% solution of β-resorcylaldehyde, the tube shaken, and the time (t) noted for the appearance of the precipitate. In each case, increasing concentration of acid first diminished and then increased the time required :

*Condensation of Resorcylaldehyde with Bases analogous to Triphenylmethane-*C*-leucosulphonic Acid.*

Preparation of Bases.—p′p″p‴-*Triaminotriphenylmethane.* Finely powdered, dried triphenylmethane (10 g.) was slowly added to a constantly stirred mixture of 78 g. of nitric acid (d 1·42) and 120 g. of concentrated sulphuric acid at — 5—0°, and after the temperature of the whole had been allowed to rise slowly to about 15° (½ hour), the reaction mixture was poured into much cold water, and the solid trinitrotriphenylmethane was filtered off, boiled with 75% acetic acid, filtered, dried, and recrystallised from chloroform–ether; m. p. 212·5° (yield, 65%).

The trinitro-compound was dissolved in boiling glacial acetic acid, and to the red solution zinc powder was added until the colour had disappeared. The whole was diluted with water, excess of zinc filtered off, ammonia added to the solution, and the base filtered, dried, dissolved in dilute hydrochloric acid, the hydrochloride precipitated by the addition of concentrated hydrochloric acid, and finally dissolved in water, from which the free base was precipitated with ammonia, filtered, dried, and recrystallised from absolute alcohol. It had m. p. 201°.

pp′-*Diaminotriphenylmethane.* This was prepared by a slight modification of Baeyer and Villiger's method (*Ber.*, 1904, **37**, 2860); part of it was acetylated, and the diacetyl derivative (m. p. 233—234°) was oxidised to the carbinol, which was purified by conversion to the hydrochloride (Doebner's violet) and reprecipitation with ammonia. It had m. p. 173°.

p-*Aminotriphenylmethane.* A mixture of benzhydrol (5 g.) (from benzophenone), aniline hydrochloride (3·5 g.), and powdered anhydrous zinc chloride (4 g.) was immersed for 20 hours in the vapour of a mixture of toluene and xylene at 140°—this temperature

is of extreme importance. The whole was cooled, the tube broken, washed with water, shaken with a mixture of ether and sulphuric acid, and the curdy, insoluble amine sulphate filtered off, recrystallised from water, dried, extracted with ether (Soxhlet) until no brown coloration of the ether was observed, and finally dissolved in much boiling water; the base was then precipitated by sodium hydroxide and crystallised from light petroleum (aggregates of colourless plates, m. p. 84·5°). The acetyl derivative had m. p. 167° (compare Baeyer and Villiger, *loc. cit.*).

p-*Aminotriphenylcarbinol.* The methane was oxidised as in the case of the diamino-compound (compare Baeyer and Lohr, *Ber.*, 1890, **23**, 1623). *p*-Acetamidotriphenylcarbinol crystallises in fine, lustrous needles, m. p. 175·5°. To obtain the free amine, the pure acetyl derivative (4·5 g.) was mixed with 250 c.c. of dilute sulphuric acid (1 in 5) and 30 c.c. of alcohol, and the whole was boiled until clear (3 hours). The solution was filtered and caustic soda added to the hot filtrate (not sufficient to neutralise it) until a few drops gave a crystalline deposit on cooling. The bulk of the solution was then allowed to cool, and the aminotriphenylcarbinol sulphate crystallised in orange plates, which were dried and extracted in a Soxhlet, as in the case of the diamino-compound. The pure sulphate was then dissolved in hot water and the base precipitated with ammonia. It had m. p. 115°, but could not be obtained in a crystalline condition from any solvent (compare Baeyer and Lohr, *loc. cit.*).

Unlike the di- and tri-amino-derivatives, the mono-amino-carbinol is not readily soluble in sulphurous acid, and in an attempt to prepare the *C*-leucosulphonic acid by dissolving the carbinol in hot sulphurous acid solution, a crystalline solid was obtained of m. p. 125—128° (decomp.) (Found: N, 3·72; S, 5·6). The compound most nearly corresponding to this is the sulphite

$$[(C_6H_5)_2C(OH)\cdot C_6H_4\cdot NH_2]_2,H_2SO_3,$$

which requires N, 4·4; S, 5·1%. When heated on the water-bath, the crystals became deep orange in colour, in agreement with the fact that feebly coloured salts of the carbinol become deeply coloured when heated. Hence the *C*-leucosulphonic acid could not be obtained because of the insoluble nature of the sulphite first formed on the addition of sulphurous acid to the carbinol.

Aqueous solutions of the aldehyde were mixed with sulphurous acid solutions of the above bases in order to trace the regularity in sulphur and nitrogen content of the precipitates. The estimations were carried out after the solids had been washed with aqueous sodium bicarbonate and dried, and the results are summarised as follows.

Amine.	N%.	S%.	Calc. for 1 aldehyde to each NH_2-group N%.	S%.
$CH(C_6H_4\cdot NH_2)_3$	5·3	trace	5·97	0·0
$CHPh(C_6H_4\cdot NH_2)_2$	4·6	,,	5·06	0·0
$CPh(OH)(C_6H_4\cdot NH_2)_2$	4·1	3·4	4·43	5·1
$CHPh_2\cdot C_6H_4\cdot NH_2$	3·5	0·0	3·5	0·0

It is thus seen that only in the cases of the carbinols where *C*-leucosulphonic acids are formed is any appreciable quantity of sulphur left in the solids, and the proportion of nitrogen falls quite regularly with number of amino-groups present. It is also noteworthy that all the precipitates contained sulphur until washed with dilute bicarbonate, and that the colour change was not so marked in the case of the methanes as the carbinols.

Condensations of Other Aldehydes with Schiff's Reagent.—The aldehydes used here were prepared by the methods given in the literature.* The majority of these were almost insoluble in water and hence were first dissolved in alcohol, which had to be freed from traces of aldehyde. For this purpose it was boiled with solid caustic soda and distilled, the middle fraction being mixed with about 2 c.c. of Schiff's reagent and again fractionated; the first portion was rejected, but about 1 l. of alcohol, which gave a very faint pink colour with Schiff's reagent only after the lapse of ½ hour, was thus obtained. The aldehyde to be tested (0·25 g. approx.) was then dissolved in 5 c.c. of the alcohol, 5 c.c. of the reagent (made up as before) were added, and the mixture was very gently shaken to avoid atmospheric oxidation of the alcohol. The results are given on p. 2222.

Note on the Stability of Schiff's Reagent.—As is well known, Schiff's reagent when heated develops a red colour similar to that obtained in normal aldehyde reactions. It has been found that this colour disappears when the solution is cooled if it has not been either boiled or heated for a considerable time, for the appearance and disappearance of the colour depend on the amount of sulphur dioxide present in this solution. Damianovich (*Chem. Abs.*, 1910, **4**, 1681) heated Schiff's reagent in a sealed tube, and therefore noted the same phenomenon. *pp'*-Diaminotriphenylcarbinol behaves in exactly the same way, the development of a deep violet colour in the heat and its disappearance in the cold being very striking. Absorption spectra were photographed and the bands were almost identical in the first case with those observed in pararosaniline hydrochloride, and in the second case with those in Doebner's violet. A colour change was also noted in the case of

* Neither orcinol nor indole condenses with diphenylformamidine to give an aldehyde-anil (compare Shoesmith and Haldane, J., 1923, **123**, 2705).

the mono-amino-compound and here the hot solution was yellow and the cold colourless, but for reasons given this was not so satisfactory as the others. Wieland and Scheuing (*loc. cit.*) have proved that when Schiff's reagent is boiled until a precipitate appears the following reaction takes place:

$$2C(NH_2\cdot C_6H_4)_2(SO_3H)\cdot C_6H_4\cdot NH\cdot SO_2H \longrightarrow \underset{(A.)}{} \quad \underset{(B.)}{C(NH_2\cdot C_6H_4)_3\cdot SO_3\cdot NH_2{:}C_6H_4{:}C(C_6H_4\cdot NH_2)_2}.$$

The formation of the colour suggests that an intermediate stage has been observed and that the full cycle of changes is as follows:

$$A \underset{\text{Cooled (SO}_2\text{ regained by C)}}{\overset{\text{Heated (SO}_2\text{ lost to solution)}}{\rightleftharpoons}} \underset{(C.)}{(NH_2\cdot C_6H_4)_3C\cdot SO_3H} \overset{\text{Further heating}}{\underset{\text{Cooling}}{\rightleftharpoons}} \underset{(D;\ \text{coloured})}{(NH_2\cdot C_6H_4)_2C{:}C_6H_4{:}NH,H_2SO_3}$$

$$\Big\downarrow \text{Loss of } SO_2 \text{ from boiling solution}$$

$$(NH_2\cdot C_6H_4)_2C{:}C_6H_4{:}NH \quad (E.)$$

Unchanged C combines with E to form B by salt formation.

In order to avoid this disadvantage of Schiff's reagent, a "modified reagent" has been suggested independently by Prudhomme (*Bull. Soc. Ind. Mulhouse*, 1904, **74**, 169) and by Wertheim (*J. Amer. Chem. Soc.*, 1922, **44**, 1834), which is prepared from pararosaniline and sodium hyposulphite. Towards such a reagent the *o*-hydroxybenzaldehydes behave as towards a Schiff's reagent containing about 1 g. of "free" sulphur dioxide per 100 c.c.

The authors wish to acknowledge a grant from the Earl of Moray Research Fund and a teaching fellowship to one of them (J. B. S.) from the Carnegie Trustees during the tenure of which the investigation was completed.

EDINBURGH UNIVERSITY. [*Received, June 27th*, 1927.]

CCXCVII.—*The Action of Phosphorus Pentabromide on the Isomeric β-Methoxyphenylethyl Alcohols.*

By JOHN BALDWIN SHOESMITH and ROBERT JORDAN CONNOR.

DURING attempts to prepare the isomeric β-methoxyphenylethyl bromides by the method which served for the corresponding methyl derivatives (Shoesmith and Connor, this vol., p. 1768), it has been discovered that when the phosphorus pentabromide reacts with the isomeric β-methoxyphenylethyl alcohols, the nuclear directing power of the methoxyl group is so great that it causes the formation of

nuclear-brominated derivatives of the expected β-methoxyphenylethyl bromides. Thus the only compounds isolated in a pure state are β-5-*bromo*-2-*methoxyphenylethyl bromide* from the ortho-alcohol, β-6-*bromo*-3-*methoxyphenylethyl bromide* from the meta-, and β-3-*bromo*-4-*methoxyphenylethyl bromide* from the para-alcohol. The orientation of the disubstituted β-phenylethyl bromides has been proved in each case by oxidation to the corresponding known bromomethoxybenzoic acid.

Whilst carrying out preliminary experiments on the most satisfactory methods for obtaining substituted β-phenylethyl alcohols, the authors found that β-phenylethylamine in aqueous hydrochloric acid yields with nitrous acid an appreciable quantity of β-phenylethyl chloride in sharp contrast to the production of pure alcohols from the isomeric tolylmethylamines (Shoesmith and Slater, J., 1924, **125**, 2278).

Experimental.

Three series of reactions by which the isomeric β-methoxyphenylethyl alcohols might conceivably be prepared were investigated:

(1) $R\cdot CHO \xrightarrow{CH_2(CO_2H)_2} CHR{:}CH\cdot CO_2H \xrightarrow[\text{amalg.}]{Na} CH_2R\cdot CH_2\cdot CO_2H \xrightarrow[+NH_3]{SOCl_2} CH_2R\cdot CH_2\cdot CONH_2 \xrightarrow{NaOCl} CH_2R\cdot CH_2\cdot NH_2 \xrightarrow{HNO_2} CH_2R\cdot CH_2\cdot OH$ (Haworth, Perkin, and Rankin, J., 1924, **125**, 169).

(2) $R\cdot CHO \xrightarrow[+\text{alkali}]{CH_3NO_2} CHR{:}CH\cdot NO_2 \xrightarrow[\text{acid}]{Zn+} CH_2R\cdot CH{:}NOH \xrightarrow[\text{amalg.}]{Na} CH_2R\cdot CH_2\cdot NH_2 \longrightarrow CH_2R\cdot CH_2\cdot OH$ (Rosenmund, *Ber.*, 1909, **42**, 4778).

(3) $R\cdot Br \xrightarrow[CH_2Cl\cdot CH_2OH]{Mg+} CH_2R\cdot CH_2\cdot OH$ (Grignard, *Compt. rend.*, 1905, **141**, 44).

The yield of amine obtained by scheme (1) was much better than that by (2), but the poor yield of alcohol from amine led to the adoption of (3), which involved the laborious preparation of large quantities of the isomeric bromoanisoles.

The following is the best method for the preparation of *o*-methoxybenzaldehyde [used in (1) and (2)] in quantity: Salicylaldehyde (122 g.) was emulsified in a flask fitted with a reflux condenser by vigorous stirring with 40 c.c. of water, and a solution of potassium hydroxide (85 g. in 160 c.c. of water) added alternately with methyl sulphate (157 g.). The appearance and disappearance of the yellow colour of the potassium compound of the aldehyde served as an excellent indication of the course of the reaction; excess of alkali was avoided and hence the reaction temperature could be allowed to

rise without affecting the yield, which was always about 100 g., b. p. 236—237°.

The amines obtained in series (1) had b.p.'s as follows: R = C_6H_5, 88—89°/18 mm.; R = *o*-MeO·C_6H_4, 127—128°/21 mm.; R = *m*-MeO·C_6H_4, 126—127°/14 mm.; R = *p*-MeO·C_6H_4, 131—132°/18 mm.

Action of Nitrous Acid on β-Phenylethylamine in Hydrochloric Acid Solution.—The amine hydrochloride, precipitated from a benzene solution of the amine by hydrogen chloride, was dissolved in a small quantity of water, and dilute hydrochloric acid added, followed by an aqueous solution of sodium nitrite. The whole was allowed to stand for 2 hours and the reaction was completed by 30 minutes' heating on the water-bath. The oil was extracted with ether, washed, dried, and distilled, the lowest fraction, b. p. 82—87°/21 mm., being collected separately. It was a colourless, non-pungent oil, containing hydrolysable chlorine, and when treated with fuming nitric acid at —15° (compare Barger, J., 1909, **95**, 2193) it yielded β-*p*-nitrophenylethyl chloride, m. p. 46—47°, unaltered by admixture with an authentic specimen. When sulphuric acid was employed in place of hydrochloric acid only very small, impure yields were obtained.

As examples of the methods used in scheme (2), the following are given, since the compounds have not been previously described.

m-*Methoxy-ω-nitrostyrene.*—To a vigorously stirred solution of *m*-methoxybenzaldehyde (28 g.) and nitromethane (13 g.) in alcohol (40 c.c.), 25% methyl-alcoholic potassium hydroxide (23 c.c.) was slowly added, followed by a solution of sodium hydroxide (4 g. in 20 c.c. of water), after which the almost solid product was poured into ice-water and, when *completely in solution*, decomposed with the calculated quantity of ice-cold sulphuric acid; the crude yellow m-*methoxy-ω-nitrostyrene* was filtered, washed, and dried. It crystallised from alcohol in light yellow plates, m. p. 93—94° (Found: N, 8·0. $C_9H_9NO_3$ requires N, 7·8%).

The nitrostyrene (13 g.) was mixed with zinc dust (13 g.) and the mixture added to a vigorously stirred solution of 25 c.c. of glacial acetic acid in 65 c.c. of alcohol, the temperature being kept at 35°. After 10 minutes, alcohol (20 c.c.) was added, and when the temperature had fallen to 15° the solid was filtered off and extracted with ether; the extract was washed with aqueous sodium carbonate and then extracted with sodium hydroxide. m-*Methoxyphenylacetaldoxime* was precipitated from this on the addition of sodium bicarbonate, and was filtered, washed, dried, and recrystallised from ligroin, and finally from water; white needles, m. p. 92·5—93° (Found: N, 8·5. $C_9H_{11}NO_2$ requires N, 8·5%).

From this oxime in alcoholic acetic acid only a very small quantity of β-*m*-methoxyphenylethylamine could be obtained by the action of 3% sodium amalgam.

Action of Phosphorus Pentabromide on β-o-*Methoxyphenylethyl Alcohol.*—o-Bromoanisole, b. p. 220°/744 mm., prepared by the action of methyl sulphate on *o*-bromophenol, was converted into β-o-*methoxyphenylethyl alcohol* in the manner already described (Shoesmith and Connor, *loc. cit.*). It is a colourless liquid, b. p. 130—131°/11 mm. (Found: C, 71·8; H, 7·77. $C_9H_{12}O_2$ requires C, 71·1; H, 7·9%). The alcohol (10 g.) was slowly added to phosphorus pentabromide (35 g.) in dry benzene (50 c.c.), the whole being cooled in ice-water. After 30 minutes, dry air was slowly drawn through the solution for 4 hours during which time the pentabromide slowly disappeared. The solution was then washed with ice-water, dried, the benzene distilled, and the residue fractionated under diminished pressure. No definite fraction could be separated other than one at 160—165°/12 mm., which solidified and crystallised from alcohol in fine, non-pungent, white needles of β-5-*bromo*-2-*methoxyphenylethyl bromide*, m. p. 55° [Found: C, 36·9; H, 3·5; Br (total), 53·7; Br (hydrolysable), 27·2. $C_9H_{10}OBr_2$ requires C, 36·7; H, 3·4; Br (total), 54·4; Br (hydrolysable), 27·2%].

The compound resisted oxidation with alkaline permanganate but was oxidised finally according to the scheme $CH_2R{\cdot}CH_2Br \xrightarrow[KOH]{alc.} CHR{:}CH_2 \xrightarrow[+H_2SO_4]{K_2Cr_2O_7} R{\cdot}CO_2H$. Approximately 0·5 g. of the bromide was heated on the water-bath for 30 minutes with 5 c.c. of 20% alcoholic potassium hydroxide; the whole was diluted with water, extracted with ether, the ether distilled, and the residue boiled for 3 hours with 1·2 g. of potassium dichromate and 7 c.c. of 20% sulphuric acid; the resinous oxidation product was separated and boiled with aqueous sodium hydroxide, excess of dilute hydrochloric acid was added, the liberated acid was extracted with ether, and the ether solution in turn extracted with sodium carbonate, from which on acidification and ether-extraction an acid was obtained. Recrystallised from water, it had m. p. 118—119°. 5-Bromo-2-methoxybenzoic acid has m. p. 119° (compare *Gazzetta*, 1886, **16**, 408). This established the constitution of the bromide as above.

Action of Phosphorus Pentabromide on β-m-*Methoxyphenylethyl Alcohol.*—*m*-Bromonitrobenzene was reduced to *m*-bromoaniline by West's method (J., 1925, **127**, 994) and converted into *m*-bromophenol (compare B.P. 200714)—for the necessary details of this process we are greatly indebted to Dr. H. H. Hodgson. This phenol with methyl sulphate gave *m*-bromoanisole, b. p. 214°/729 mm.,

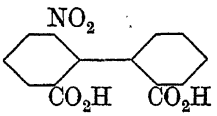
which was then converted into β-m-*methoxyphenylethyl alcohol* in the usual manner. The alcohol is a colourless liquid, b. p. 135—137°/12 mm. (Found: C, 71·1; H, 7·6%).

When the alcohol was treated with phosphorus pentabromide, as in the previous case, no definite fraction could be separated, but when excess of pentabromide was used in the cold, a colourless, non-lachrymatory, non-pungent oil, b. p. 163—165°/13 mm., was isolated [Found: Br (total), 53·8; Br (hydrolysable), 27·2%]. The compound was oxidised much more readily than its isomeride, and gave an acid, m. p. 160—161°, which did not depress the m. p. of an authentic sample of 6-bromo-3-methoxybenzoic acid (J., 1925, **127**, 880), kindly supplied by Dr. H. H. Hodgson. This characterised the oil as β-6-*bromo*-3-*methoxyphenylethyl bromide*.

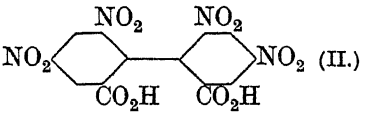
Action of Phosphorus Pentabromide on β-p-*Methoxyphenylethyl Alcohol.*—The alcohol was obtained from *p*-bromoanisole in the usual manner, and when purified had b. p. 138—140°/11 mm., m. p. 24° (compare Grignard, *loc. cit.*). When 1 mol. of pentabromide was used per mol. of alcohol, a colourless oil, b. p. 130—131°/11 mm., was obtained, which was almost pure β-p-*methoxyphenylethyl bromide* [Found: Br (hydrolysable), 35·0. $C_9H_{11}OBr$ requires Br (hydrolysable), 37·2%]. It was non-pungent and non-lachrymatory, and very similar in properties to the β-tolylethyl bromides (Shoesmith and Connor, *loc. cit.*), but further fractionation produced no improvement in the quality of the sample. With excess of pentabromide a colourless oil of b. p. 187—188°/19 mm. was formed [Found: Br (hydrolysable), 27·0%]. From this oil an acid of m. p. 217° was obtained on oxidation. 3-Bromo-4-methoxybenzoic acid has m. p. 218° (Balbiano, *Gazzetta*, 1881, **11**, 406), and the oil was therefore β-3-*bromo*-4-*methoxyphenylethyl bromide*.

The authors wish to acknowledge a grant from the Earl of Moray Research Fund and a Carnegie Teaching Fellowship to one of them (J. B. S.) which have enabled this investigation to be carried out.

EDINBURGH UNIVERSITY. [*Received, July 23rd*, 1927.]

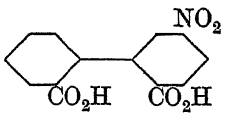


CCXCVIII.—*Investigations in the Diphenyl Series. Part VII. The Relative Stability of Optically Active Diphenic Acids.*

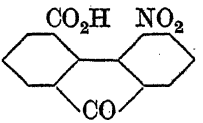


By FRANK BELL and PERCY HARRY ROBINSON.

THE theory advanced to account for the asymmetry of certain diphenyl derivatives (Part VI, this vol., p. 1695; *J. Soc. Chem. Ind.*, 1926, **45**, 864) definitely indicates that the optical activity



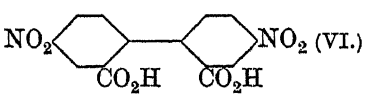
of such compounds should gain in permanence with an increase in the number of groups in the central positions. Up to the present, it has not proved possible to prepare in an optically active condition a compound with only two central groups, although some of the alkaloidal salts of "non-resolvable" acids show marked heterogeneity (compare Christie and Kenner, J., 1923, **123**, 779; 1926, 470).



It is now found that 6-nitrodiphenic acid (I) is very much less optically stable than 4 : 4′ : 6 : 6′-tetranitrodiphenic acid (II). Thus

(I.) 

 (II.)

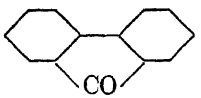


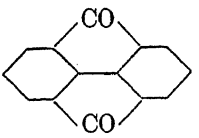
an aqueous solution of the sodium salt of the former acid steadily falls in rotatory power, whilst no such change can be perceived in the case of the latter acid. Further, boiling acetic anhydride racemises 6-nitrodiphenic acid in a very short time, whilst 4 : 4′ : 6 : 6′-tetranitrodiphenic acid loses only 25% of its activity after boiling with acetic anhydride for 10 hours. The failure which has attended attempts to resolve 5-nitrodiphenic acid (III) and 2 : 2′-dinitrodiphenyl-4 : 4′-dicarboxylic acid could have been anticipated from

(III.) 

 (IV.)

the "obstacle" theory. It may be noted that 5-nitrodiphenic acid readily forms an *anhydride*, and with sulphuric acid easily undergoes condensation to form a *fluorenone* derivative, in marked contrast to 4 : 4′ : 6′-trinitrodiphenic acid (V) which is unaffected





(V.) 

 (VI.)

by sulphuric acid at 160°. 4 : 4′-Dinitrodiphenic acid (VI) also does not undergo fluorenone formation (Underwood and Kochmann, *J. Amer. Chem. Soc.*, 1924, **46**, 2069).

Although the failure to resolve fluorenone-4-carboxylic acid has been already reported by Mills, Palmer, and Tomkinson (J., 1924, **125**, 2365), it appeared possible that the introduction of a nitro-group in position 5 might stabilise the enantiomorphous forms which arise if the fluorene system is non-planar. However, 5-nitrofluorenone-4-carboxylic acid (IV) was not resolved by crystallisation of its morphine or quinidine salts, and this result can be interpreted

as indicating that the 4 : 5-positions of fluorene are farther apart than are the 6 : 6′-positions in a diphenic acid. This conclusion agrees with the fact that, although such systems as (VII) are readily formed, attempts to prepare compounds of type (VIII) have repeatedly failed (see Meyer, Meyer, and Taeger, *Ber.*, 1920, **53**, 2034).

(VII.)   (VIII.)

EXPERIMENTAL.

d- *and* l-6-*Nitrodiphenic Acids.*—The normal quinine salt of 6-nitrodiphenic acid was systematically crystallised from alcohol until it was separated into a slightly less soluble salt, $[\alpha]_{5461}$ + 286·6° ($c = 2·5$ in chloroform), and a slightly more soluble salt, $[\alpha]_{5461}$ − 122·4° ($c = 2·5$ in chloroform). The former on decomposition gave the *d*-acid with $[\alpha]_{5461}$ + 65·2° ($c = 3·01$ in ethyl alcohol), whilst the latter gave the *l*-acid with $[\alpha]_{5461}$ − 66·4° ($c = 4·91$ in ethyl alcohol). The *l*-acid had $[\alpha]_{5461}$ + 433° ($c = 4·69$ in 0·261*N*-sodium hydroxide), whilst the *d*-acid, obtained from its morphine salt, had $[\alpha]_{5461}$ − 434° ($c = 4·73$ in 0·426*N*-sodium hydroxide).

The solution of the sodium salt was kept at room temperature, and the following observations were made:

Time (days)	0	2	9	23	36·5	51
α_{5461}	−20·51°	−18·61°	−14·42°	−8·23°	−4·00°	−1·50°

Solutions of *d*-6-nitrodiphenic acid (1 g.) in 10 c.c. of acetic acid and in 10 c.c. of acetic anhydride were boiled under similar conditions for 1 hour, and they then had α_{5461} + 11·55° and 0·0° respectively ($l = 2$). After the acetic acid solution had been boiled for a further period of 5 hours, it had α_{5461} + 0·94°.

d-6-Nitrodiphenic acid (1 g.) was converted into 5-nitrofluorenone-4-carboxylic acid (see below). The acid obtained was inactive ($c = 2·4$; $l = 2$).

l-6-Nitrodiphenic acid was dissolved in excess of thionyl chloride and the solution evaporated in a vacuum. The residue was crystallised from benzene–light petroleum and gave the *l* + *dl*-acid dichloride, m. p. 65—68°, $[\alpha]_{5461}$ − 209·5° ($c = 5·04$; $l = 2$), whilst the mother-liquor on evaporation gave a further crop of the dichloride with $[\alpha]_{5461}$ − 220·6° ($c = 2·31$; $l = 2$ in chloroform).

d- *and* l + dl-4 : 4′ : 6 : 6′-*Tetranitrodiphenic Acids.*—Boiling alcoholic solutions of tetranitrodiphenic acid (35·7 g. in 1 l.) and

quinidine (30·5 g. in ½ l.) were mixed, and the precipitated salt was filtered off and boiled with alcohol until the residue attained constant rotatory power $[\alpha]_{5461}$ + 243·5° (c = 2·15 in 14·7N-acetic acid); m. p. 252° (decomp.). The alcoholic filtrates were evaporated, the residue was dissolved in acetic acid, and the resultant solution poured into dilute hydrochloric acid. The liberated tetranitrodiphenic acid was extracted with ether, and the well-washed extract dried with sodium sulphate and evaporated. The residue ($[\alpha]_{5461}$ *ca.* − 50°) was boiled with benzene, and the more soluble material was repeatedly crystallised from benzene until it attained constant rotatory power. *l* + *dl*-Tetranitrodiphenic acid formed needles which, after being heated at 130° for ½ hour, melted at 224—226° and had $[\alpha]_{5461}$ − 138·5° (c = 1·7 in ethyl alcohol). The less soluble quinidine salt was decomposed (*a*) by dissolving it in acetic acid and pouring the solution into dilute hydrochloric acid, (*b*) by dissolving in pyridine and pouring the solution into dilute ammonia, (*c*) by grinding with concentrated hydrochloric acid. The acids, recovered as described above and dried at 140°, had almost the same rotatory power, showing that racemisation does not occur during the recovery process.

d-4 : 4′ : 6 : 6′-Tetranitrodiphenic acid, m. p. 226—227° (Found : equiv., 211. Calc. : 211) (0·3696 g. in 20 c.c. of ethyl alcohol in a 2 dm. tube) gave :

λ	4359	4602	5461	5790	6708
α	+16·70°	+11·64°	+5·26°	+4·12°	+2·58°

whence $[\alpha]_{5461}$ +142·3°.

0·4209 G. in 20 c.c. of 1·033N/10-NaOH in a 2 dm. tube gave :

λ	4359	4602	5106	5218	5461
α	+29—31°	+19·6—20·0°	+10·84°	+9·72°	+8·00°
λ	5790	5896	6104	6708	
α	+6·33°	+5·86°	+5·08°	+3·78°	

whence $[\alpha]_{5461}$ + 190·5°.

After 39 days, this solution had α_{5461} + 8·08°.

A solution of *d*-tetranitrodiphenic acid in acetic anhydride (1 g. in 10 c.c.), with α_{5461} + 23·15°, had after 2 hours' boiling α_{5461} + 18·14°, and after 9 hours' boiling α_{5461} + 17·12°.

l-Tetranitrodiphenic acid was dissolved in thionyl chloride by boiling for 2 hours under reflux, and the solution was evaporated in a vacuum. The residue was difficultly soluble and melted indefinitely. Though no product was isolated in a pure condition, the optical activity was preserved, since $[\alpha]_{5461}$ − 133° (c = 2 in pyridine).

5-Nitrodiphenic acid was prepared by the process described by

Schmidt and Lumpp (*Ber.*, 1908, **41**, 4315). After 1 hour's boiling with acetic anhydride, the solution on cooling deposited crystals of *5-nitrodiphenic anhydride*, m. p. 193—195° (Found: C, 62·4; H, 2·9. $C_{14}H_7O_5N$ requires C, 62·4; H, 2·6%). 5-Nitrodiphenic acid (1·5 g.) in sulphuric acid (5 c.c.) was heated at 160° for ¼ hour, and after cooling poured into water. The precipitated *6(?)-nitrofluorenone-4-carboxylic acid* melted at 282° after crystallisation from acetic acid (Found: equiv., 270·5. $C_{14}H_7O_5N$ requires equiv., 269). 5-Nitrodiphenic acid gave non-crystallisable quinine, morphine, and quinidine salts. The brucine salt on crystallisation from water gave successive crops with $[\alpha]_{5461}$ — 10·4°, — 10·9°, — 11·2°, —11·1° ($c = 2·5$; $l = 2$ in 14·7*N*-acetic acid), indicating that no resolution had taken place.

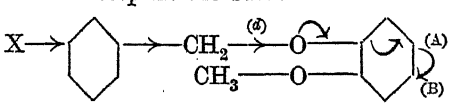
5-Nitrofluorenone-4-carboxylic acid was prepared by the method of Moore and Huntress (*J. Amer. Chem. Soc.*, 1927, **49**, 1324). The quinidine salt showed slight irregularity in rotatory power ($[\alpha]_{5461}$ *ca.* — 20·6°; $c = 2·5$ in chloroform) but no resolution was effected. The morphine salt was crystallised from alcohol and showed a constant rotatory power of $[\alpha]_{5461}$ — 73·5° ($c = 2$ in 14·7*N*-acetic acid).

2 : 5 : 7(?)-*Trinitrofluorenone-4-carboxylic acid*, obtained by heating 5-nitrofluorenone-4-carboxylic acid (2·5 g.) with nitric acid (*d* 1·5; 50 c.c.) at 100° for 2 hours, pouring into water, and crystallising the resulting mass from aqueous alcohol, forms glistening, pale yellow plates, m. p. 254—255° (Found: C, 46·5; H, 1·7. $C_{14}H_5O_9N_3$ requires C, 46·8; H, 1·4%).

2 : 2′-Dinitrodiphenyl-4 : 4′-dicarboxylic acid was prepared from 4-bromo-3-nitrobenzoic acid. Its excessive insolubility militated against the production of uniform normal alkaloidal salts. The brucine salt on crystallisation from water varied in rotatory power between $[\alpha]_{5461}$ — 40° and $[\alpha]_{5461}$ — 56° ($c = 2$ in pyridine), but the liberated acid was inactive when observed in 1·033*N*/10-sodium hydroxide.

Quinine salts of 4-nitrodiphenic acid. An alcoholic solution of quinine (2 mols.) and 4-nitrodiphenic acid (1 mol.) was allowed to crystallise slowly. Successive crops had $[\alpha]_{5461}$ + 94·4°, + 84·0°, + 77·2° ($c = 2·5$ in chloroform), and the mother-liquor on evaporation and desiccation gave a solid with $[\alpha]_{5461}$ + 11·9°. Recrystallisation of the intermediate crops raised the rotatory power to $[\alpha]_{5461}$ + 106·4°; m. p. 180° (indefinite) (Found: C, 66·3; H, 5·6%). The liberated 4-nitrodiphenic acid was inactive in every case. The difference in rotatory power may be attributed to: (*a*) resolution of the alkaloidal salt; (*b*) admixture of acid and normal quinine salts and quinine; (*c*) differences in the number of

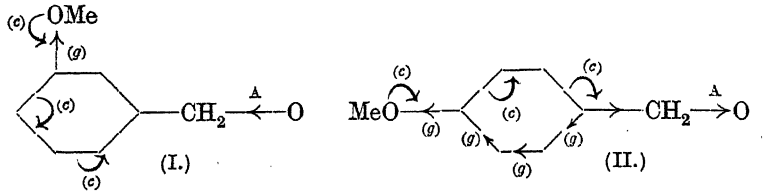
molecules of solvent of crystallisation—none of the salts lost more than 0·5% by weight on drying for 1 hour at 120°, however; or (*d*) possible presence of 6-nitro- and 4 : 4′-dinitro-diphenic acids as impurities.



In conclusion, the authors wish to express their thanks to the Department of Scientific and Industrial Research for a grant made to one of them.

BATTERSEA POLYTECHNIC, S.W. 11. [*Received, July 6th,* 1927.]

CCXCIX.—*The Relative Directive Powers of Groups of the Forms* RO *and* RR′N *in Aromatic Substitution. Part VI. The Nitration of* m- *and* p-*Chlorobenzyl Ethers of Guaiacol.*



By ALBERT EDWARD OXFORD and ROBERT ROBINSON.

IN studying the relative directive powers of substituted benzyloxy-groups, we examine, in effect, the influence of the modified benzyl group on the electrons of the oxygen atom, and an important feature of the method is that the reactive centres are spatially removed from the benzyl group. The annexed diagram serves to illustrate this point, and just as Flürscheim secured a more just comparison of groups by excluding for certain purposes the ortho-derivatives, so we imagine that the device of relaying the effects of a group and estimating them at a distant point in the molecule constitutes a further step in the same direction.

In the case represented, X and also X·C_6H_4 are hypothetical kations that have a smaller electron affinity than a proton: this produces an electron displacement (*d*) in the sense indicated and relative to the mean positions of electrons in the corresponding position in the methoxy-group. The contiguous oxygen atom and the associated crotenoid system are thus stimulated, and the velocity of substitution at (B) is greater than that at (A). Groups are compared by putting them separately into competition with methoxyl, and in Part II (J., 1926, 383) it was shown in this way that the directive powers of the *m*-nitrobenzyloxy- and *p*-nitrobenzyloxy-groups are approximately equal (67; MeO = 100). Similarly, the directive power of the *m*-methoxybenzyloxy-group was found to be 92, indicating that in the absence of conjugative

disturbances, admittedly never completely eliminated in the formal systems, the methoxyl group must be regarded as one that has a greater electron affinity than hydrogen (I; resultant effect $g>c$ at A). Unfortunately, the directive power of the *p*-methoxybenzyloxy-group could not be determined; we had anticipated a considerably augmented value (>113, the directive power of the benzyloxy-group) as the result of the combined conjugative and general effect shown in (II) ($c>g$ at A).

The chlorine atom has a greater electron affinity than the methoxyl group, implying an increased general effect and a decreased conjugative effect, and the theoretical disparity between the directive powers of *m*- and *p*-chlorobenzyloxy-groups is thus smaller than that which should exist between the directive powers of the *m*- and *p*-methoxybenzyloxy-groups. Actually, we find that *m*-chlorobenzyloxy- has the directive power 69, and *p*-chlorobenzyloxy- 82. In both cases, therefore, the general effect of chlorine is paramount, but the higher value for the para-derivative is in harmony with our theoretical anticipations, and is probably due to crotenoid conjugation analogous to that symbolised in (II). The close approach of the directive power of *m*-chlorobenzyloxy- to that of *m*-nitrobenzyloxy-, showing that the electron affinity of chlorine is almost as strong as that of the nitro-group, need not occasion surprise, since the charges in the semi-polar double bonds, often assumed to be integral, are not really effective as such on account of the distortion and polarisation of the atoms that must enfeeble their external fields. It is probable that the difference between Cl and NO_2 lies not so much in their respective electron affinities as in the circumstance that Cl possesses free electrons, whereas the N of NO_2 does not. Therefore in C–Cl there may be occasional phases, non-existent in the case of C–NO_2, in which the co-valency with the carbon atom is increased, or alternatively, in which the electron density in the neighbourhood of the carbon atom is increased by the chlorine atom to such an extent that a co-valency change would occur if an electron-seat were available. The C–Cl group is thus the more plastic, and the electric intensity of the external fields varies over a greater range. This condition would be sufficient to account for such facts as the predominating *op-*

substitution of $Ph{\cdot}CH_2{\cdot}Cl$ as compared with the *mp*-substitution of $Ph{\cdot}CH_2{\cdot}NO_2$, even although the *average* electron affinities of Cl and NO_2 were approximately equal. The method of examination through a relay atom overcomes this difficulty to a large extent, because the phases at the C–Cl group that favour the reaction examined cannot be effective unless they happen to synchronise with a phase of the relay atom ($\overset{\curvearrowright}{O}$—C in the cases considered in this communication) also promoting reaction. It is obvious that this requirement must augment the relative importance of the normal conditions and diminish the magnitude of effects of the infrequent phases, $C\overset{\curvearrowleft}{—}Cl$ and $C\leftarrow\!\!—Cl$.

Experimental.

Shoesmith and Slater (J., 1926, 219) obtained *m*-chlorobenzyl bromide, b. p. 109°/10 mm., from *m*-nitrobenzaldehyde through *m*-chlorobenzaldehyde and *m*-chlorobenzyl alcohol, which was treated with hydrogen bromide in benzene solution. We have employed two methods: (*A*) Aceto-*p*-toluidide ⟶ 3-chloro-*p*-toluidine (Chattaway and Orton, J., 1900, **77**, 792) ⟶ 2-chloro-4-methylphenylhydrazine ⟶ *m*-chlorotoluene ⟶ *m*-chlorobenzyl bromide (by refluxing with the theoretical amount of bromine). (*B*) *m*-Nitrobenzyl alcohol ⟶ *m*-aminobenzyl alcohol (Lutter, *Ber.*, 1897, **30**, 1065) ⟶ *m*-chlorobenzyl alcohol (in excellent yield) ⟶ *m*-chlorobenzyl bromide (by means of bromine and red phosphorus, compare Part II, *loc. cit.*). Both processes yielded an oil, b. p. 120—123°/24—25 mm., and the specimens were identified by conversion into 5-nitro-2-*m*-chlorobenzyloxyanisole, m. p. 121°. A mixture of the two specimens melted at the same temperature.

p-Chlorobenzyl bromide was obtained by the bromination of *p*-chlorotoluene (44 g.) (Jackson and Field, *Ber.*, 1878, **11**, 905). After crystallisation from 85% alcohol, 15 g. of nearly colourless needles, m. p. 50°, were obtained (Shoesmith and Slater, *loc. cit.*, give m. p. 51°). The following guaiacol and nitroguaiacol ethers were prepared by methods closely resembling those employed previously (Part II, *loc. cit.*) for the corresponding *m*- and *p*-nitrobenzyloxy-derivatives. The crude products never melted more than 1° lower than the true m. p., but were recrystallised two or three times, a process which did not alter the m. p.'s.

2-m-*Chlorobenzyloxyanisole*, $MeO{\cdot}C_6H_4{\cdot}O{\cdot}CH_2{\cdot}C_6H_4Cl$, b. p. 207—208°/15 mm., crystallised from light petroleum in slender needles, m. p. 46—47° (Found: C, 67·2; H, 5·4. $C_{14}H_{13}O_2Cl$ requires C, 67·6; H, 5·3%). It is readily soluble in most organic solvents.

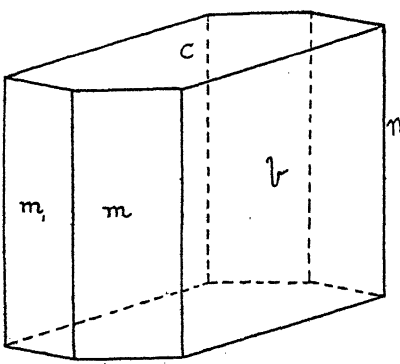
4-*Nitro*-2-m-*chlorobenzyloxyanisole*, $MeO{\cdot}C_6H_3(NO_2){\cdot}O{\cdot}CH_2{\cdot}C_6H_4Cl$,

crystallises from alcohol in minute, slender, colourless needles, m. p. 129—130·5° (Found: Cl, 12·3. $C_{14}H_{12}O_4NCl$ requires Cl, 12·1%).

5-*Nitro*-2-m-*chlorobenzyloxyanisole* crystallises from alcohol in colourless, feathery needles, m. p. 121° (Found: C, 57·0; H, 4·4. $C_{14}H_{12}O_4NCl$ requires C, 57·2; H, 4·1%).

2-p-*Chlorobenzyloxyanisole* crystallises from methyl alcohol in colourless, rectangular prisms, and from light petroleum in large, very well-defined prisms, m. p. 70° (Found: Cl, 14·3. $C_{14}H_{13}O_2Cl$ requires Cl, 14·3%). A description of these (Fig. 1) is contributed by Mr. H. E. Buckley, of the Crystallography Department of this University.

FIG. 1.



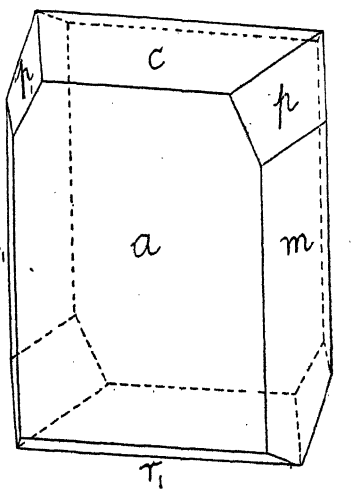


FIG. 2.

Symmetry: rhombic. Axial ratios: $a : b : c = 0{\cdot}7054 : 1 : 0{\cdot}7013$. Forms developed: b(010, tabular), c(001), m(110); (011) is very rare. Mean angular values: 011—001, 35° 3′ (6 angles; limits, 35° 0′—35° 12′); 010—110, 54° 48′ (24 angles; limits, 54° 35′—55° 1′). Cleavage: imperfect, parallel to 100.

4-*Nitro*-2-p-*chlorobenzyloxyanisole* crystallises from alcohol in colourless, lustrous, feathery needles, m. p. 115—117° (Found: Cl, 11·8%).

5-*Nitro*-2-p-*chlorobenzyloxyanisole* crystallises from alcohol in colourless, flat needles, m. p. 120—120·5° (Found: Cl, 12·0%). Mr. Buckley has kindly examined the crystals (Fig. 2) deposited on slow evaporation of a solution in light petroleum.

System: monoclinic prismatic. Axial ratios: $a : b : c = 2{\cdot}699 : 1 : 1{\cdot}708$. $\beta = 74°\ 40'$. Habit: somewhat tabular on a(100). Forms generally developed: a(100), m(110), $r(\bar{1}01)$, c(001),

and *p*(111). Mean angular values (calculated values in parentheses): *ac* 74° 40′, *am* 68° 59′, *ra* 69° 5′, *mc* 84° 37′ (84° 33′), *mr* 36° 15′ (36° 15′), *m* (110) *m*′ (1$\bar{1}$0) 42° 3′ (42° 3′), *pc* 56° 12′ (56° 1′).

Mixtures of 4- *and* 5-*Nitro*-2-m-*chlorobenzyloxyanisoles*.—The following freezing points were observed, the first number of each pair indicating the % of the 5-nitro-isomeride in the mixture: 15·36, 123·7° (1); 22·62, 119·85° (2); 30·42, 115·05° (3); 38·09, 110·0° (4); 43·12, 106·0° (5); 46·34, 103·65° (6).

Nitration of 2-m-*Chlorobenzyloxyanisole*.—The conditions given for the nitration of 2-*p*-nitrobenzyloxyanisole (Part II, *loc. cit.*, p. 389) were followed exactly. 1·7214 G. of the ether gave 2·0119 g. of the dried nitration product (yield, 99·0%), which was almost colourless and melted to a transparent liquid only slightly darker than that formed on fusion of the pure nitro-ethers. The filtrate and washings from the nitration were colourless and gave no coloration on the addition of sodium hydroxide. Since this product was found to behave as a binary mixture, it was not considered necessary to purify it by washing with methyl alcohol or in any other way. The f. p. of the nitration product was 107·55°, and from the graph we find: 5-nitro-isomeride, 41·1% [the Lagrange interpolation formula gave 41·3%, from points (2) to (5) inclusive]. A mixture of the nitration product (1·3779 g.) and the 4-nitro-isomeride (0·4796 g.) had f. p. 115·1°, practically coinciding with point (3) (30·42% of the 5-nitro-isomeride) and showing 40·9% of the 5-nitro-isomeride in the nitration product. A mixture of the nitration product (1·3779 g.) and the 4-nitro-isomeride (0·7884 g.) froze at 117·9° (5-nitro-isomeride, 25·95% from the graph), giving 40·8% of the 5-nitro-isomeride in the nitration product. A mixture of the 5-nitro-isomeride (0·6151 g., 41%) and of the 4-nitro-isomeride (0·8865 g.) froze at 107·8°, whilst the addition of 4-nitro-isomeride (0·5494 g.), reducing the 5-nitro-isomeride to 30·0%, raised the f. p. to 115·4°. These observations confirm those used in constructing the graph, and it appears that the nitration product contains 41% of the 5-nitro-isomeride. Hence the directive power of the *m*-chlorobenzyloxy-group is 69·5 (MeO = 100).

Mixtures of 4- *and* 5-*Nitro*-2-p-*chlorobenzyloxyanisoles*.—The following freezing points were observed, the first number of each pair indicating the % of the 5-nitro-isomeride in the mixture: 0, 116·3° (1); 9·8, 111·25° (2); 20·48, 106·0° (3); 32·26, 99·25° (4); 36·73, 95·6° (5); 44·86, 89·55° (6); 49·82, 84·8° (7). In (7) the first f. p. was 84·8°; the temperature then fell to 84·6°, and gradually rose to 86·05°, at which it remained constant for several minutes. This behaviour indicates the formation of an equimolecular compound of the components.

Nitration of 2-p-*Chlorobenzyloxyanisole.*—Except for the numerical details, the remarks made above on the *m*-isomeride are applicable to this case in every respect. (*a*) 1·9816 G. gave 2·3169 g. of the dried nitration product (yield, 99·0%) (Found : C, 57·1; H, 4·1. Calc. for $C_{14}H_{12}O_4NCl$: C, 57·2; H, 4·1%). (*b*) 1·2848 G. gave 1·4942 g. (yield, 98·5%). Nitration product (*a*) froze at 89·15°, (*b*) at 89·0°, and the f. p. 89·1° corresponds on the graph to 45·4% of the 5-nitro-isomeride. Mixtures of the nitration product (1·4424 g.) with the 4-nitro-isomeride (0·3487 g. and 0·6065 g.) had f. p.'s 96·0° and 99·55°, respectively. Both these values are very close to determined points (5 and 4 respectively) : the first corresponds to 36·24% of the 5-nitro-isomeride, giving 45·0% of this in the nitration product, and the second to 31·74% of the 5-nitro-isomeride, giving 44·8% in the nitration product. The f. p. of a mixture of the 5-nitro-isomeride (0·7226 g., 44·85%) and the 4-nitro-isomeride (0·8884 g.) was 89·2°. Hence the nitration product contains 45% of the 5-nitro-isomeride, and the directive power of the *p*-chlorobenzyloxy-group is 82 (MeO = 100).

THE UNIVERSITY, MANCHESTER. [*Received, July 20th,* 1927.]

CCC.—*The Thermal Dissociation of Carbonyl Chloride.*

By HORACE INGLESON.

THE object of the present work was to obtain satisfactory values for the dissociation constant of a chemical change. As carbonyl chloride dissociates at temperatures sufficiently low to admit of accurate determinations being made, it was decided to study this particular change. Reference to the literature showed serious differences in the results of investigators prior to 1921; these results are summarised in Table I. At the lower temperatures, the values are in bad agreement. Thus, an approximate calculation shows that the value at 341° obtained by extrapolation from Horak's data (Diss., Berlin, 1909) would be of the order of 4000, and not 8280 as calculated from the results of Atkinson, Heycock, and Pope (J., 1920, **117**, 1410). At the higher temperatures, there is a similar lack of agreement among different workers : in nearly every case the results of Atkinson, Heycock, and Pope correspond to a smaller degree of dissociation than that found by other workers.

Bodenstein and Dunant (*Z. physikal. Chem.*, 1908, **61**, 437) used the streaming method in their experiments, and determined the equilibrium both from the thermal combination of carbon monoxide and chlorine and from the dissociation of carbonyl chloride. They

concluded that their results confirmed the theory of Nernst as well as could be expected in the absence of values for the specific heat of carbonyl chloride. Horak (*loc. cit.*) used a quartz spiral manometer in order to measure the pressure developed in a heated porcelain tube filled with the gas, whereas Atkinson, Heycock, and Pope (*loc. cit.*) applied the streaming method to measure the extent of the thermal dissociation of the gas in the presence of a catalyst at temperatures between 101° and 517°.

During the progress of the present work, Christiansen (*Z. physikal. Chem.*, 1922, **103**, 99) published the results of an investigation of the factors affecting the velocity of decomposition of the gas at different temperatures. He concluded that the decomposition was accelerated by the chlorine produced, but his work gives very little information concerning the dissociation constants.

In 1924, Bodenstein and Plaut (*Z. physikal. Chem.*, **110**, 399) described experiments made at temperatures between 373° and 451°, and their results are included in Table I. They were able to confirm the observation of Christiansen that the chlorine accelerates the decomposition.

Preliminary Experiments at the Boiling Point of Sulphur.

1. *Chemical Series.*—From a consideration of the difficulties inherent in the streaming method, it seemed likely that some modification of the static method would be more suitable for carrying out the experiments. In the first series of eight experiments, which gave a mean value of $K_c = 354$, a known weight of carbonyl chloride was heated in a closed, thin-walled bulb of glass by suspending it in the vapour of sulphur boiling under atmospheric pressure. At the end of 8 hours, the bulb was quickly removed from the heating bath into a rapid current of carbon dioxide; it was shielded from the light, and the chlorine was determined iodometrically.

This series of experiments and later series in which a similar method was used have been called " chemical." It was decided to control these results by a second set of experiments at the same temperature, based on methods which may be termed " physical."

2. *Physical Series.*—In this series, a glass bulb, filled with a known amount of carbonyl chloride, was heated as before, but the pressure corresponding to equilibrium was measured in a manometer containing mercury after the interposition of an " air buffer." This series gave the value $K_c = 364$ as the mean of eight experiments. Since the agreement of the results of the two series at the boiling point of sulphur was satisfactory, the methods were applied at the boiling point of mercury.

Preliminary Experiments at the Boiling Point of Mercury.

1. *Physical Series.*—The experiments were carried out in the manner just described except that a small amount of charcoal was used to accelerate the rate of attainment of equilibrium. The mean of four concordant results was $K_c = 3007$.

2. *Chemical Series.*—On account of the small extent of decomposition, the chlorine determinations were checked by making careful measurements of the amount of carbon monoxide formed. It was found that the percentage decomposition calculated from the determination of the chlorine was smaller in every instance than that derived from the carbon monoxide measurements; *e.g.*, in one experiment the carbon monoxide measurements indicated 9·1% decomposition (corresponding to $K_c = 3249$), whilst 7·8% decomposition ($K_c = 4429$) was calculated from the chlorine determinations. The means of the values from the chlorine and carbon monoxide determinations were, respectively, $K_c = 4350$ and $K_c = 3181$. It will be seen that the value obtained in the physical experiments, $K_c = 3007$, agrees better with the latter than with the former. As it was clear that the chemical method could not be used with advantage, the physical method was modified so that continuous observation of the pressure of the decomposing gas could be made. By this means, it was found possible to establish the cause of the discrepancy between the two sets of results.

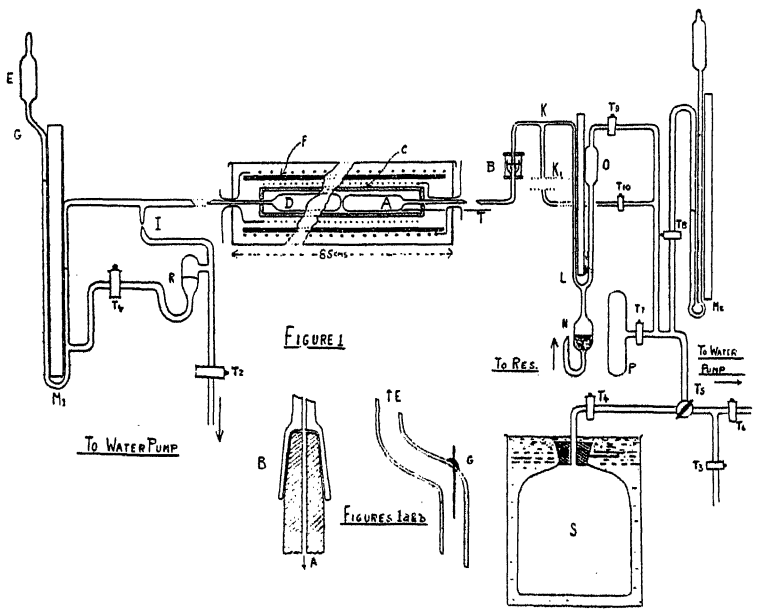
3. *Second Physical Series.*—The apparatus used consisted of a reaction vessel of glass which was joined to a U-tube containing concentrated sulphuric acid. By suitable manipulation of a tap, the U-tube could be made to serve as a manometer which protected the mercury in a second manometer from attack by the chlorine produced in the decomposition. The reaction vessel was filled with carbonyl chloride at room temperature to a convenient pressure, and after the heating of the vapour-bath had commenced, the

levels of the acid in the U-tube were maintained nearly constant by gradually increasing the pressure of the air in one limb of the tube. Readings of the pressure of the gases in the bulb were made at regular intervals after the temperature of the bath became constant. It was expected that the pressure would gradually increase to a constant value, the rate of increase slowly falling to zero. It was found, however, that the rate of increase of pressure did not fall to zero, but only decreased to a small constant value even after prolonged heating had taken place. This suggested that the observed rate of change was not determined simply by the dissociation of carbonyl chloride. On removing the bulb from the heating bath, a marked etching of the inner surface was noticed. The white solid which gave the etched appearance showed the reactions of a chloride.

The results of the eight experiments comprising this series gave an average value of $K_c = 3031$, which is in good accord with the results from the chemical determinations of the carbon monoxide ($K_c = 3181$) and from the first physical series ($K_c = 3007$). These three results lend support to the following explanation of the non-equivalence of the chlorine and carbon monoxide in the chemical series. During the prolonged heating, the materials of the bulb were attacked by the chlorine present and evolution of gas took place. The removal of the chlorine caused a disturbance of the equilibrium and further dissociation of carbonyl chloride took place to re-establish it. Thus, analysis by the chemical method gives a quantity of free chlorine which is too small, whilst the amount of gas determined as carbon monoxide is too large. From this it may be concluded that trustworthy results cannot be obtained in experiments in which the gases are heated for long periods in glass bulbs. A bulb of transparent fused quartz was therefore employed in the later experiments.

Later Experiments.

The results obtained in the five series of experiments made at 357°, 389°, 415°, 444·1°, and 481·4° have been summarised in Table I. Experiments were first made in vapour baths at 357° and 444·1°; subsequent experiments were precisely similar except that they were carried out in an electric furnace. Those at 389° and 415° were chosen so as to give nearly equal intervals, and when the results at these four temperatures were plotted it was found that a straight line passing through the points corresponding with 357°, 415°, and 444·1° did not pass exactly through that corresponding with 389°. Further experiments were made at 481·4°, which clearly showed that a straight-line relationship exists between



the reciprocals of the temperature and the logarithms of the constants.

Experimental.

The phosgene used throughout was obtained from Kahlbaum in sealed glass bombs. The apparatus is shown in Fig. 1. The quartz bulb, A, had a capacity of about 175 c.c. and was placed inside the heavy copper tube, C. It was joined to the rest of the apparatus through the ground joint, B. This was specially made in order to contain the smallest possible volume (see Fig. 1A), and was lubricated with a thin layer of chlorinated lanoline from which all traces of volatile substances had been removed. The whole was sealed by immersion in mercury, and the two sections of the joint were securely held together. The copper tube was about 65 cm. in length and 5·4 cm. in diameter, and had a wall thickness of 9 mm. Thick copper plates were fixed to the ends of the tube after the bulbs A and D had been placed in position. The tube was evenly wound with heavy gauge nickel-chrome wire, the winding being carried as near to the ends of the tube as possible. The tube F extended beyond the ends of the copper tube for a length of about 8 cm. It reduced the loss of heat from the ends of the copper tube and also kept this tube in an enclosure at a fairly uniform temperature. The tubes were carefully packed in kieselguhr in an iron box. The bulb D was of glass and had a capacity of about 500 c.c. The manometer M_1 carried an evacuated bulb, E, and had a stout platinum wire fused in at G (see Fig. 1B). The T-piece, I, served only in the drying and filling of the bulb, D. The portion of the apparatus just described is called the air-regulator. It served as an air thermometer and also controlled the current supplied to the furnace. The windings round the iron and copper tubes were in parallel and the circuits were so arranged that when that round the copper tube was broken by the operation of the air-regulator, about 2% of the total current was cut off. Fluctuations in the total current caused by changes in the voltage at the laboratory mains were compensated for by the adjustment of a rheostat by hand. This regulation of the current was carried out continuously during the whole time required for an experiment. Observations showed that it was easy to maintain the temperature constant to $\pm 0{\cdot}25°$ when the temperature of the laboratory was kept fairly constant. The pressure of the carbonyl chloride at room temperature is shown in Tables II and III under the heading p_1. After the pressure of the air in the large bottle, S, had been adjusted to be nearly equal to p_1, the tap, T_4, was closed. The bottle was kept in a well-regulated thermostat. The quartz bulb and all the connecting tubes were repeatedly evacuated and washed

out with the gas before being filled. Air-free, concentrated sulphuric acid was allowed to close the seal, L, and enter O to a convenient height. The pressure of the gas in the quartz bulb was measured on the vacuum-type manometer, M_2. The heights of the mercury in the manometers were read to 0·1 mm. with the aid of a cathetometer. The temperature of the gas was read on a mercury thermometer, T, graduated to 0·1°, which had been checked at the melting point of ice and at the transition point of the system $Na_2CrO_4,10H_2O$–$Na_2CrO_4,6H_2O$–H_2O. After the pressure and temperature of the air in the bulb D had been measured, a nitrogen-filled

FIG. 1.

thermometer was put in position, the tap T_4 was opened and the heating current passed through the furnace. Well-dried air was admitted into S to keep the levels of the acid in the seal nearly stationary and thus compensate for the gradual increase in pressure of the gases in the quartz bulb. During the heating, approximate measurements were made of the pressures of the gases in the bulbs. It was observed that up to about 350° the pressures increased roughly in proportion to their initial values. Then the gases in the quartz bulb began to exert a proportionately greater pressure than did the air in the bulb D. This effect became more and more marked, and the rate of decomposition as deduced from pressure measurements passed through a maximum value after the highest temperature

had been reached. This behaviour is in accord with the observations of Christiansen (*loc. cit.*). When the pressure of the decomposing gas ceased to increase, the experiment was discontinued. Heating of the bulb was in all cases continued for 12—24 hours after chemical equilibrium appeared to have been reached. The pressures corresponding to equilibrium are given in Tables II and III in columns headed p_2.

In order to provide a check upon the high temperatures employed, air was frequently substituted for carbonyl chloride in the bulb A. Measurements of the quantity pv/T for the quartz bulb and the tubing connected to it were made. The value of T at the high temperature was deduced from measurements of the pressures in the air-regulator. As an example of the values found at the low and high temperatures, a determination at 389° is given: pv/T at 19·2° = 157·7; pv/T at 389° = 157·5.

In determining the true value of the concentrations of the gases composing the equilibrium mixture, several corrections were introduced. A small amount of carbonyl chloride in the tubing between the furnace and the meniscus of the acid in the seal was exposed either to bright daylight or to an electric lamp, and thus was not at the temperature of the furnace when the final pressure measurements were made. It is evident that if the equilibrium mixture of gases in the hot bulb could be separated from the gas in the cold tubing and then allowed to regain its original composition and temperature of filling, it would not exert a pressure p_1, but a smaller pressure.

The separate series of experiments which gave the mean values shown in Table I are discussed below.

TABLE II.

Results obtained at the boiling point of mercury.

No.	p_1 (mm.).	Temp.	p_2 (mm.).	% Dec.	K_c (corr.).	B. p. (°K.)

					Mean 3654	

Table II gives the results of experiments made at the boiling point of mercury; the alteration of the boiling point with the change n the atmospheric pressure was taken into account. (Data for this correction, and also for that of the series at the b. p. of sulphur, are taken from the *Chemiker Kalender*, 1922, Vol. 2, pp.

129, 130.) The temperature at which each experiment was made is shown in the last column of the table.

It is considered that the results are more trustworthy than any hitherto obtained at 357°. The values of the constant are calculated directly from the percentage decomposition (% Dec.) after the use of the corrections referred to above.

3	187·00	17·35	751·93	55·22	143·2
				Mean	151·6

Of the experiments in Table III*a*, Nos. 1—4 were made at 388° and the others at 389°. The mean from Expts. 5—9 is $K_c = 1395$, or, excluding No. 7, $K_c = 1409$. It was found that a trace of sulphuric acid had entered the quartz bulb in Expts. 1—4; the effect of this would be to give too large a final reading of the pressure p_2 and thus too small a value for K_c. Furthermore, since the value $K_c = 1409$, from Expts. 5, 8, and 9, approximates more closely to the smoothed curve representing the results at other temperatures (see p. 2252), this value is regarded as the more trustworthy and is quoted in Table I.

A comparison of the results given in Table IIIc (which all relate to temperatures between 443·7° and 444·8°) with the values obtained in the preliminary experiments at the boiling point of sulphur shows a very satisfactory agreement between the three sets of values.

In the graph shown in Fig. 2 the values of log $K_c/100$ have been plotted against the reciprocals of the corresponding absolute temperatures, the Centigrade temperatures being shown along the

FIG. 2.

Reciprocals of absolute temperature.

course of the graph. The values now found are seen to be approximately intermediate between the most satisfactory values hitherto published. When plotted on a scale sufficiently large to take account of 0·0025 in the logarithms and of 5×10^{-7} in the reciprocals of the temperatures, the points corresponding to the temperatures 481·4°, 444·1°, 415·0°, and 357·0° lie exactly on a straight line. The value of K_c at 389° interpolated from this line is 1429, whereas the experimentally determined value is 1409, *i.e.*, about 1% smaller. There is little doubt that the curves of Horak and of Bodenstein and Plaut point to a value of the constant at 357° which is too

large. It is considered that the author's graph reproduces the values of the constant over a range of 120° with considerable accuracy.

Heat of Reaction.

Thomsen (" Thermochemische Untersuchungen," Vol. II, p. 359), in repeating the work of Berthelot on the heat of the reaction $CO + Cl_2 = COCl_2$, measured both (1) the heat change which occurs when carbonyl chloride is passed into aqueous potassium hydroxide, and (2) the heat evolved by the combustion of a mixture of the gas with hydrogen in an atmosphere of oxygen. Berthelot had used the first method and found a value of 18,000 cals., but Thomsen showed that the true value was much higher and obtained results of 26,620 and 25,650 cals. by the two methods. There is thus a difference of 970 cals. between the values given by Thomsen, the mean being 26,100 cals.

The results now obtained have been used to calculate this heat of reaction (Q_v), which has been assumed to remain constant within each temperature-range shown in Table IV. The range (4*a*) has been included to show the effect upon Q_v and Q_p of using the interpolated value (1429) of K_c at 662° K. instead of the experimental result (1409), which gives the results in range (4). Since Thomsen's data apply at constant pressure at room temperature, the comparison of his results must be made with those shown in col. 3 which are the heats of reaction at constant pressure at the mean temperatures shown in col. 4. The mean of these is 25,500 cals. at an average temperature of 416°, thus differing from Thomsen's mean by 600 cals.

TABLE IV.

Temp. ranges (°K.).	Q_v.	Q_p.	Mean temp., °K.
(1) 754·4—717·1	24,030	25,500	735·7
(2) 717·1—688	24,530	25,930	702·6
(3) 688—630	24,340	25,660	659
(4) 688—662	23,620	24,970	675
(4*a*) 688—662	24,100	25,450	675

It appears doubtful whether this difference between the two values has any real significance as it is within the limits of experimental error in Thomsen's results.

Summary.

The values found by different authors for the dissociation constant of carbonyl chloride show wide divergences, and experiments have therefore been made over a range of 120°—from 360° to 480°. It has been shown that trustworthy results cannot be obtained in experiments in which carbonyl chloride is heated in glass reaction

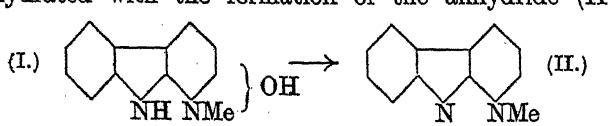
vessels for long periods. The results obtained in quartz vessels agree fairly well with those of Bodenstein and Plaut.

The values of the logarithms of the constants when plotted against the reciprocals of the absolute temperatures lie on a straight line.

Values calculated for the heat of the reaction show that this changes by an amount less than the uncertainty in Thomsen's values when measured at room temperature and at temperatures between 300° and 500°.

These facts lead to the conclusion that the difference between the sum of the molar heats of carbon monoxide and chlorine and that of carbonyl chloride is constant up to 500°, and that its numerical value is small.

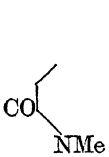
Qualitative evidence was obtained in support of the observations of Christiansen that the decomposition of carbonyl chloride is catalysed by the products of decomposition.



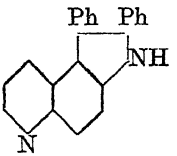
The author wishes to express his thanks to Mr. D. L. Chapman and Mr. H. J. George for the help and criticism which they have given during the course of the work. He is also indebted to the Department of Scientific and Industrial Research for a grant which enabled him to undertake the work.

THE SIR LEOLINE JENKINS LABORATORIES,
JESUS COLLEGE, OXFORD. [*Received, June 15th,* 1927.]

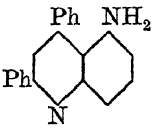
CCCI.—*Polynuclear Heterocyclic Aromatic Types. Part III. Pyrroloquinoline Derivatives.*

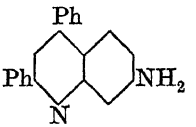


By REGINALD CLIFFORD FAWCETT and ROBERT ROBINSON.



IN Part II of this series (Armit and Robinson, J., 1925, **127**, 1604) several anhydronium bases of the carboline type were described, and 3-carboline methohydroxide (I), for example, was shown to be dehydrated with the formation of the anhydride (II). An

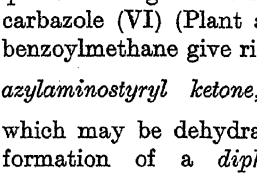




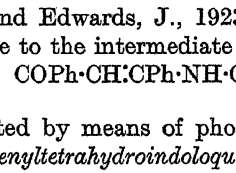
attempt was made to reproduce this phenomenon in the case of a base in which the pyridine and pyrrole rings were separated by a naphthalene nucleus, but without definite result; we have now made similar trials with compounds in which the separation of the heterocyclic nuclei is by a benzene nucleus. A study of the literature showed that the particular combinations of fused

rings which we wished to examine are not contained in known substances, and some difficulty has been experienced in effecting the necessary syntheses. 6-Aminoquinoline and benzoin (compare Japp and Murray, J., 1894, **65**, 889) could be condensed with formation of a *diphenylpyrroloquinoline* (III), but the *methosulphate* of this base, on treatment with aqueous potassium hydroxide, does not appear to yield an anhydro-base. It was thought that less ambiguous results would be obtained if the quinoline ring were

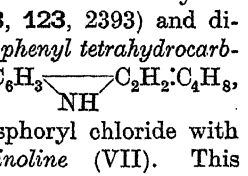
(IIIA.)



(III.)



(IV.)

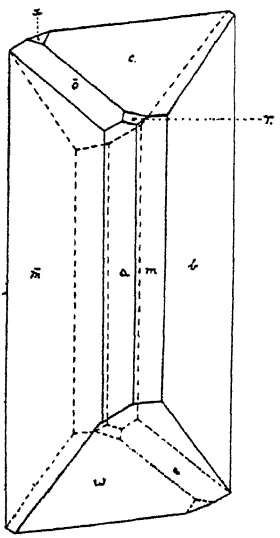


(V.)

phenylated in positions 2 and 4 in order to stabilise the α- and γ-carbinols and thus prevent oxidation to quinolones. The condensation of dibenzoylmethane and *p*-aminoacetanilide could not, however, be effected. With *m*-phenylenediamine the isomeric *aminodiphenylquinolines* (IV, V) were obtained, although in such poor yield that further work along these lines was prohibited.

We therefore turned our attention to a scheme in which the quinoline ring is the last to be introduced. 6-Aminotetrahydrocarbazole (VI) (Plant and Edwards, J., 1923, **123**, 2393) and dibenzoylmethane give rise to the intermediate *phenyl tetrahydrocarbazylaminostyryl ketone*,  , which may be dehydrated by means of phosphoryl chloride with formation of a *diphenyltetrahydroindoloquinoline* (VII). This

(VI.)



(VII.)

(VIII.)

yellow base gives red salts, and when dissolved in organic solvents it absorbs a molecular proportion of oxygen so as to produce a *dioxy-compound*, $C_{27}H_{22}O_2N_2$. The *substance* derived from the *methosulphate* of (VII) by the action of aqueous potassium hydroxide has, apparently, the composition $C_{28}H_{24}N_2,2H_2O$. In view of its deep green colour and the avidity which it displays for oxygen, it is better regarded as a hydrate of the anhydro-base (VIII) than

of the methohydroxide of (VII) (which should be red, like the methosulphate). Probably the most satisfactory conception of the nature of these intensely-coloured, hydrated anhydro-bases, several of which have now been found to exist, is that which would class them with the pyranhydrones and flavanhydrones as quinhydrones. Thus the substance under discussion would, on this hypothesis, have the composition, $C_{28}H_{24}N_2,C_{28}H_{26}N_2O,3H_2O$. The first component would be the fractional dipolar anhydronium base (compare Part II, *loc. cit.*), whilst the second would be a partly dissociated carbinol-amine, also a fractional dipole, balancing the first and cohering to it through electrostatic attraction. Such a conception of the molecular combination seems to be generally applicable to the quinhydrones.

FIG. 1.

EXPERIMENTAL.

5 : 6 - (2′ : 3′ - *Diphenylpyrrolo*)(4′ : 5′) - *quinoline* (III).—This base may be obtained from *p*-nitroaniline in an over-all yield of 43%, the yield in the last stage described below being 95%. A mixture of 6-aminoquinoline (7 g.), its hydrochloride (3 g.), and benzoin (15·5 g.) was heated for 4 hours at 150—160°. On cooling, the mass set to a hard cake which was ground with aqueous ammonia, and the yellow powder collected, washed, dried, and crystallised from methyl alcohol and then from ethyl acetate ; short, yellow prisms (19 g.), m. p. 167—168° (Found, in material dried at 100° : C, 81·4; H, 5·4; in material dried at 140° in a high vacuum : C, 86·0; H, 5·3. $C_{23}H_{16}N_2,H_2O$ requires C, 81·6; H, 5·3; $C_{23}H_{16}N_2$ requires C, 86·2; H, 5·0%). The molecule of water is tenaciously held and only removed very slowly at 110—120° in a vacuum. Solutions of the substance in most organic solvents are yellow and exhibit a green fluorescence.

A sample of this base was crystallised from ethyl acetate, and the following crystallographic description was kindly supplied by Mr. H. E. Buckley, of the Crystallography Department of this University :

Symmetry : anorthic, pinacoidal. Habit : short prisms, parallel to zone (001). Forms developed : $a(100)$, $b(010)$, $c(001)$, $m(110)$, $\bar{m}(1\bar{1}0)$, $o(1\bar{1}1)$, $w(11\bar{1})$, $r(101)$, $x(0\bar{1}3)$.

Table of Observed Angles.

(001—0$\bar{1}$3)	17° 29′	1	17° 29′

Axial angles: $a = 80° 37′$; $\beta = 70° 8′$; $\gamma = 77° 3′$.
$a : b : c = 0{\cdot}601 : 1 : 0{\cdot}530$.

Optics. When the crystal is laid on face $\overline{m}(1\bar{1}0)$, which is usually the largest face, there is an extinction, in parallel polarised light, practically parallel to the edge given by the $c(001)$ face and the prism. From observations in convergent polarised light, it appears that the birefringence is very strong and positive, whilst the dispersion appears to be of the type $\rho > \nu$.

The *hydrogen sulphate* and the *hydrochloride* crystallise from water and from dilute hydrochloric acid respectively in stellar clusters of pale yellow plates. The solution in concentrated sulphuric acid is both colourless and non-fluorescent. The *picrate* crystallises from alcohol in bright yellow needles, m. p. 218° (decomp.).

The Methosulphate.—Pure methyl sulphate (4 g.) in dry benzene (10 c.c.) was added to a solution of diphenylpyrroloquinoline (5 g.) in hot dry benzene (100 c.c.), and the mixture boiled. Bright yellow needles soon appeared and in 10 minutes filled the liquid. The salt was isolated and crystallised from water in yellow needles (5 g.), m. p. 218—219° (Found: S, 7·1. $C_{25}H_{22}O_4N_2S$ requires S, 7·2%). The orange-yellow, alcoholic solution exhibits a faint fluorescence, but the light yellow acetic acid solution has a vivid light green fluorescence. The colourless solution in concentrated sulphuric acid is not fluorescent, but on the addition of water the yellow colour and green fluorescence appear. The solubility in water is approximately: at 25°, 1 part in 70 parts; at 95°, 1 part in 7 parts. Decomposition of this methosulphate with 50% aqueous potash yielded an amorphous red powder.

2-Keto-1-methyl-5 : 6-(2′ : 3′-diphenylpyrrolo)(4′ : 5′)-1 : 2-dihydroquinoline (III, modified as in IIIA).—A cold concentrated aqueous solution of the above methosulphate (4 g.) was added to a 10% sodium hydroxide solution (50 c.c.) containing potassium ferri-

cyanide (5·9 g.), and the mixture was kept for an hour and frequently shaken. The product was isolated by means of ether and then extracted with boiling light petroleum; the solutions on concentration to a small volume deposited a pale yellow powder. The *quinolone* crystallised from ether in pale yellow needles, m. p. 195·5° (Found: C, 78·8; H, 5·2. $C_{24}H_{18}ON_2,H_2O$ requires C, 78·3; H, 5·4%); it is readily soluble in most organic solvents.

5- *and* 7-*Amino*-2 : 4-*diphenylquinoline* (IV, V).—*p*-Aminoacetanilide condenses with dibenzoylmethane to an anil, but ring closure of this could not be effected under a variety of conditions. The action of sulphuric acid on the anil, followed by treatment with aqueous sodium hydroxide gave a *substance*, m. p. 237·5—238·5°, crystallising from alcohol. This appeared to be the sodium salt of a sulphonic acid of the required base. 70% Sulphuric acid and also zinc chloride gave no useful results. We therefore directed our attention to *m*-phenylenediamine derivatives, but here too the experiments met with little success, since the yields of the desired aminodiphenylquinolines were only 5%. A mixture of *m*-phenylenediamine (6 g.) and dibenzoylmethane (12 g.) was heated at 140° for 1 hour; powdered zinc chloride (10 g.) was then introduced, and the temperature maintained at 175—180° for 5 hours. The bases produced were rendered to benzene, and the dried extract on concentration and keeping deposited a mixture of short, thick, prismatic needles and fine, silky needles. These were separated, and after many crystallisations from alcohol and benzene the two forms were obtained pure, their m. p.'s not being altered by further crystallisation; the former variety had m. p. 168·5° (Found: C, 85·0; H, 5·5%), and the latter had m. p. 187° (Found: C, 84·5; H, 5·8. $C_{21}H_{16}N_2$ requires C, 85·1; H, 5·4%); by analogy with other 5- and 7-substituted quinoline derivatives, the substance, m. p. 168·5°, should be the 5-substituted isomeride. The yellow colour of the base, m. p. 187°, is the paler of the two, but in other respects the properties of these substances are closely similar; a mixture had m. p. 142°. The bases may be diazotised, and then couple with β-naphthol to give bright red azo-compounds.

6-*Amino*-1 : 2 : 3 : 4-*tetrahydrocarbazole* (VI).—*p*-Nitrophenylhydrazine (the method of Hodgson and Beard, *J. Soc. Chem. Ind.*, 1926, **45**, 56T, gives almost theoretical yields) was converted into 6-nitrotetrahydrocarbazole, as described by Borsche, Witte, and Bothe (*Annalen*, 1908, **359**, 53) (yield, 80%), but the recorded processes for the reduction of this substance (compare Perkin and Plant, J., 1921, **119**, 1833; Plant and Edwards, *loc. cit.*) gave only 20—40% yields. The use of sodium sulphide as the reducing agent led to still lower results, but a 73% yield was obtained by

means of iron powder and hydrochloric acid in alcoholic solution (compare West, J., 1925, **127**, 494). 6-Nitrotetrahydrocarbazole (20 g.), dissolved in boiling 90% alcohol (70 c.c.) (reflux condenser, mechanical stirrer, and wide, stoppered side-tube) and concentrated hydrochloric acid (1 c.c.), was reduced by the gradual addition of iron powder (24 g.) during 45 minutes and subsequent boiling for 3—4 hours. The mixture was filtered hot and the residue washed with boiling alcohol; the amine (12·5 g.) was isolated from the filtrate by precipitating neutral impurities with concentrated hydrochloric acid (50 c.c.) and separating the hydrochloride by the further addition of hydrochloric acid (100 c.c.). Extraction of the neutral substances by water yielded some more amine hydrochloride, and the final acid mother-liquor was concentrated, basified with ammonia and the crude base crystallised from water.

Phenyl α-Tetrahydrocarbazylamino(6)*-styryl Ketone.*—A mixture of dibenzoylmethane (9·5 g.), 6-aminotetrahydrocarbazole (7·6 g.), and acetic acid (35 c.c.) was refluxed for 1 hour, and the solvent then removed by distillation under diminished pressure. The residue crystallised from alcohol in yellow prisms (8 g.), m. p. 229·5—230° (Found: C, 82·1; H, 6·2. $C_{27}H_{24}ON_2$ requires C, 82·6; H, 6·1%). This substance has very feebly basic properties, and when boiled with hydrochloric acid it first gives a red substance and is then slowly hydrolysed. Its solution in concentrated sulphuric acid is yellow and non-fluorescent, but on keeping the colour fades and a bright violet fluorescence develops; on the addition of water a red salt is precipitated.

2 : 4-*Diphenyl*-5 : 6-(4′ : 5′ : 6′ : 7′-*tetrahydroindolo*)(2′ : 3′)-*quinoline* (VII).—This substance may be obtained from the foregoing ketone in several ways, *e.g.*, (1) by keeping a cold sulphuric acid solution for 24 hours, (2) by heating a sulphuric acid solution to 60—65° for 5 minutes, (3) by passing hydrogen chloride into a solution in acetic acid, and (4) by heating it with half its weight of zinc chloride or phosphoric anhydride. The best procedure is the following: A mixture of the ketone (12·5 g.) and phosphoryl chloride (80 c.c.) was boiled for 1 hour, and the red liquid then gradually added to ice and water with stirring. The dull red solid was collected, washed with water, and triturated with ammonia; the resulting light yellow powder was collected, washed, dried at 105°, and extracted with ether in a Soxhlet apparatus from which air was excluded by means of carbon dioxide; the ethereal solution, on keeping, deposited yellow crystals which were collected and washed in an atmosphere of carbon dioxide, and finally dried in a vacuum desiccator (total yield, 9·5 g., 76%) (Found: C, 86·4; H, 6·1. $C_{27}H_{22}N_2$ requires C, 86·6; H, 5·9%). 2 : 4-*Diphenyl*-

5 : 6-(4′ : 5′ : 6′ : 7′-*tetrahydroindolo*)(2′ : 3′)-*quinoline* crystallises from ether in yellow prisms, m. p. 235°, and dissolves in most organic solvents to yellow solutions exhibiting a greenish-blue fluorescence. Its salts are red and sparingly soluble in water. The red solution in acetic acid gives a pink precipitate on addition of water, whilst the colourless solution in sulphuric acid exhibits a brilliant violet fluorescence. The *picrate*, prepared in alcoholic solution in an atmosphere of carbon dioxide, crystallised in orange-red needles, m. p. 241° (decomp. 243°). The most characteristic property of the base is the ease with which it absorbs oxygen from the air when in solution in organic solvents, especially ether or chloroform; it appears to be relatively stable in the solid state. The product, *dioxydiphenyltetrahydroindoloquinoline*, is readily isolated and crystallises from ether in long, colourless needles which decompose suddenly with bright incandescence at 168°, but without melting (Found: C, 79·4; H, 5·6; N, 6·7. $C_{27}H_{22}O_2N_2$ requires C, 79·8; H, 5·4; N, 6·9%). The dirty green solution in concentrated sulphuric acid slowly develops a most intense green fluorescence, giving the effect of opacity. The incandescence observed on heating suggests that this curious substance is a peroxide.

Metho-derivatives.—A mixture of the base (5 g.), pure methyl sulphate (3·6 g.), and benzene (140 c.c.) was boiled for 2·5 hours, air being displaced from the apparatus by nitrogen. The solvent was removed by distillation, the residual red oil dissolved in dry acetone (about 20 c.c.), and on keeping, red needles separated. These were collected (3·5 g.), and a further quantity (0·6 g.) could be obtained from the mother-liquor by concentration to two-thirds of its volume (further concentration gave uncrystallisable material). The separated *methosulphate* is sparingly soluble in acetone and moderately readily soluble in water. On heating, it decomposes at a high temperature without melting. The colourless solution in concentrated sulphuric acid exhibits a brilliant violet fluorescence. The related *methopicrate* crystallised from acetone in long, slender, meshed, orange-red needles, m. p. 252—254° (decomp.).

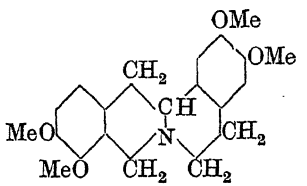
The methosulphate (4 g.) was added to benzene (100 c.c.) and 50% aqueous potassium hydroxide (50 c.c.), and the mixture heated for 1½ hours with occasional shaking; air in the apparatus was displaced by nitrogen. The bright red colour in both layers disappeared, the aqueous solution becoming colourless and the benzene layer intense brilliant green. In all the subsequent operations access of air was prevented by nitrogen. The aqueous layer was siphoned off and potassium hydroxide (35 g.) added to

the benzene layer, which was then boiled for 1 hour, filtered, and dried for 12 hours over potassium hydroxide. The solution was filtered, heated, and the base precipitated by the addition of boiling light petroleum (b. p. 60—80°) as a bright green solid, which was collected and dried in a vacuum. At this stage there was for the first time a momentary contact with air, but the desiccator had been previously filled with nitrogen and was quickly evacuated. Weighing was carried out with the utmost dispatch, since absorption of oxygen was obviously indicated during the operation (Found: C, 79·3, 78·8; H, 6·4, 6·3. $C_{28}H_{28}O_2N_2$ requires C, 79·2; H, 6·6%). The dark green powder becomes brown and then black when exposed to air. Treatment with acids gives red salts resembling the metho-salts mentioned above, and the solution in sulphuric acid exhibits violet fluorescence.

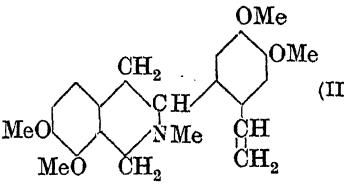
The authors desire to thank the Government Grant Committee of the Royal Society for a grant which defrayed a part of the cost of the work, and the Advisory Council of the Department of Scientific and Industrial Research for a grant that enabled one of them to take part in the investigation.

THE UNIVERSITY, MANCHESTER. [*Received, July 11th*, 1927.]

CCCII.—*The Conversion of Palmatine into its Cryptopine Analogue (Cryptopalmatine).*



By ROBERT DOWNS HAWORTH, JOSEPH BLAKE KOEPFLI, and WILLIAM HENRY PERKIN, jun.



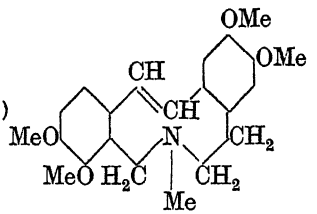
AN examination of the structural formulæ of the naturally occurring alkaloids of the ten-membered ring type, such as cryptopine and protopine, reveals the relationship between these alkaloids and those of the protoberberine series. Thus the protoberberine alkaloids berberine and coptisine (Kitasato, *Proc. Imp. Acad. Tokyo*, 1926, **2**, 124) are related to the ten-membered ring alkaloids β-homochelidonine and protopine, respectively. These relationships, together with the interconvertibility of the two types, leave little doubt that the further examination of natural products will result in the discovery of new affinities of the same kind. *epi*-Berberine, the protoberberine derivative corresponding to cryptopine, has so far not been isolated from natural sources, whilst the ten-membered ring analogue of palmatine has not been described either as a natural or as a synthetical product. This analogue of palmatine, for which we suggest the name "*cryptopalmatine*" (V), has now been obtained from palmatine by a process similar to that

employed in the synthesis of β-homochelidonine, cryptopine, and protopine (Haworth and Perkin, J., 1926, **129**, 445, 1769).

Tetrahydropalmatine (I) * was treated with methyl iodide and thus converted into the *methiodide* which exists in the usual α- and β-modifications, readily separable by crystallisation from methyl alcohol and then from water. The *β-methochloride*, obtained from the methiodide by the action of silver chloride, is a well-defined,

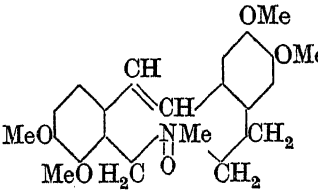
(I.)

(II.)



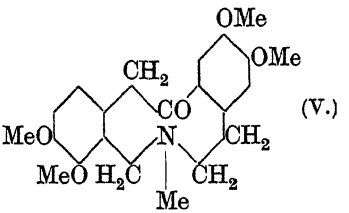
crystalline substance, whereas the corresponding *α-methochloride* has only been isolated as a hygroscopic syrup. When the methiodides or methochlorides are heated with methyl-alcoholic potassium hydroxide, *anhydromethyltetrahydropalmatine B* (II) is obtained as a crystalline substance, m. p. 115—116°, the constitution of which is proved by the facts (i) that it is a stable substance remaining unchanged after digestion with methyl alcohol or chloroform, and (ii) that its sparingly soluble, crystalline *hydrochloride* is not converted into tetrahydropalmatine methochloride by prolonged boiling with dilute hydrochloric acid.

Tetrahydropalmatine methiodide was next converted into the corresponding methohydroxide, by treatment with silver hydroxide in aqueous suspension, and the methohydroxide decomposed by evaporating the solution in a good vacuum, whereby a mixture of *anhydromethyltetrahydropalmatine A* (III) and B (II) was obtained, in which unfortunately the latter modification largely predominated. The former base possesses the properties characteristic of the "A" type, since it is unstable and is converted into tetrahydropalmatine methochloride by warming with dilute hydrochloric acid. Owing to the poor yield of this base, further experiments could only be carried out on a very small scale, and no attempt was made to isolate in a pure condition the amine oxide (IV), which results from the action of perbenzoic acid on the anhydro-base A (III). It was, however, observed that the amine oxide is soluble in water and yields a colourless, sparingly soluble *hydrochloride*. On warming with glacial acetic acid and hydrochloric acid, this amine oxide is readily converted into *cryptopalmatine* (V), a well-defined base which



* We are indebted to Professor Späth for some of the palmatine iodide used in this investigation, but most of the material was prepared by us from berberine by the method of Späth and Quietensky (*Ber.*, 1925, **58**, 2267).

separates from ether in prisms, m. p. 148—150°, and, like cryptopine, gives a characteristic red-violet coloration with sulphuric acid.



(III.)

(IV.)

(V.)

We hope, at a later date, to be able to obtain further quantities of cryptopalmatine, so that it may be possible to make a more complete examination of this interesting base.

Experimental.

Tetrahydropalmatine α- and β-Methiodides.—Tetrahydropalmatine (4 g.), methyl iodide (5 c.c.), and benzene (40 c.c.) were heated on the steam-bath for 4 hours, and the pale yellow methiodide (4·6 g.) was collected, dried, and fractionally crystallised from methyl alcohol (200 c.c.). The first fractions, recrystallised from water, yielded the *β-methiodide* as stout prisms, m. p. 266° (decomp.) * (Found: C, 53·0; H, 5·8. $C_{22}H_{28}O_4NI$ requires C, 53·1; H, 5·6%). This substance is very sparingly soluble in methyl alcohol or water. The last fractions from the crystallisation from methyl alcohol were recrystallised from water, and the *α-methiodide* separated in colourless prisms, m. p. 230°. The crystals contain water of crystallisation, but they lose it at 110° and fall to a powder (Found, in material dried at 110°: C, 53·2; H, 5·9).

Tetrahydropalmatine α- and β-Methochlorides.—The methiodide (*i.e.*, the mixture of the α- and β-forms), suspended in water, was heated with excess of silver chloride on the steam-bath for 3 hours. The filtered solution was concentrated to a small bulk, whereupon the *β-methochloride* separated and was collected. The mother-liquor, on further concentration, yielded the *α-methochloride* as a

* The melting points of the salts given in this and the following papers vary very much with the rate of heating, and must be considered as only approximate.

hygroscopic syrup. The β-methochloride crystallises from water in colourless prisms, m. p. 250° (decomp.) (Found: C, 64·8; H, 7·2. $C_{22}H_{28}O_4NCl$ requires C, 65·1; H, 6·9%). The α-methochloride separates from water as a syrup, which is readily soluble in alcohol and is precipitated as an oil on the addition of ether. It is converted into the α-methiodide, m. p. 230°, by the addition of potassium iodide to the aqueous solution.

Anhydromethyltetrahydropalmatine B (II).—Tetrahydropalmatine methochloride was heated on the steam-bath for 2 hours with excess of 10% methyl-alcoholic potassium hydroxide. The solution was diluted with water, the oily base extracted with ether, and the extract dried, filtered, and concentrated; *anhydromethyltetrahydropalmatine B* then separated in stout, colourless prisms, m. p. 115—116° (Found: C, 71·3; H, 7·5. $C_{22}H_{27}O_4N$ requires C, 71·5; H, 7·3%). This base is very soluble in the usual organic solvents with the exception of petroleum. It is stable towards hot aqueous methyl alcohol or chloroform and yields a sparingly soluble *hydrochloride* which crystallises from water in nodular clusters of needles, m. p. 210° (decomp.); these contain water of crystallisation some of which is lost at 100°, the crystals falling to a powder, but 1 mol. of water is retained after drying at 110° (Found, in material dried at 110°: C, 63·0; H, 7·1. $C_{22}H_{28}O_4NCl,H_2O$ requires C, 62·4; H, 7·1%).

Anhydromethyltetrahydropalmatine A (III).—Tetrahydropalmatine methiodide (3 g.) was digested with a suspension of silver hydroxide until conversion into the methohydroxide was complete. The filtered solution was evaporated and the residue heated for an hour at 100°, both processes being conducted in a vacuum. The syrup which remained was extracted several times with ether, in order to separate the anhydro-bases from any undecomposed methohydroxide, and the ether allowed to evaporate slowly; *anhydromethyltetrahydropalmatine A* gradually separated in needles (0·1 g.), m. p. 131—132° (Found: C, 71·5; H, 7·1. $C_{22}H_{27}O_4N$ requires C, 71·5; H, 7·3%), whilst the modification B (1·5 g.) slowly crystallised from the mother-liquors. Anhydromethyltetrahydropalmatine A is an unstable base which dissolves in cold dilute hydrochloric acid and may be liberated from the solution by sodium hydroxide. After boiling in dilute acid for some time, the base does not separate on the addition of sodium hydroxide, conversion into tetrahydropalmatine methochloride evidently having taken place.

Cryptopalmatine (V).—Anhydromethyltetrahydropalmatine A (0·2 g.) in chloroform (5 c.c.) was gradually added to an ice-cold ethereal solution of perbenzoic acid (0·25 g. in 25 c.c.). The mixture was kept over-night during which it acquired a greenish-yellow tint,

but no crystalline material separated as in the cases previously examined (Haworth and Perkin, *loc. cit.*). When the mixture was shaken with very dilute hydrochloric acid and the extract concentrated in a vacuum, the *hydrochloride* of the amine oxide (IV) separated in colourless prisms, m. p. 198—200° (decomp.) with previous darkening. Owing to scarcity of material the amine oxide was not isolated, but it was observed to be soluble in water because an aqueous solution of the hydrochloride remained clear on the addition of sodium hydroxide.

The hydrochloride (0·1 g.) was dissolved in glacial acetic acid (2 c.c.) and concentrated hydrochloric acid (2 c.c.), boiled for 2 minutes, the brown solution diluted with water, made alkaline with sodium hydroxide, and the amorphous base extracted with chloroform; when the extract was dried and the solvent removed, a brown semi-solid mass remained. This was dissolved in a little alcohol, mixed with a large volume of ether, filtered from amorphous material, the ethereal solution well washed with water, dried over potassium carbonate, filtered, and the solvent allowed to evaporate slowly, whereupon *cryptopalmatine* separated in small, colourless prisms, m. p. 148—150° (Found: C, 68·6; H, 6·8. $C_{22}H_{27}O_5N$ requires C, 68·8; H, 7·0%). A solution of the base in glacial acetic acid developed a reddish-violet coloration on the addition of concentrated sulphuric acid.

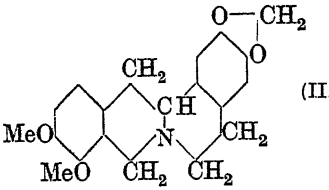
CCCIII.—*Synthetical Experiments in the* iso*Quinoline Group. Part VII. A Synthesis of* 3:11-*Dimethoxyprotoberberinium Salts.*

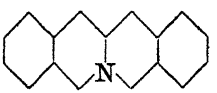


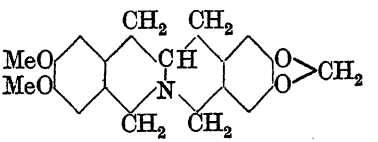
By SATYENDRA NATH CHAKRAVARTI, ROBERT DOWNS HAWORTH, and WILLIAM HENRY PERKIN, jun.

A COMPARISON of the constitutional formulæ of groups of alkaloids brings to light many curious generalities. It is difficult to understand why so many of these substances are built up on a common skeleton and why certain groups, and more particularly methoxy- and methylenedioxy-groups, should play so prominent a part in their structure. Attention has already been directed to the fact (J., 1926, 33) that the alkaloids palmatine, berberine, corydaline, and many others are all derived from the same angular structure (I),

a point clearly illustrated by the formula of tetrahydroberberine (II). It was also pointed out that β-homochelidonine, cryptopine,

(I.)





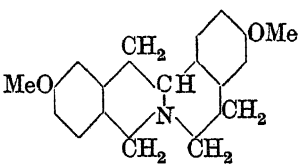
(II.)

and protopine, although not actually derivatives of (I), readily yield quaternary salts which are built up on this skeleton. In order to obtain some light on the reason why the skeleton (I) is so commonly selected by nature, the alkaloid 2 : 3-methylenedioxy-11 : 12-dimethoxy-6 : 15 : 16 : 17-tetrahydroparaberine (IV),* isomeric with tetrahydroberberine, but differing from it in containing the linear structure (III), was synthesised (*loc. cit.*, p. 42).

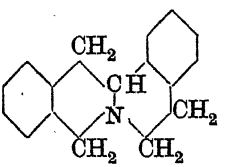
(III.)

(IV.)

During the course of those experiments, it soon became evident that the various stages in the synthesis did not proceed so smoothly as in the case of the corresponding stages in the synthesis of tetrahydro-ψ-berberine, and furthermore, the properties of the substance (IV) were not nearly so definite and characteristic as those of tetrahydroberberine. In particular, the property of yielding highly coloured quaternary salts on treatment with iodine or other oxidising agents, so strikingly shown by tetrahydroberberine, fails entirely in the case of the paraberine analogue (*loc. cit.*, p. 37). These observations led to the suggestion that the greater ease of formation and more characteristic properties of alkaloids built up on the angular type may have some bearing on the occurrence and preferential selection of this type in nature.



Another remarkable feature, not only of the alkaloids of the berberine group, but also of many others of widely different origin, *e.g.*, narcotine, cryptopine, corycavidine, and glaucine, is the occurrence in the molecule of two catechol nuclei, usually modified by methoxy- or methylenedioxy-groups, although in some cases, *e.g.*, corydine and corytuberine, a hydroxy-group remains free. There can be no doubt that the presence of these methoxy- and methylenedioxy-groups has a profound bearing on the ease of synthesis and

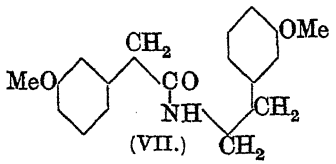


* This alkaloid is actually more directly related to tetrahydro-ψ-*epi*berberine (J., 1924, 125, 1677).

characteristic properties of these alkaloids, and there are also indications, to which reference has been made (this vol., p. 2262), that these groups also greatly influence the possibility of converting the alkaloids into derivatives of the ten-membered ring type (compare J., 1926, 446), and consequently into alkaloids of the β-homochelidonine group. In view of these considerations it seemed to be of interest to attempt to prepare alkaloids which, although built up on the angular skeleton (I), do not contain a catechol nucleus, and to compare the ease of synthesis and characteristic properties of such substances with these features in the case of the alkaloids of the palmatine–berberine type.

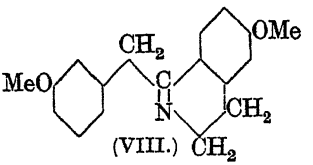
The present communication deals with the synthesis of 3 : 11-*dimethoxytetrahydroprotoberberine* (V) * containing two methoxy-groups, and in the succeeding investigation we describe the synthesis of tetrahydroprotoberberine itself (VI), which contains no methoxy-groups and to which special interest attaches because it is the parent of the whole palmatine–berberine group of alkaloids.

(V.)



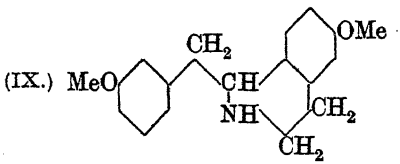
(VI.)

The synthesis of 3 : 11-dimethoxyprotoberberine and its derivatives was conducted in the following manner. β-*m*-Methoxyphenylethylamine, prepared by a slight modification of the method of Helfer (*Helv. Chim. Acta*, 1924, **7**, 945), was condensed with *m*-methoxyphenylacetic acid, prepared by a method similar to that employed by Pschorr (*Annalen*, 1912, **391**, 41), and the m-*methoxyphenylaceto*-β-m-*methoxyphenylethylamide* (VII) so obtained was converted, in a yield of 80%, into a syrupy base of which the *picrate* is crystalline. This base, which is probably 6-*methoxy*-1-(3′-*methoxybenzyl*)-3 : 4-*dihydro*isoquinoline (VIII), oxidises rapidly on exposure to air and is readily reduced by zinc and sulphuric acid to 6-*methoxy*-1-(3′-*methoxybenzyl*)-1 : 2 : 3 : 4-*tetrahydro*isoquinoline (IX), an oily base yielding a crystalline *sulphate* and *picrate*. Ring-closure of the *formyl* derivative was effected in the usual manner with phosphorus oxychloride, giving a 66% yield of a yellow crystalline base, m. p. 130°, which is doubtless 3 : 11-*dimethoxydihydroprotoberberine* (X).

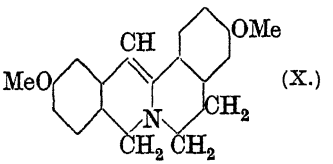


Although we have no direct evidence that the two ring-closures, *i.e.*, the conversion of (VII) into (VIII) and (IX) into (X), have taken place in the para-positions to the methoxy-groups, there can be little doubt that this is the case, since, judging from analogy,

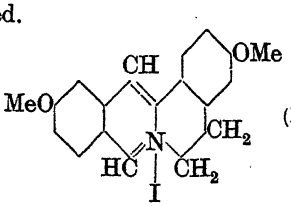
* The nomenclature is discussed in J., 1925, **127**, 1462.



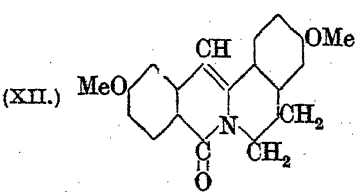
ring-closure in the ortho-positions is most unlikely. Synthetical experiments which are in progress will, we hope, decide this point.

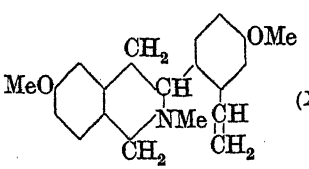


(VII.)



(VIII.)





Dimethoxydihydroprotoberberine (X) gives well-characterised, pale yellow salts of which the *hydrochloride*, the *hydriodide*, and the *picrate* are described. It is reduced by zinc dust and sulphuric acid to 3 : 11-dimethoxytetrahydroprotoberberine (V), a colourless crystalline base, m. p. 111°, which may also be obtained, although in smaller yield, from (IX) by condensation with formaldehyde. Of the colourless crystalline salts, the *hydrochloride*, *hydriodide*, and *picrate* are described.

(XI.)

When 3 : 11-dimethoxytetrahydroprotoberberine (V) is oxidised with iodine in alcoholic solution, it yields 3 : 11-*dimethoxyprotoberberinium iodide* (XI), a yellow quaternary salt from which the corresponding yellow *chloride* was prepared. The iodide (XI) is decomposed in the usual manner by potassium hydroxide giving 3 : 11-*dimethoxyoxyprotoberberine* (XII) and dimethoxydihydroprotoberberine (X), which are readily separated, in that the former is insoluble and the latter soluble in dilute mineral acids.

(XIII.)

3 : 11-*Dimethoxytetrahydroprotoberberine methiodide*, obtained by heating the base (V) with methyl iodide, was readily separated into

α- and β-forms by crystallisation from water (compare Pyman, J., 1913, **103**, 825; Haworth and Perkin, J., 1926, 1772), and these were converted into the corresponding *methochlorides*, of which the β-form is crystalline, whereas the α-modification is a syrup. The methiodide was next converted into *anhydromethyl*-3 : 11-*dimethoxytetrahydroprotoberberine B* (XIII) by the action of alcoholic potassium hydroxide, and the interesting observation was made that this is the only base which is obtained when the methiodide is converted by silver hydroxide into the corresponding methohydroxide and the aqueous solution is evaporated in a good vacuum. The structure assigned to this base is confirmed by its stability towards aqueous methyl alcohol and chloroform, and by its yielding a stable and sparingly soluble *hydrochloride*. It is clear from these experiments that the presence of two methoxy-groups attached to the annular skeleton of tetrahydroberberine as in (V) does not allow the formation of the ten-membered ring, at all events under the usual conditions.

The other points of general interest which emerge from this investigation are (i) that the synthetical experiments described proceed almost as readily, if perhaps not quite so smoothly, when only two methoxy-groups are present as they do in the case of the corresponding syntheses in the berberine series, and (ii) that the deep yellow colour of the salts of berberine and allied alkaloids becomes much less intense when only two methoxy-groups are present in the molecule.

EXPERIMENTAL.

m-Methoxybenzaldehyde is obtained in a yield of 80% by the following method : *m*-Hydroxybenzaldehyde (250 g.), methyl alcohol (750 c.c.), and sodium hydroxide (85 g.), dissolved in the minimum of water, are heated on the steam-bath, and freshly distilled methyl sulphate (290 g.) is added sufficiently rapidly to maintain brisk ebullition; a further quantity of methyl sulphate (200 g.) is then added, the mixture being kept alkaline by the addition of 50% sodium hydroxide. The product is kept for ½ hour, the methyl alcohol removed by distillation, and the residue diluted with water and extracted with ether. The extract is dried with sodium sulphate, the ether removed, and the *m*-methoxybenzaldehyde distilled under reduced pressure. *m*-Methoxycinnamic acid was prepared by heating *m*-methoxybenzaldehyde (100 g.), malonic acid (160 g.), and piperidine (5 c.c.) in pyridine (250 c.c.) solution for 1½ hours on the steam-bath, and then boiling for 15 minutes on the sand-bath. The product, on being poured into excess of dilute hydrochloric acid, gave an almost quantitative yield of *m*-methoxycinnamic acid, m. p. 117°. This acid was reduced with sodium amalgam to β-*m*-methoxyphenylpropionic acid in the manner described by Helfer (*loc. cit.*).

m-Methoxyphenylacetic acid was prepared by the method of Pschorr (*loc. cit.*), but a different procedure was adopted in the separation of the products of the hydrolysis of the az-lactone. After hydrolysing the latter with sodium hydroxide, the solution was saturated with sulphur dioxide, the benzoic acid collected, the filtrate acidified and boiled, and the m-*methoxyphenylpyruvic acid* collected and recrystallised from glacial acetic acid, separating in small crystals, m. p. 150° (Found: C, 61·6; H, 5·1. $C_{10}H_{10}O_4$ requires C, 61·8; H, 5·1%). This acid is readily soluble in hot alcohol but rather sparingly soluble in cold acetic acid or toluene. It was oxidised in cold alkaline solution with hydrogen peroxide, and *m*-methoxyphenylacetic acid, m. p. 68°, was obtained in good yield on acidifying the alkaline solution.

m-*Methoxyphenylacet*-β-m-*methoxyphenylethylamide* (VII).—(i) Equivalent quantities of β-*m*-methoxyphenylethylamine (Helfer, *loc. cit.*) and *m*-methoxyphenylacetic acid were heated at 180° for 3 hours. Alternatively, (ii) *m*-methoxyphenylacetic acid (6 g.), dissolved in a little chloroform, was gently boiled for ½ hour with thionyl chloride (3·5 g.); the chloroform was removed and the residual yellow oil added to an emulsion of β-*m*-methoxyphenylethylamine (5 g.) in potassium hydroxide (40 c.c. of 10%), the mixture being well shaken during the addition. By either method, the *amide* was obtained as an oil which did not crystallise in contact with the usual solvents.

6-*Methoxy*-1-(3′-*methoxybenzyl*)-3 : 4-*dihydro*isoquinoline (VIII).—The amide just described (20 g.) was heated with phosphorus oxychloride (50 c.c.) for 2 hours on the steam-bath and then kept over-night. The mixture was decomposed and extracted with hot water (charcoal), filtered from tar, the filtrate made alkaline with sodium hydroxide, and extracted several times with benzene (A). Some of the benzene extract was dried over potassium carbonate, the solvent removed, and the oily base dissolved in alcohol and mixed with an alcoholic solution of picric acid. The yellow *picrate* of (VIII) which separated is sparingly soluble in alcohol and readily soluble in hot glacial acetic acid, from which it separates in small needles, m. p. 155° (Found: C, 56·3; H, 4·6. $C_{24}H_{22}O_9N_4$ requires C, 56·5; H, 4·3%).

6-*Methoxy*-1-(3′-*methoxybenzyl*)-1 : 2 : 3 : 4-*tetrahydro*isoquinoline (IX).—This was obtained by extracting the benzene extract (A) with dilute sulphuric acid, and reducing the acid solution with zinc dust. The solution was made alkaline with ammonia, the tetrahydro-base extracted with chloroform, dried over potassium carbonate, and the solvent removed, leaving the base as an oil. The *hydrochloride*, obtained by dissolving the oil in hot dilute hydro-

chloric acid, and cooling, separated in needles, m. p. 192° (decomp.) (Found: C, 67·9; H, 6·9. $C_{18}H_{22}O_2NCl$ requires C, 67·6; H, 6·9%). The *sulphate* is readily soluble in hot water and crystallises in rhombs. The *picrate*, prepared in alcoholic solution, is sparingly soluble in hot alcohol, and separates from glacial acetic acid as a crystalline powder, m. p. 148° (Found: C, 56·6; H, 4·6. $C_{24}H_{24}O_9N_4$ requires C, 56·3; H, 4·8%).

3 : 11-*Dimethoxydihydroprotoberberine* (X).—The N-*formyl* derivative of (IX) was prepared by adding a slight excess of formic acid to a dry benzene solution of the base; the benzene was removed, and the residue heated in an oil-bath at 200° for 2 hours. The whole (13 g.) was dissolved in dry toluene (50 c.c.), phosphorus oxychloride (30 c.c.) added, and the mixture boiled for 1½ hours. The product was diluted with petroleum ether, the dark brown oil which separated was dissolved in alcohol, made alkaline with sodium hydroxide, and diluted with water; when the sides of the vessel were scratched vigorously, the *base* (X) separated as a yellow powder (8 g.), which crystallised from alcohol or benzene in shining, yellow, rhombic prisms, m. p. 130° (Found: C, 78·0; H, 6·6. $C_{19}H_{19}O_2N$ requires C, 77·8; H, 6·5%). This base is sparingly soluble in alcohol, more soluble in benzene, and readily soluble in chloroform. It is a strong base yielding pale yellow, crystalline salts with mineral acids. The solution in concentrated sulphuric acid is yellowish-brown and becomes deep red on the addition of a crystal of potassium nitrate. The *hydrochloride* is rather sparingly soluble in water or dilute hydrochloric acid, and crystallises from the former in silky needles containing $4H_2O$ which is lost at 105° (Found: loss at 105°, 17·0. Calc. for $4H_2O$: 17·9. Found in material dried at 105°: C, 68·7; H, 6·1. $C_{19}H_{20}O_2NCl$ requires C, 69·2; H, 6·1%). The *hydriodide*, obtained by adding sodium iodide to the aqueous solution of the hydrochloride, is a yellow, crystalline powder, very sparingly soluble in boiling water (Found: C, 54·6; H, 4·8. $C_{19}H_{20}O_2NI$ requires C, 54·2; H, 4·8%). The *picrate*, prepared in alcoholic solution, is very sparingly soluble in alcohol, and separates from glacial acetic acid as a bright yellow, crystalline powder, m. p. 232° (Found: C, 57·4; H, 4·1. $C_{25}H_{22}O_9N_4$ requires C, 57·5; H, 4·2%).

3 : 11-*Dimethoxytetrahydroprotoberberine* (V).—This substance was obtained in two ways. (i) Dimethoxydihydroprotoberberine (X) was reduced by zinc dust and dilute sulphuric acid until the solution became colourless; the product was filtered, the filtrate made alkaline with ammonia, the base extracted with chloroform, dried over potassium carbonate, the solvent removed, and the residue dissolved in dilute hydrochloric acid, from which the *hydrochloride* of the base separated on cooling. This was collected, dissolved in

water, decomposed with concentrated ammonia, and the almost colourless 3 : 11-*dimethoxytetrahydroprotoberberine* crystallised from alcohol or dry benzene. (ii) The tetrahydro-base (IX; p. 2270) was dissolved in methyl alcohol, mixed with sodium bicarbonate and a slight excess of 40% formaldehyde, and the mixture warmed for a few minutes on the steam-bath; on the addition of water and some salt, a gum separated, which was thoroughly washed with cold water and heated with concentrated hydrochloric acid on the steam-bath for a few minutes; the gummy hydrochloride was redissolved in water, decomposed with ammonia, the base extracted with chloroform, and the solvent removed. The residual syrup was rubbed with ether, which removed unchanged tetrahydro-base, and the sparingly soluble residue of dimethoxytetrahydroprotoberberine was crystallised from alcohol or benzene. The yield was small, however, and various modifications of this method failed to effect much improvement.

3 : 11-Dimethoxytetrahydroprotoberberine separates from alcohol or dry benzene in jagged prisms, m. p. 111° (Found: C, 77·6; H, 7·1. $C_{19}H_{21}O_2N$ requires C, 77·3; H, 7·1%), readily soluble in chloroform, or in methyl or ethyl alcohol; the base and its salts are rather more soluble than dimethoxydihydroprotoberberine and its salts. The hydrochloride is readily soluble in hot water, from which it separates in characteristic, colourless rosettes, m. p. 199° (Found: C, 68·8; H, 6·7. $C_{19}H_{22}O_2NCl$ requires C, 68·8; H, 6·6%). The *hydriodide*, obtained by adding sodium iodide to the aqueous solution of the hydrochloride, is moderately soluble in boiling water and separates as a crystalline powder with a very slight yellow tinge, m. p. 205° (Found: C, 54·4; H, 5·2. $C_{19}H_{22}O_2NI$ requires C, 53·9; H, 5·2%). The *picrate*, prepared in alcoholic solution, separates from glacial acetic acid or alcohol in bright yellow needles, m. p. 139—140° (decomp.) (Found: C, 57·5; H, 4·9. $C_{25}H_{24}O_9N_4$ requires C, 57·3; H, 4·6%).

The 3 : 11-*Dimethoxyprotoberberinium Salts*.—Dimethoxytetrahydroprotoberberine (V), dissolved in the minimum of boiling alcohol, was mixed with anhydrous sodium acetate, and an alcoholic solution of iodine slowly added until a permanent coloration remained. The dark brown granular *periodide* was collected, washed with water, suspended in hot water, and decomposed by adding aqueous sulphurous acid. The pale yellow *iodide* (XI) separated from water, in which it is very sparingly soluble, in pale yellow needles, m. p. 242° (Found: C, 54·2; H, 4·4. $C_{19}H_{18}O_2NI$ requires C, 54·4; H, 4·3%). The *chloride* is readily obtained by digesting an aqueous suspension of the iodide with excess of silver chloride for 2 hours on the steam-bath; after filtering, concentrating, and adding hydrochloric acid,

the mass of pale yellow needles of the chloride is recrystallised from dilute hydrochloric acid and left on porous porcelain exposed to air for 2 days, m. p. 200° (decomp.). The salt contains $3H_2O$ which is lost at 105° (Found: loss at 105°, 13·5. Calc. for $3H_2O$: 14·1. Found in material dried at 105°: C, 69·3; H, 5·8. $C_{19}H_{18}O_2NCl$ requires C, 69·6; H, 5·5%). The *picrate* was obtained, by adding aqueous picric acid to the hot aqueous solution of the chloride, as yellow flocks almost insoluble in alcohol and sparingly soluble in glacial acetic acid, from which it separates as a feathery mass of long, yellow needles, m. p. 238° (Found: C, 55·5; H, 3·9. $C_{25}H_{22}O_{10}N_4$ requires C, 55·8; H, 4·1%).

3 : 11-*Dimethoxyoxyprotoberberine* (XII).—A boiling aqueous solution of 3 : 11-dimethoxyprotoberberinium chloride (2 g.) was added to a hot solution of potassium hydroxide (8 g.) in water (32 c.c.), and the whole heated on the steam-bath for 2 hours. The yellow mass which separated was collected and thoroughly extracted with dilute hydrochloric acid (A); the residue was dissolved in hot glacial acetic acid, mixed with an equal volume of boiling water, and allowed to stand, the oxy-derivative (XII) then separating as a mass of colourless needles, m. p. 143° (Found: C, 74·1; H, 5·7. $C_{19}H_{17}O_3N$ requires C, 74·3; H, 5·5%). 3 : 11-*Dimethoxyoxyprotoberberine* is sparingly soluble in the usual solvents, except glacial acetic acid, and insoluble in dilute mineral acids. It dissolves in concentrated sulphuric acid to a yellow solution which changes to brown on the addition of a crystal of potassium nitrate.

The hydrochloric acid extracts (A) gradually deposited a mass of pale yellow needles, which were collected, dissolved in water, and precipitated with ammonia. The precipitate was washed and recrystallised from alcohol; the resulting yellow rhombic prisms, m. p. 130°, proved to be identical with the 3 : 11-dimethoxydihydroprotoberberine (X) described on p. 2271.

3 : 11-*Dimethoxytetrahydroprotoberberine Methiodide*.—The base (V; 10 g.) and methyl iodide (15 c.c.) were boiled for 15 minutes, the excess of methyl iodide was removed, and the residue dissolved in boiling water (300 c.c.) and cooled; the β-*methiodide* separated and was crystallised from water as colourless prisms, m. p. 245° (decomp.) (Found: C, 54·9; H, 5·7. $C_{20}H_{24}O_2NI$ requires C, 54·9; H, 5·5%). The α-*methiodide*, obtained by concentrating the mother-liquors, separated from water in colourless nodules, m. p. 224° (Found: C, 55·2; H, 5·6). The methochlorides were obtained by digesting an aqueous suspension of the mixed methiodides with silver chloride. The filtered solution was evaporated to dryness, the pale yellow syrup dissolved in alcohol, and ether slowly added; the β-*methochloride* then separated in colourless needles, m. p. 245° (decomp.).

(Found: C, 69·2; H, 7·1. $C_{20}H_{24}O_2NCl$ requires C, 69·4; H, 6·9%). The *α-methochloride* was precipitated as a syrup by the addition of more ether to the alcohol–ether mother-liquor of the β-methochloride. It was not obtained in a crystalline state, but the addition of sodium iodide to its aqueous solution precipitated the α-methiodide, m. p. 224°.

Anhydromethyl-3 : 11-*dimethoxytetrahydroprotoberberine* (XIII).—(i) The mixed methochlorides (1 g.) were boiled with 25% methyl-alcoholic potassium hydroxide (6 c.c.) for 2 hours, the mixture was diluted with water, the oily base extracted with ether, and the solvent removed, leaving the crude base as a colourless oil which did not solidify; it was soluble in the usual organic solvents and yielded the sparingly soluble *hydrochloride* (see below) when it was stirred with dilute hydrochloric acid. (ii) An aqueous solution of the mixed methiodides or methochlorides was decomposed with silver hydroxide, filtered, the filtrate concentrated in a good vacuum, and the residue extracted with benzene. This left a small amount of material which was dissolved in water and concentrated, giving crystals of 3 : 11-*dimethoxytetrahydroprotoberberine methocarbonate*, m. p. 216°, which dissolved with effervescence in dilute hydrochloric acid (Found: C, 67·9; H, 6·9. $C_{21}H_{25}O_5N$ requires C, 67·9; H, 6·7%). The benzene extract, on concentration, yielded an oil which gave a sparingly soluble hydrochloride and was identical with the oil obtained by method (i); all its properties showed that it was an anhydro-base of the "B" type. *Anhydro*-3 : 11-*dimethoxytetrahydroprotoberberine B* is an oil which decolorises a solution of bromine in chloroform and also an acid solution of permanganate. It is recovered after boiling for several hours with aqueous alcohol or chloroform. The sparingly soluble hydrochloride crystallises from water in small needles, m. p. 236° (decomp.), and is recovered unchanged after boiling with dilute hydrochloric acid for 6 hours (Found: C, 69·2; H, 6·9. $C_{20}H_{24}O_2NCl$ requires C, 69·4; H, 6·9%). When the base (XIII) was mixed with perbenzoic acid, no crystalline material separated. The mixture was extracted with dilute hydrochloric acid, the acid extract evaporated in a vacuum, and the resulting gum warmed with glacial acetic acid and concentrated hydrochloric acid. The reddish solution obtained yielded an amorphous, dark slime on the addition of ammonia, but no crystalline substance could be isolated from it.

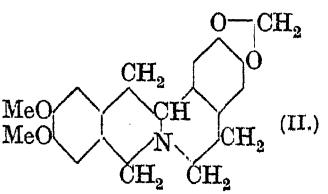
CCCIV.—*Synthetical Experiments in the* iso*Quinoline Group. Part VIII. A Synthesis of Protoberberinium Salts.*

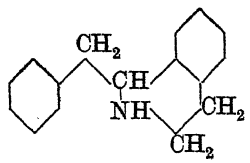


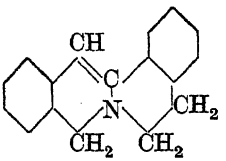
By SATYENDRA NATH CHAKRAVARTI, ROBERT DOWNS HAWORTH, and WILLIAM HENRY PERKIN, jun.

IT is pointed out (preceding paper) that the parent substance of the alkaloids of the palmatine–berberine series is protoberberine, the synthesis of which is now described. It was thought probable that the methods which had proved so successful in the syntheses of ψ-berberine and other similar cases might fail in the present case because the absence of the methylenedioxy- or methoxy-groups might inhibit one or other of the necessary ring-closures. These anticipations were, in fact, largely realised, for although the synthesis was ultimately successful, the yields obtained, especially in the case of the second ring-closure, were so poor that the accumulation of sufficient material for the study of protoberberine was a very tedious process. Clearly, then, the presence of the catechol nuclei is an important factor in facilitating the building up of these alkaloids, and this fact is in harmony with the presence of these nuclei in so many of the naturally occurring alkaloids of this and similar groups.

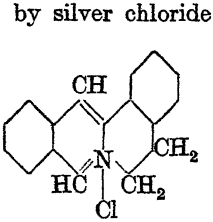
As in previous cases, the first object was the synthesis of *tetrahydroprotoberberine* (I), and the methods employed were similar to those which had been successful in the synthesis of tetrahydro-ψ-berberine (II) and allied substances. Phenylacet-β-phenylethylamide, prepared from phenylacetic acid and β-phenylethylamine,

(I.)

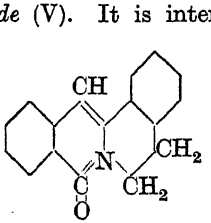




(II.)



was converted into 1-benzyl-3 : 4-dihydro*iso*quinoline by the action of phosphorus pentoxide (compare Decker and Kropp, *Ber.*, 1909, **42**, 2075; Pictet and Kay, *ibid.*, p. 1976; Forsyth, Kelly, and Pyman, J., 1925, **127**, 1663). On reduction with dilute sulphuric acid and zinc, the dihydro-base yielded 1-benzyl-1 : 2 : 3 : 4-tetrahydro*iso*quinoline (III; compare Forsyth, Kelly, and Pyman, *loc. cit.*, p. 1664), an oily base which gives a crystalline hydriodide and *sulphate*. The conversion of this substance into tetrahydroprotoberberine (I) presented considerable difficulty. The usual con-



densation with formaldehyde was unsuccessful, but it was ultimately found that treatment of the N-*formyl* derivative with phosphorus

(III.) 

 (IV.)

oxychloride under strictly defined conditions (see p. 2278) yielded small quantities of *dihydroprotoberberine* (IV), the yield under the most favourable conditions not exceeding 10%. (The substitution of phosphorus pentoxide for the oxychloride did not effect any improvement.) The base (IV) was not isolated as such, but was immediately reduced by zinc dust and hydrochloric acid to tetrahydroprotoberberine (I), m. p. 85°, which crystallises well and yields a crystalline *hydrochloride* and *picrate*. When the tetrahydro-base is oxidised in alcoholic solution by iodine, it is converted into *protoberberinium iodide*, which is much less highly coloured than berberinium iodide, crystallises in yellow needles, and is converted by silver chloride into the *chloride* (V). It is interesting

(V.) 

 (VI.)

that this salt crystallises from water with $4H_2O$, thus resembling berberinium chloride and the other analogously constituted chlorides of this series, all of which contain water of crystallisation. In this case, again, the loss of colour is very striking, since the intense yellow so characteristic of berberinium chloride has almost disappeared in the case of protoberberinium chloride, the crystals of which have only a pale yellow tinge.

Protoberberinium chloride is decomposed by potassium hydroxide in the usual manner and yields *oxyprotoberberine* (VI), m. p. 102°, but the dihydroprotoberberine which is evidently produced at the same time could not be isolated in a pure state owing to the small amount of material at our disposal. Attention may be directed to the unexpectedly large effect which the elimination of methoxy- and methylenedioxy-groups has in producing low melting points in the derivatives of protoberberine: thus tetrahydroprotoberberine has m. p. 85°, whereas tetrahydroberberine melts at 170° and

tetrahydropalmatine at 147°; oxyprotoberberine has m. p. 102°, whereas oxyberberine melts at 200° and oxypalmatine at 183°.

Tetrahydroprotoberberine methiodide (VII), prepared by heating the base with excess of methyl iodide, was readily separable into α- and β-forms. When treated with alcoholic potassium hydroxide, the methiodide was converted into *anhydromethyltetrahydroprotoberberine* (VIII), a syrupy base which yields a sparingly soluble *hydrochloride*. The same anhydro-base was obtained when the

(VII.)  (VIII.) 

methiodide was digested with silver hydroxide and the solution evaporated in a good vacuum. No trace of the isomeric base containing a ten-membered ring could be isolated, and the constitution (VIII) is assigned to anhydromethyltetrahydroprotoberberine because the base is stable towards methyl alcohol and chloroform, and the sparingly soluble hydrochloride is also stable towards boiling dilute hydrochloric acid—conditions under which the ten-membered isomeride would be converted into a quaternary chloride. It would appear, therefore, that, in the absence of methoxy- or methylenedioxy-groups, there is no tendency towards the formation of the ten-membered anhydro-base.

EXPERIMENTAL.

1-*Benzyl*-1 : 2 : 3 : 4-*tetrahydro*isoquinoline (III).—To a boiling solution in xylene (100 c.c.) of phenylacet-β-phenylethylamide (20 g.), obtained by heating molecular proportions of phenylacetic acid and β-phenylethylamine at 180° (Decker and Kropp, *loc. cit.*), phosphorus pentoxide (40 g.) was added, and the boiling continued for ¼ hour; the mixture was poured into water, the toluene layer removed, and the aqueous layer made strongly alkaline with sodium hydroxide. The 1-benzyl-3 : 4-dihydro*iso*quinoline which separated as an oil (Pictet and Kay, *loc. cit.*) was rapidly extracted with benzene and thence with dilute sulphuric acid; the acid extract gradually deposited the *sulphate* in regular cubes, m. p. 216° (Found : C, 60·4; H, 5·4. $C_{16}H_{15}N,H_2SO_4$ requires C, 60·2; H, 5·3%). The sulphuric acid solution of the sulphate was heated with excess of zinc dust for 1½ hours, reduction then being complete. The hot solution was filtered, decomposed with ammonia, the oily base

extracted with chloroform, the extract dried over potassium carbonate, the solvent removed, and the residual oil dissolved in hot dilute sulphuric acid. The *1-benzyl-1 : 2 : 3 : 4-tetrahydroisoquinoline sulphate*, which gradually formed, crystallised from water with $5H_2O$, of which $4H_2O$ were lost at 100°, m. p. 191° (decomp.) [Found: loss at 100°, 11·2. $(C_{16}H_{17}N)_2,H_2SO_4,5H_2O$ requires $4H_2O$, 11·2. Found in material dried at 100°: C, 67·8; H, 6·7. $(C_{16}H_{17}N)_2,H_2SO_4,H_2O$ requires C, 68·3; H, 6·8%]. This sulphate is less soluble in dilute sulphuric acid than in water.

Tetrahydroprotoberberine (I).—This base could not be obtained by treating the foregoing base with formaldehyde in the usual manner. A variety of conditions were examined and, although small quantities of crystalline hydrochlorides were sometimes formed, they always gave rise to gummy bases on decomposition with alkali. Ultimately the following method was found to give the desired result although the yield was not more than 10%. 1-Benzyl-1 : 2 : 3 : 4-tetrahydro*iso*quinoline (24 g.) and anhydrous formic acid (5 g.) were heated in an oil bath at 200—205° until effervescence had ceased (3 hours). The product was dissolved in toluene and boiled with phosphorus oxychloride (48 c.c.) for 1½ hours; light petroleum was then added, the clear liquid decanted from the dark-coloured gum, the latter extracted with dilute hydrochloric acid (charcoal), and the solution of dihydroprotoberberine hydrochloride reduced by heating with excess of zinc dust for 2 hours, during which the yellow solution became colourless. The hot liquid was filtered, the filtrate decomposed with ammonia, the base extracted with chloroform, dried over potassium carbonate, the chloroform removed, and the residue dissolved in hot dilute hydrochloric acid, from which *tetrahydroprotoberberine hydrochloride* gradually separated. This was collected, recrystallised from water (charcoal), the purified salt dissolved in water, decomposed with ammonia, the base extracted with ether, dried over potassium carbonate, filtered, and the ether allowed to evaporate slowly, whereupon *tetrahydroprotoberberine* crystallised in clusters of colourless needles, m. p. 85° (Found: C, 87·2; H, 7·3. $C_{17}H_{17}N$ requires C, 86·8; H, 7·2%); it dissolves readily in the usual organic solvents, with the exception of petroleum, and crystallises well from either ether or methyl alcohol. It is a strong base dissolving in dilute acids and giving well-characterised salts. Its solution in concentrated sulphuric acid is colourless even after the addition of a crystal of potassium nitrate. This reaction distinguishes tetrahydroprotoberberine from other alkaloids of this series, for the sulphuric acid solutions of all those containing methoxy- or methylenedioxy-groups develop coloration under these conditions. The colours are probably

due to nitration occurring in the nuclei activated by these substituent groups.

Tetrahydroprotoberberine hydrochloride is readily soluble in water, from which it separates in slender needles, m. p. 232° (Found: C, 75·4; H, 6·8. $C_{17}H_{18}NCl$ requires C, 75·1; H, 6·6%), and very sparingly soluble in dilute hydrochloric acid. The still more sparingly soluble, crystalline *hydriodide* separates when a solution of sodium iodide is added to the aqueous solution of the hydrochloride. The *picrate* crystallises in small yellow needles, m. p. 151°, when an alcoholic solution of the base is mixed with picric acid; it is soluble in glacial acetic acid or hot alcohol, sparingly soluble in cold alcohol, and almost insoluble in water (Found: C, 59·0; H, 4·6. $C_{23}H_{20}O_7N_4$ requires C, 59·5; H, 4·3%).

The Protoberberinium Salts (as V).—Tetrahydroprotoberberine, dissolved in the minimum of boiling alcohol, was mixed with anhydrous sodium acetate, and an alcoholic solution of iodine added until a permanent colour remained. The dark brown, granular precipitate of the *periodide* was collected, washed well with water, suspended in water, decomposed with sulphur dioxide, and the resulting yellow *iodide* recrystallised from boiling water; fine yellow needles, m. p. 232° (decomp.) (Found: C, 56·2; H, 4·1. $C_{17}H_{14}NI$ requires C, 56·2; H, 3·9%). The *chloride* was readily obtained when an aqueous suspension of the iodide was digested with excess of silver chloride for 2 hours on the steam-bath. After filtering, concentrating, and adding hydrochloric acid, the chloride separated as a mass of needles having only a slight yellow tinge; it was recrystallised from water and left on porous porcelain exposed to the air for 2 days. It then had the composition $C_{17}H_{14}NCl,4H_2O$, and after heating at 100° it still retained $\frac{1}{2}H_2O$ (Found: loss at 100°, 18·3. $C_{17}H_{14}NCl,4H_2O$ requires $3\frac{1}{2}H_2O$, 18·5. Found in material dried at 100°: C, 74·2; H, 5·5. $C_{17}H_{14}NCl,\frac{1}{2}H_2O$ requires C, 73·8; H, 5·4%). *Protoberberinium picrate* was obtained as yellow flocks on adding aqueous picric acid to a hot aqueous solution of the chloride; it crystallised from glacial acetic acid, in which it is sparingly soluble, in fine, yellow needles, m. p. 192—193°.

Oxyprotoberberine (VI).—A boiling solution of protoberberinium chloride (0·5 g.) in water (5 c.c.) was added to a hot solution of potassium hydroxide (2·5 g.) in a little water, and the mixture heated on the steam-bath for 3 hours; the oil which separated solidified on long standing. It was usually extracted with ether, the ether removed, and the residual gum extracted several times with very dilute hydrochloric acid. By this treatment the dihydroprotoberberine present was removed, but we were not successful

in isolating the small quantities of this substance in a pure state. The residue, insoluble in dilute hydrochloric acid, was dissolved in hot glacial acetic acid and mixed with a few drops of boiling water; *oxyprotoberberine* then gradually separated and, after a second treatment with acetic acid, it was obtained pure in slender, satiny, colourless needles, m. p. 102° (Found: C, 82·6; H, 5·5. $C_{17}H_{13}ON$ requires C, 82·6; H, 5·3%). It is rather sparingly soluble in the usual organic solvents, with the exception of glacial acetic acid, and does not dissolve in dilute mineral acids. The pale yellow solution in concentrated sulphuric acid becomes pale brown on the addition of a crystal of potassium nitrate.

Tetrahydroprotoberberine Methiodides (VII).—Tetrahydroprotoberberine (5 g.) and methyl iodide (10 c.c.) were heated under reflux for ½ hour, the excess of methyl iodide was evaporated, and the solid dissolved in boiling water (250 c.c.); the *β-methiodide*, which separated on cooling, recrystallised from water in colourless prisms, m. p. 230—232° (decomp.) (Found: C, 57·2; H, 5·4. $C_{18}H_{20}NI$ requires C, 57·3; H, 5·3%). The *α-methiodide* gradually separated from the aqueous mother-liquor in colourless nodules, and crystallised from alcohol in small needles, m. p. 212° (Found: C, 57·1; H, 5·2). The *methochloride* was obtained by heating an aqueous suspension of the mixed methiodides with silver chloride. It is very soluble in water and separates as a syrup on concentration.

Anhydromethyltetrahydroprotoberberine (VIII).—Tetrahydroprotoberberine methiodide (or methochloride) was heated with excess of 10% methyl-alcoholic potassium hydroxide for 3 hours. The mixture was diluted with water, the oily base extracted with ether, dried over potassium carbonate, filtered, and the ether removed, leaving the base as an oil which did not crystallise. When triturated with dilute hydrochloric acid, it was converted into the sparingly soluble hydrochloride, and this crystallised from water in small prisms, m. p. 234—235° (decomp.), containing water of crystallisation, which is lost at 100°, the substance falling to a fine powder (Found: C, 75·0; H, 7·0. $C_{18}H_{20}NCl$ requires C, 75·6; H, 7·0%). The same base is the only ether-soluble product obtained when tetrahydroprotoberberine methiodide is treated with silver hydroxide, and the solution evaporated in a good vacuum. The ether-insoluble residue was completely soluble in water and appeared to be undecomposed *methohydroxide*. After being boiled with aqueous methyl alcohol for 4 hours, the base (VIII) was recovered unchanged and identified by conversion into the sparingly soluble hydrochloride. It was also unchanged by boiling with chloroform for 3 hours, whilst the hydrochloride was recovered after being heated with dilute hydrochloric acid on the steam-bath for 6 hours.

We wish to thank Mr. Fred Hall for carrying out the analyses required during this and the two preceding investigations. One of us (S. N. C.) desires to thank the United Provinces Government for a Scholarship which has enabled him to take part in these researches.

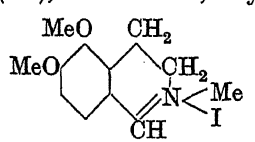
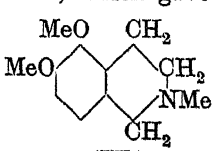
ARMSTRONG COLLEGE, UNIVERSITY OF DURHAM,
NEWCASTLE-ON-TYNE. [*Received, August 5th*, 1927.]

CCCV.—5 : 6-*Dimethoxy*-2-*methyl*-1 : 2 : 3 : 4-*tetrahydro*-iso*quinoline and some Derivatives.*



By ROBERT DOWNS HAWORTH.

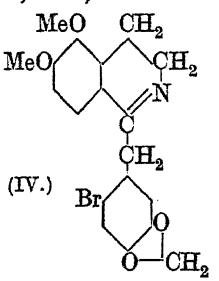
THE present communication describes some experiments which were undertaken in order to discover whether the introduction of a nitro-group into a suitable position in the benzene nucleus of a 2-methyl-1 : 2 : 3 : 4-tetrahydro*iso*quinoline derivative is capable of inducing such a reactivity in the 1-methylene group as could be utilised in synthetical work connected with the *iso*quinoline alkaloids. Suitable nitro*iso*quinoline derivatives are not readily accessible, and it has been necessary to synthesise 8-*nitro*-5 : 6-*dimethoxy*-2-*methyl*-1 : 2 : 3 : 4-*tetrahydro*iso*quinoline* (I) in order to test the above possibility.



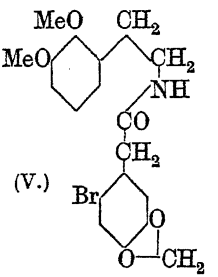
2 : 3-Dimethoxycinnamic acid, prepared by condensing 2 : 3-dimethoxybenzaldehyde with malonic acid, was converted into β-2 : 3-dimethoxyphenylpropionic acid by reduction with sodium amalgam (Perkin and Robinson, J., 1914, **105**, 2387). The *amide* of this acid was treated with sodium hypochlorite, and the resulting β-2 : 3-*dimethoxyphenylethylamine* converted into its N-*formyl* derivative, which yielded 5 : 6-*dimethoxy*-3 : 4-*dihydro*iso*quinoline* on treatment with phosphorus oxychloride. This oily base was converted to a crystalline *methiodide* (II), which was reduced by zinc dust and dilute sulphuric acid to 5 : 6-*dimethoxy*-2-*methyl*-1 : 2 : 3 : 4-*tetrahydro*iso*quinoline* (III), a colourless, oily base, which gave a

(I.)

(II.)

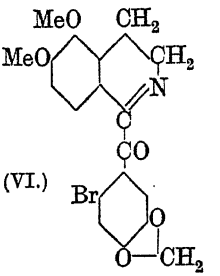


(III.)



crystalline *hydriodide* and *picrate*. When this base was nitrated in glacial acetic acid it was converted into the required base (I), which,

however, did not condense with piperonal or veratraldehyde in the presence of either piperidine or methyl-alcoholic potassium hydroxide, from which it might be inferred that the effect of the nitro-group on the 1-methylene group is neutralised by the methylimino-grouping.



6′-*Bromo*-5:6-*dimethoxy*-3′:4′-*methylenedioxy*-1-*benzyl*-3:4-*dihydro*isoquinoline (IV) has been prepared from 3′:4′-*methylenedioxy*-6′-*bromophenylaceto*-β-2:3-*dimethoxyphenylethylamide* (V), and, like other bases of this type, it is oxidised by the air to 6′-*bromo*-5:6-*dimethoxy*-3′:4′-*methylenedioxy*-1-*benzoyl*-3:4-*dihydro*isoquinoline (VI) (compare Buck, Haworth, and Perkin, J., 1924, **125**, 2176).

(IV.)

(V.)

(VI.)

EXPERIMENTAL.

β-2:3-Dimethoxyphenylpropionic acid was prepared as follows: 2:3-Dimethoxybenzaldehyde (10 g.), malonic acid (13 g.), pyridine (25 c.c.), and piperidine (0·5 c.c.) were heated for 1½ hours on the water-bath, then boiled for ½ hour, and poured into dilute hydrochloric acid; the 2:3-dimethoxycinnamic acid was collected (yield, 95%), dissolved in 20% sodium hydroxide, and reduced at 80° with 4% sodium amalgam (200 g.). The mixture was filtered, acidified with hydrochloric acid, and the β-2:3-dimethoxyphenylpropionic acid collected and recrystallised from hot water (m. p. 68°).

β-2:3-*Dimethoxyphenylpropionamide*.—The foregoing acid (10 g.) was dissolved in chloroform (20 c.c.) and allowed to react for 1½ hours with thionyl chloride (6 c.c.) at the ordinary temperature. The mixture was poured into concentrated ammonia (50 c.c.) and water (50 c.c.), the chloroform removed by distillation, the residual liquid filtered from a little tar, and cooled; the resulting *amide* (9·5 g.) was crystallised from benzene in large, irregular prisms, m. p. 99—100° (Found: C, 62·8; H, 7·1. $C_{11}H_{15}O_3N$ requires C, 63·1; H, 7·2%), readily soluble in ether, alcohol, and hot water or benzene, but sparingly soluble in petroleum ether.

β-2:3-*Dimethoxyphenylethylamine*.—The amide (10 g.) was shaken with a solution of sodium hypochlorite, prepared by absorbing

chlorine (from 33 g. of potassium permanganate and concentrated hydrochloric acid) in 10% sodium hydroxide (100 c.c.). When it had dissolved, the temperature was raised to 70° for 1 hour, the solution cooled, treated with sodium hydroxide (90 g.), heated to 80° for 1½ hours, cooled, thoroughly extracted with benzene, the extract dried, the benzene removed, and the residual oil (8 g.) distilled under diminished pressure. β-2 : 3-*Dimethoxyphenylethylamine* boils at 190°/70 mm. (Found: C, 66·5; H, 8·4. $C_{10}H_{15}O_2N$ requires C, 66·3; H, 8·3%).

The *hydrochloride* is very soluble in water or alcohol, and separates as an oil on the addition of ether to the alcoholic solution. The *picrate*, prepared in alcoholic solution, crystallised from alcohol in yellow plates, m. p. 174—176° (Found: C, 47·1; H, 4·5. $C_{16}H_{18}O_9N_4$ requires C, 46·8; H, 4·4%).

5 : 6-*Dimethoxy*-3 : 4-*dihydroisoquinoline Methiodide* (II).—The above amine (10 g.) and anhydrous formic acid (7 g.) were heated at 180—200° for 3 hours. The resulting N-*formyl* derivative was dissolved in toluene (50 c.c.), phosphorus oxychloride (30 c.c.) added, and the mixture boiled for 1 hour; it was then diluted with petroleum ether (b. p. 40—60°), the solvent decanted from the brown gum, the latter dissolved in a little alcohol, poured into dilute hydrochloric acid, and non-basic impurities were extracted with benzene. The acid layer was made alkaline with sodium hydroxide, extracted with benzene, the extract dried over potassium carbonate, and the benzene removed, leaving 5 : 6-*dimethoxy*-3 : 4-*dihydroisoquinoline* (5 g.) as an oil which did not crystallise, but which dissolved completely in dilute hydrochloric acid to a pale yellow solution. The oil was boiled under reflux with methyl iodide, excess of the latter was removed by distillation, and the solid *methiodide* dissolved in methyl alcohol and precipitated by ether; pale yellow needles, m. p. 174—175° (Found: C, 43·3; H, 4·9. $C_{12}H_{16}O_2NI$ requires C, 43·2; H, 4·8%). This methiodide is very soluble in water and in methyl and ethyl alcohols, the yellow solutions possessing a green fluorescence.

5 : 6-*Dimethoxy*-2-*methyl*-1 : 2 : 3 : 4-*tetrahydroisoquinoline* (III).—The methiodide (II) (2 g.) was dissolved in dilute sulphuric acid, heated with excess of zinc dust on the water-bath until the solution became colourless, and filtered; the filtrate was made alkaline with ammonia, the oily base extracted with chloroform, the extract dried over potassium carbonate, and the solvent removed, whereby the *base* (III) was obtained as an oil which did not solidify on long standing. The *hydrochloride* was very soluble in water or alcohol. The *hydriodide* was obtained by adding potassium iodide to a solution of the base in dilute hydrochloric acid and recrystallising the

precipitated solid from ethyl alcohol; colourless nodules, m. p. 201° (decomp.) (Found: C, 43·2; H, 5·5. $C_{12}H_{18}O_2NI$ requires C, 43·0; H, 5·4%). The *picrate* separates from alcohol in yellow needles, m. p. 164° (decomp.).

8-*Nitro*-5 : 6-*dimethoxy*-2-*methyl*-1 : 2 : 3 : 4-*tetrahydro*isoquinoline (I).—A solution of the tetrahydro-base (1 g.) in glacial acetic acid (25 c.c.) was treated with concentrated nitric acid (2 c.c.) in acetic acid (5 c.c.) containing urea, the temperature being maintained below 20° for 4 hours. The nitration mixture was diluted with water, made alkaline with ammonia, the buff-coloured nitro-compound collected, and crystallised from aqueous methyl alcohol; almost colourless prisms, m. p. 104—105° (Found: C, 57·1; H, 6·4. $C_{12}H_{16}O_4N_2$ requires C, 57·2; H, 6·3%). The 8-*nitro*-5 : 6-*dimethoxy*-2-*methyl*-1 : 2 : 3 : 4-*tetrahydro*isoquinoline is readily soluble in the usual organic solvents, and gradually turns green on exposure to light. It was reduced with zinc dust and hydrochloric acid and filtered; the addition of ferric chloride then produced a blue coloration. Numerous unsuccessful attempts were made to condense this base with piperonal or veratraldehyde under a variety of conditions, piperidine and alcoholic potassium hydroxide being used as catalysts.

6′-*Bromo*-3′ : 4′-*methylenedioxyphenylaceto*-β-2 : 3-*dimethoxyphenylethylamide* (V) was obtained by heating molecular proportions of β-2 : 3-dimethoxyphenylethylamine and 6-bromohomopiperonylic acid at 180° for 1½ hours. The *amide* crystallised from ethyl alcohol in colourless needles, m. p. 131° (Found: C, 53·9; H, 4·8. $C_{19}H_{20}O_5BrN$ requires C, 54·0; H, 4·7%).

6′-*Bromo*-5 : 6-*dimethoxy*-3′ : 4′-*methylenedioxy*-1-*benzyl*-3 : 4-*dihydro*isoquinoline (IV) was prepared by boiling the amide (V) (5 g.) for 1½ hours with phosphorus oxychloride (15 c.c.) and toluene (25 c.c.), adding petroleum ether, and decanting the solvents from the gum. The latter was dissolved in dilute sulphuric acid, filtered from tarry material, and made alkaline with sodium hydroxide; the oily base which separated rapidly hardened, and was collected, washed with water, and crystallised from ethyl alcohol; rhombic plates, m. p. 134—135° (Found: C, 55·9; H, 4·6. $C_{19}H_{18}O_4NBr$ requires C, 56·4; H, 4·5%). Alcoholic solutions of this base were slowly oxidised on exposure to the air to 6′-*bromo*-5 : 6-*dimethoxy*-3′ : 4′-*methylenedioxy*-1-*benzoyl*-3-4-*dihydro*isoquinoline (VI), which crystallises from alcohol in colourless warts, m. p. 168° (Found: C, 54·7; H, 4·1. $C_{19}H_{16}O_5NBr$ requires C, 54·5; H, 3·8%), and gives an intense green coloration on being warmed with acetic anhydride.

THE UNIVERSITY OF DURHAM, ARMSTRONG COLLEGE,
NEWCASTLE-ON-TYNE. [*Received, August 9th*, 1927.]

CCCVI.—*Investigations on the Bivalency of Carbon. Part I. The Displacement of Chlorine from Diphenylchloromethane. s-Tetraphenyldimethyl Ether.*

By Allan Miles Ward.

The formation of *s*-tetraphenyldimethyl ether on boiling diphenylbromomethane with water was explained by Nef (*Annalen*, 1897, **298**, 234) on the assumption that the reaction proceeded through a phase involving bivalent carbon:

$$CHPh_2Br \xrightarrow{-HBr} CPh_2< \xrightarrow{H_2O} CHPh_2\cdot OH$$
$$\qquad\qquad\qquad\quad \Big| \xrightarrow{CHPh_2\cdot OH} (CHPh_2)_2O$$

If this be so, the same considerations as those advanced for α-chloroethylbenzene (Ward, this vol., p. 445) should apply to the velocity coefficients for the displacement of the halogen atom from diphenylchloromethane. Thus the rates of displacement of the chlorine should be uninfluenced by the presence or the absence of sodium hydroxide. This is now shown to be the case for aqueous (10% by vol.) ethyl-alcoholic solutions at 25°. When sodium hydroxide is present in a concentration equivalent to the diphenylchloromethane, the velocity coefficient is that of a unimolecular reaction and of the same value as when sodium hydroxide is absent. When the concentration of the sodium hydroxide is doubled, the reaction remains unimolecular, but the velocity is somewhat decreased. A similar observation is recorded by Senter and Tucker (J., 1916, **109**, 697) for the reaction between water and the phenylbromoacetate ion.

In ethyl-alcoholic solution without added water, the presence of sodium ethoxide produced no change in the velocity of the displacement of the halogen (it was unnecessary for the alcohol to be completely anhydrous in these experiments, and lime-dried material was therefore used throughout); the presence of sodium hydroxide caused a considerable increase in the rate at 25·0°, but the reaction remained unimolecular. Observations at 35·0° in the presence and in the absence of sodium hydroxide showed similar differences, but the temperature coefficients calculated from the two sets of results were in agreement. With increasing concentration of water, the velocity of the reaction increased, being about 30 times as great when 20% of water was present as in the absolute-alcoholic solution. In the previous communication on α-chloroethylbenzene (*loc. cit.*), all velocity measurements were made in 20% aqueous-alcoholic solutions, and comparison with the velocity coefficients

of the present reaction under similar conditions shows that the halogen is displaced some 166 times more rapidly from $CHPh_2Cl$ than from CHPhMeCl.

In the kinetic experiments, the products from diphenylchloromethane were benzhydrol and diphenylmethyl ethyl ether. These conclusions are based on (1) a Zeisel determination on the products, and (2) the reaction between the products and hydrogen chloride, whereby diphenylchloromethane is re-formed from both benzhydrol and diphenylmethyl ethyl ether. In some of the experiments described, the estimation of chlorine by (2) gave low results for diphenylchloromethane, and repeated treatment with hydrogen chloride did not alter these values. In these experiments, the products were distilled at atmospheric pressure, but when all distillations were carried out under reduced pressure, the chlorine thus estimated agreed more closely with the calculated value for diphenylchloromethane. There can thus be no doubt that the low values obtained in some experiments were due to the presence of other substances formed during the distillation of the benzhydrol–diphenylmethyl ethyl ether mixture. Indeed, it was found by Goldthwaite (*Amer. Chem. J.*, 1903, **30**, 461) that *pp'*-dibromodiphenylmethyl ethyl ether on being heated at 300° decomposed entirely to *pp'*-dibromodiphenylmethane and *pp'*-dibromobenzophenone, together with a lower-boiling fraction, probably ethyl alcohol, and a gas, possibly ethylene. Bacon (*ibid.*, 1905, **33**, 92) obtained benzophenone, tetraphenylethane, and acetaldehyde on submitting diphenylmethyl ethyl ether to similar treatment. Nef (*loc. cit.*, p. 236) had previously observed that benzhydrol at 300° decomposes completely to diphenylmethane, benzophenone, and tetraphenylethane. The analytical results would point, however, to the decomposition of the ether being very much less at atmospheric pressure than that of the benzhydrol. The Zeisel determinations are of interest in showing that some 8% of benzhydrol is formed when lime-dried alcohol is used, this no doubt being due to the water present in this solvent. In aqueous (10% by vol.) ethyl-alcoholic solution, the proportion of benzhydrol formed is higher in the absence of sodium hydroxide than in its presence, being 18% and 14%, respectively, and this provides further evidence that hydroxyl ions are not directly active in the substitution.

The reaction mechanism derived from the kinetic results and from the products of reaction may thus be stated

$$CHPh_2Cl \longrightarrow CPh_2< + HCl \text{ (slow)}$$
$$CPh_2< + H_2O \longrightarrow CHPh_2{\cdot}OH \text{ (rapid)}$$
$$CPh_2< + EtOH \longrightarrow CHPh_2{\cdot}OEt \text{ (rapid)}$$

exactly as for α-chloroethylbenzene, and no experimental results are obtained contrary to Nef's hypothesis that the reaction proceeds through the phase $CPh_2<$.

It is shown also that *s*-tetraphenyldimethyl ether may be formed with ease from benzhydrol by boiling it under reflux with hydrochloric acid, just as, under similar conditions, αα′-diphenyldiethyl-ether and styrene are formed from phenylmethylcarbinol (Ward, *loc. cit.*). If the former reaction proceeds through the phase $CPh_2<$ as postulated, no unsaturated hydrocarbon of the styrene type could be formed, and the ether was, in fact, the only product isolated. The effects of varying the times of heating at 100° and of altering the concentration of hydrochloric acid were observed in relation to the proportion of ether formed. With increasing concentration of hydrochloric acid, the proportion of ether formed passed through a maximum, and the amount of diphenylchloromethane increased from zero at first, until, with concentrated acid, it became the main product of reaction. Conversely, when *s*-tetraphenyldimethyl ether was boiled with concentrated hydrochloric acid, diphenylchloromethane was the main product, whereas with *N*/2-acid no change occurred. Moreover, it was found in these experiments that when the products were distilled and then treated with hydrogen chloride, values for the chlorine content were obtained which were too low for diphenylchloromethane. This was doubtless due to the decomposition of the original products of reaction on distillation, as in the case of the benzhydrol–diphenylmethyl ethyl ether mixtures (p. 2286). Thus Nef (*loc. cit.*, p. 236) found that *s*-tetraphenyldimethyl ether on being heated at 300° decomposed to benzophenone, diphenylmethane, and tetraphenylethane. In the present experiments, the products of distillation were not systematically examined except in the case of one experiment with *s*-tetraphenyldimethyl ether, in which diphenylmethane was isolated. The presence of this as a product of secondary decomposition would account for the anomalous chlorine results. When the products of the reaction between concentrated hydrochloric acid and benzhydrol or *s*-tetraphenyldimethyl ether were examined by methods avoiding distillation or heating at higher temperatures, no evidence was obtained for the formation of any substances other than diphenylchloromethane, benzhydrol, and *s*-tetraphenyldimethyl ether.

Although the results find a complete explanation on the basis of Nef's hypothesis, other interpretations may possibly be formulated. Thus assuming that diphenylchloromethane reacts in virtue of its ions as in (1)—(4), the kinetic results would then necessitate

that (1) should be a time reaction and (2) and (3) extremely rapid.

$$(1)\ CHPh_2Cl \longrightarrow CHPh_2^{\cdot} + Cl'$$
$$(2)\ CHPh_2^{\cdot} + OH' \longrightarrow CHPh_2{\cdot}OH$$
$$(3)\ CHPh_2^{\cdot} + OEt' \longrightarrow CHPh_2{\cdot}OEt$$
$$(4)\ CHPh_2^{\cdot} + OCHPh_2' \longrightarrow (CHPh_2)_2O$$

Although an increase in the hydroxyl-ion concentration from about 10^{-8} (in 10% aqueous ethyl-alcoholic solution) to 0·176 (in the presence of sodium hydroxide) would thus greatly increase the velocity of (2), it would not affect the measured velocity, which *ex hypothesi* depends solely on (1). Also, from the equilibrium $EtOH + OH' \rightleftharpoons OEt' + H_2O$, an increase is seen to take place in the ethoxyl-ion concentration parallel with that in the hydroxyl-ion concentration, but the increased velocity of (3) would not influence the measurable velocity. Slowness of (1) and rapidity of (2) and (3) would be almost inevitably connected, since each represents the very slight tendency for the formation of $CHPh_2^{\cdot}$ ions. The same considerations hold concerning phenylmethylcarbinol (*loc. cit.*). Should the reaction in this case proceed through the phase CHPhMe$^{\cdot}$, it must be assumed that this is capable of losing a hydrogen ion in order to account for the production of styrene. The halogen displacement from the triarylmethyl chlorides may be assumed to take place as in (1), but the hexaaryldimethyl ethers have not been prepared by this method (compare Gomberg, *J. Amer. Chem. Soc.*, 1913, **35**, 200). In this connexion an examination of systems of the type $CR_1R_2R_3Cl$ should provide valuable data.

Experimental.

Diphenylchloromethane was prepared from benzhydrol by means of hydrogen chloride in benzene solution (Böeseken, *Rec. trav. chim.*, 1903, **22**, 313; Montagne, *ibid.*, 1906, **25**, 405) and was obtained as a colourless liquid, b. p. 158·5—159·5°/12 mm., which solidified to a colourless solid, m. p. 20·5° (Engler and Berthge, *Ber.*, 1874, **7**, 1128, give m. p. 14°, and Böeseken gives m. p. 12—14°). It was kept in small sealed glass tubes, for turbidity developed rapidly in contact with the atmosphere. The chlorine was determined (i) by heating a weighed sample in aqueous ethyl alcohol and titrating the liberated acid with standard alkali until the colour change of the indicator (phenolphthalein) was permanent (Found : Cl, 17·64. Calc. : Cl, 17·53%), and (ii) by Stepanow's method (Found : Cl, 17·47%). In all subsequent analyses, the chlorine was estimated as under (i).

Diphenylchloromethane was also prepared by suspending *s*-tetraphenyldimethyl ether (90 g.) in benzene (180 c.c.) and passing in a rapid stream of hydrogen chloride for 1 hour at room temperature. The ether dissolved completely and an aqueous layer formed; this was separated and the benzene solution dried by means of calcium chloride. The hydrogen chloride was removed in a current of carbon dioxide, and the product, b. p. 165·5°/15 mm., collected; yield, 88 g. (Found: Cl, 17·57%). Some tar remained in the distilling flask.

Products of the Reaction of Diphenylchloromethane and Ethyl Alcohol.—(*a*) Ethyl alcohol (250 c.c.), dried by refluxing and distilling over quick-lime, was added to diphenylchloromethane (5 g.). The solution was maintained at 25° for 5 days, free hydrogen chloride was then removed by means of potassium carbonate, and the alcoholic solution fractionated, 4·9 g. of liquid, b. p. 146—147°/9 mm., being obtained (Nef, *loc. cit.*, p. 234, gives b. p. 153°/15 mm. for diphenylmethyl ethyl ether) (Found: OEt, 19·6. Calc. for diphenylmethyl ethyl ether: OEt, 21·2%). The product redistilled at 281°/766 mm. (Kostanecki and Lampe, *Ber.*, 1906, **39**, 4019, give b. p. 288°) (Found: OEt, 19·2%).

(*b*) Repetition of this experiment with 15 g. of diphenylchloromethane and 500 c.c. of alcohol for 10 days gave 14·2 g., b. p. 115—119°/4 mm. (Found: OEt, 19·5, 19·4%).

(*c*) Hydrogen chloride was passed through the liquid obtained in (*a*) at room temperature. Considerable heat was developed, and after some time separation into two layers took place. Calcium chloride was added, and after standing, the products, which remained heterogeneous, were distilled. On heating, appreciable charring and marked evolution of gas took place, the material then distilling smoothly, b. p. 156—158°/11 mm. (Found: Cl, 16·1. Calc. for diphenylchloromethane: Cl, 17·53%).

(*d*) 5 G. of the product from (*b*) were dissolved in benzene (15 c.c.) and hydrogen chloride was passed in rapidly for 2 hours. Two layers were again formed and remained after drying by means of calcium chloride. The hydrogen chloride was removed in a stream of carbon dioxide, the benzene distilled under diminished pressure, and a colourless liquid obtained (4·2 g.), b. p. 120—121°/3 mm. (Found: Cl, 17·25%). Considerable dark brown gum remained in the distilling flask.

Products of the Reaction of Diphenylchloromethane with Aqueous Ethyl Alcohol.—(*e*) A solution of diphenylchloromethane (5 g.) in ethyl alcohol (225 c.c.) and water (25 c.c.) was kept at 25° for 12 hours, the water then removed by means of potassium carbonate, and the products distilled, giving 4·5 g. of liquid, b. p. 113—120°/3

mm., which redistilled at 281—288°/766 mm. (Found : OEt, 17·8%), some charred material remaining in the distilling flask. The liquid was dissolved in petroleum ether and treated with hydrogen chloride as under (*c*) above, a fraction of b. p. 162—163°/16 mm. (Found : Cl, 16·58%) being obtained.

(*f*) Ethyl alcohol (1125 c.c.), water (125 c.c.), and diphenylchloromethane (25 g.) were treated as in (*b*) and gave 21·5 g., b. p. 125—130°/3 mm. (Found : OEt, 17·3, 17·4%). Treatment of a sample (5 g.) as under (*d*) above, gave 4·4 g. of colourless liquid, b. p. 115°/1 mm. (Found : Cl, 17·22%). Some gum remained in the distilling flask.

Products of the Reaction of Diphenylchloromethane with Aqueous Ethyl-alcoholic Sodium Hydroxide.—(*g*) Diphenylchloromethane (5 g.) was dissolved in ethyl alcohol (225 c.c.) and aqueous 1·76*N*-sodium hydroxide (25 c.c.). The solution was kept at 25° for 12 hours, dried, and the liquid distilled, b. p. 116—124°/3 mm.; yield, 4·3 g. The products redistilled at 279—285°/766 mm. (Found : OEt, 18·2%). After treatment with hydrogen chloride in benzene solution, the liquid distilled at 156—158°/11 mm. (Found : Cl, 16·6%). This product was again treated with hydrogen chloride, but the chlorine content remained unchanged.

(*h*) The water in Expt. (*f*) was replaced by the same volume of aqueous 2*N*-sodium hydroxide and the same procedure followed; yield, 21·5 g.; b. p. 114—121°/3 mm. (Found : OEt, 18·2, 18·1%). A small amount of gum remained in the distilling flask. Treatment of a sample (5 g.) as under (*d*) above, gave 4·3 g. of a colourless liquid, b. p. 121—124°/4 mm. (Found : Cl, 17·29%). A small amount of brown oil remained in the distilling flask.

Reaction between Benzhydrol and Hydrochloric Acid.—In each experiment benzhydrol (5 g.) and hydrochloric acid of the normality stated were heated in a pressure flask immersed in a bath of boiling water for the times shown in the following table. The products solidified on being poured into cold water, and the *s*-tetraphenyldimethyl ether and benzhydrol were then readily separated by dissolving the mixture in hot alcohol, the main bulk of the ether crystallising in a pure condition on cooling. Addition of a little water to the alcoholic mother-liquor precipitated a mixture of the ether and benzhydrol, which was separated into its components by a repetition of this process, whilst by the addition of the aqueous alcoholic solution to excess of water, the benzhydrol was obtained in a pure condition. The purity of the benzhydrol (m. p. 68°) and of the *s*-tetraphenyldimethyl ether (m. p. 110°) was checked in these and in all subsequent experiments by determining the m. p.'s both alone and when mixed with authentic specimens. In the

HCl, *N*.	Time (hrs.).	Yields, g. Ether.	Benzhydrol.	HCl, *N*.	Time (hrs.).	Yields, g. Ether.	Benzhydrol.

1	1	0·8	4·05	3·5	6	3·9	—

final experiment, no precipitate but only a turbidity was formed on adding the aqueous alcoholic solution to excess of water. In several of the preceding experiments, mainly those in which the higher concentrations of acid were used or in which the times of heating were longer, the total yield of ether and carbinol was lower than the theoretical, and in these cases the filtrate after separation of the benzhydrol was turbid, doubtless due to the partial formation of diphenylchloromethane, as shown in the following experiments.

(*i*) Benzhydrol (5 g.) and 5*N*-hydrochloric acid (75 c.c.) were heated in a pressure flask at 100° for 1 hour. The products on being poured into cold water solidified to a pasty mass. On the addition of petroleum ether (b. p. 40—60°), a white solid was at once obtained, which on crystallisation from alcohol gave *s*-tetraphenyldimethyl ether (2·2 g.). Dilution of the alcoholic filtrate with water produced a turbidity only. The petroleum-ether solution was dried, and the solvent evaporated completely at room temperature, a pasty mass (2 g.; Cl, 7·7%) thus being obtained.

(*j*) Benzhydrol (10 g.) was boiled under reflux with concentrated hydrochloric acid (100 c.c.) for 2 hours. The oil, which did not solidify on cooling, was extracted with ether, dried and distilled; b. p. 160—161°/15 mm.; yield, 7·85 g.; Cl, 15·4%. A black gum remained in the distilling flask. In a second experiment, with only 1 hour's boiling, the following results were obtained: b. p. 159—161°/14 mm.; yield 7·6 g.; Cl, 15·2%; whilst in a third experiment, the reaction being carried out in a pressure flask immersed in a bath of boiling water for 1 hour, 7·4 g. of product (Cl, 14·9%) were obtained. This was dissolved in benzene, saturated with hydrogen chloride, and on distillation gave a liquid, b. p. 156—158°/12 mm. (Cl, 14·7%).

(*k*) Benzhydrol (50 g.) was boiled under reflux with concentrated hydrochloric acid (500 c.c.) for 2 hours. The cooled products were extracted with ether, dried, and the ether distilled under diminished pressure at room temperature. The oil (50 g.; Cl, 15·3%) so obtained was dissolved in some 250 c.c. of petroleum ether (b. p. 40—60°), but no solid separated on standing. The petroleum ether was completely removed by distillation at room temperature, excess of water added, and the mixture maintained at 25° for 3 weeks with

occasional shaking. The displacement of the halogen at the end of this period was still incomplete, and the mixture was therefore gently warmed until no further acidity developed. On cooling, the products solidified to a hard mass, which was filtered, washed with water, and dried (yield 45·5 g.). Crystallisation from petroleum ether gave a crop of 41·6 g., yielding benzhydrol (20·9 g.) and *s*-tetraphenyldimethyl ether (20·3 g.). From the petroleum-ether liquors on evaporation at room temperature a solid (3·35 g.) was obtained; on recrystallisation from petroleum ether, this gave a product (2·5 g.) which was separated into benzhydrol (0·8 g.) and *s*-tetraphenyldimethyl ether (1·6 g.). The residual liquors on evaporation at room temperature gave a small amount of solid, from which 0·1 g. of the ether was separated, and a yellow oil (*ca.* 0·5 c.c.) which completely decomposed on attempted distillation.

Reaction between s-*Tetraphenyldimethyl Ether and Hydrochloric Acid.*—(*l*) *s*-Tetraphenyldimethyl ether (10 g.) and *N*/2-hydrochloric acid (150 c.c.) were boiled under reflux for 8 hours. Solid was present all the time and 9·9 g. of ether were recovered.

(*m*) *s*-Tetraphenyldimethyl ether (50 g.) and concentrated hydrochloric acid (500 c.c.) were boiled under reflux for 1 hour. The products were cooled, extracted by ether, dried, and the solvent was removed on the water-bath. During the heating, the liquid darkened considerably (Found: Cl, 6·54%). The products on inoculation with *s*-tetraphenyldimethyl ether solidified to a stiff paste, which was filtered and washed with petroleum ether (b. p. 40—60°), *s*-tetraphenyldimethyl ether (10·5 g.) being thus obtained pure. The filtrate was distilled under diminished pressure, b. p. 145—170°/12 mm.; yield 25 g. (Found: Cl, 10·5%). A considerable amount of dark brown gum remained in the distilling flask, but the only product which was separated from this was *s*-tetraphenyldimethyl ether (1·7 g.). The above distillate (25 g.) was boiled with water for ½ hour (reflux), but remained liquid on cooling. Addition of petroleum ether yielded a solid (6·7 g.) which gave benzhydrol (5·9 g.) and *s*-tetraphenyldimethyl ether (0·4 g.). The petroleum-ether solution was dried and distilled; b. p. 146—160°/14 mm.; yield, 10 g. A considerable amount of oil, which solidified to a hard mass, remained in the distilling flask, and this on crystallisation from alcohol gave *s*-tetraphenyldimethyl ether (3 g.). Phenylhydrazine (7 g.) and alcohol (20 c.c.) were added to the distillate (10 g.) and the solution was refluxed for 9 hours, but even on cooling it remained homogeneous, thus showing benzophenone to be absent. Excess of dilute hydrochloric acid was added and the products were distilled in steam; a pleasant-smelling oil was obtained, which was extracted with ligroin, dried, and distilled,

giving fractions (1) b. p. 129—135°/11 mm., 2 c.c.; (2) b. p. 135—155°/11 mm., 4 c.c.; a small amount of liquid remained. An authentic specimen of diphenylmethane distilled at 129—130°/11 mm., and remained liquid for a considerable time after distillation, but on seeding solidified to a hard mass of long, colourless needles. Fraction (1) was similarly treated, and its behaviour was identical.

(*n*) *s*-Tetraphenyldimethyl ether (50 g.) and concentrated hydrochloric acid (500 c.c.) were boiled under reflux for 4 hours. The cooled products were extracted by ether, dried, and the solvent was removed under diminished pressure at room temperature during 7 hours; yield 47·5 g. (Found: Cl, 12·4%). The addition of petroleum ether caused a colourless solid (6·2 g.) to separate on standing, giving *s*-tetraphenyldimethyl ether (5·7 g.) and benzhydrol (0·25 g.). The petroleum ether was removed under diminished pressure at room temperature, and the colour of the products darkened, although to a very much less degree than in the preceding experiment; yield, 40·5 g. (Found: Cl, 14·2%). The replacement of the halogen was carried out exactly as in the corresponding benzhydrol experiment, a colourless, crystalline solid (37 g.) being obtained. On crystallisation from light petroleum, this gave a crop (31 g.) which yielded *s*-tetraphenyldimethyl ether (11 g.) and benzhydrol (19·5 g.). On evaporation of the liquors at room temperature a pasty solid was formed, which was washed with petroleum ether; 3·5 g. remained, yielding 3·3 g. of *s*-ether. The liquors on evaporation gave 2·3 g. of oil, which, since it still contained diphenylchloromethane, was boiled with water; on cooling, it solidified to a pasty solid, from which were separated *s*-ether (0·7 g.) and benzhydrol (0·8 g.), whilst the distillate from the small quantity of residual oil was insufficient for further examination.

Kinetic Experiments.

In the following experiments, a weighed amount of diphenylchloromethane was dissolved in ethyl alcohol (prepared by refluxing and distilling commercial absolute alcohol over quick-lime); the required amounts of water (by volume) and of sodium hydroxide or sodium ethoxide solutions were added, at the temperature of experiment, and the volume in each case was made up to 100 c.c. with ethyl alcohol. The method of experiment was that described previously (*loc. cit.*, p. 455) and the results are expressed as before, except that titrations refer to 10 c.c. of solution against alcoholic sodium hydroxide ($N/20$) or alcoholic benzoic acid ($N/20$). In each case k is calculated from the formula $k = 2{\cdot}3/t \,.\, \log_{10} a/(a - x)$ for a unimolecular reaction, t throughout being expressed in minutes, and a being based on the first titre. Typical experiments showing

the extent of the variations amongst the individual values of k are given (1 and 2), and the complete results are then summarised.

(1) Diphenylchloromethane, 0·0906 mol./l.; water, 10% (by vol.); temp. 25·0°.

Summary.

(1) The displacement of the halogen from diphenylchloromethane at 25° in ethyl-alcoholic solution (lime-dried) and in aqueous ethyl-alcoholic solutions, both alone and in the presence of sodium hydroxide, yields a mixture of diphenylmethyl ethyl ether (main product) and benzhydrol.

(2) The velocity coefficients obtained for this displacement in ethyl-alcoholic solution alone, and also in the presence of sodium hydroxide and of sodium ethoxide, at 25° and at 35°, are those of a unimolecular reaction, the sodium hydroxide, sodium ethoxide, or their ions playing no direct part in the halogen displacement. Similar results are obtained in aqueous-alcoholic solutions.

(3) Benzhydrol gives *s*-tetraphenyldimethyl ether in good yield on being boiled with dilute hydrochloric acid. With increasing concentration of acid, the yield of *s*-tetraphenyldimethyl ether passes through a maximum, and the yield of diphenylchloromethane rises, becoming the main product of the reaction when concentrated acid is used.

(4) *s*-Tetraphenyldimethyl ether is unchanged on boiling with *N*/2-hydrochloric acid, but with concentrated acid it is largely converted to diphenylchloromethane. Diphenylchloromethane may be prepared readily in a pure condition and in good yield by the action of hydrogen chloride on *s*-tetraphenyldimethyl ether suspended in benzene.

(5) The experimental evidence under (1), (2), (3), and (4) is in accordance with the hypothesis of Nef that the reactions proceed through a phase $CPh_2<$, in which but two groups are momentarily attached to carbon. An alternative mechanism involving the $CHPh_2^{\cdot}$ ion is also discussed.

The author wishes to record his thanks to Drs. Senter and Barrow for their valued interest in this work.

UNIVERSITY OF LONDON, E.C. 4. [*Received, August 5th*, 1927.]

CCCVII.—*The Determination of Dissociation Constants of Dihydric Mono- and Di-nitrophenols Electrometrically and Colorimetrically.*

By FRANK LATHE GILBERT, FRANK C. LAXTON, and EDMUND B. R. PRIDEAUX.

THE conductivities were determined by the Kohlrausch method in a gas-regulated thermostat which was maintained at 25·0° ± 0·05°. The cell constant, as determined by solutions of *N*/10- and *N*/100-potassium chloride and saturated calcium sulphate, was 0·298. The conductivity water had a specific resistance of 4—5 × 10^{-6} reciprocal ohm. The conductivities were corrected for that of the water by the usual method (Ostwald and Luther, "Physico-

chemical Measurements") at the highest dilutions, when necessary. The trustworthiness of the apparatus was tested by determining the conductivity of acetic acid, with the following results:

At v =	16	32	64	128	256
$K \times 10^6$ =	18·33	18·56	18·47	18·36	18·50

The colorimetric measurements were carried out in a small colour comparator, in daylight, and in the manner already described (J., 1924, **125**, 2110; 1925, **127**, 2499).

The Preparation and Properties of the Compounds, and the Determination of their Constants.

2 : 6-*Dinitroquinol.*—The preparation and properties of this compound have already been described (J., 1924, **125**, 2110). The dissociation constant determined by Bader (*Z. physikal. Chem.*, 1890, **6**, 287), when multiplied by 10^{-2} in order to render it comparable with the more usual mode of expression, was $0{\cdot}7 \times 10^{-4}$, at dilutions from 200 to 1600. Bader's value of λ_0, translated into modern units, is 376, whereas we find that λ_0 of the dinitro-acid is 380. It was decided to repeat the measurements of this compound for this reason and for others, among which were the circumstances that it was evidently sensitive to catalytic oxidation and that the purity of some of Bader's preparations had been questioned by subsequent workers (*e.g.*, Walker and Cormack, J., 1900, **77**, 5).

Solutions freshly made from the calculated weights of either the hydrated or the anhydrous compound were found to have the same conductivities. When they were allowed to stand in contact with the electrodes for some time, the colour changed from red to yellowish-brown, the conductivity altered, and the characteristic purple colour then no longer appeared on the addition of alkali. These changes are probably due to oxidation. The colour also changed when hydrogen was passed over the electrode, and finally a black precipitate appeared; thus reduction also probably takes place. Solutions were freshly made for each determination of conductivity, the dilutions being performed outside the cell, because it was soon evident that these changes in their first stages were accompanied by a diminution in the resistance in the more dilute, as well as in the more concentrated, solutions. Three independent series of measurements were first made, and the constants calculated in the usual manner.

	First series.				Second series.			Third series.	
v =	184	368	736	1472	203	406	812	562	1124
λ =	60·2	70·0	81·8	101	66·6	76·8	85·8	74	93·2
$K \times 10^4$ =	1·62	1·13	0·80	0·655	1·83	1·26	0·81	0·83	0·71

In the fourth series, measurements were made after 20, 40, and 60 secs., and the readings were extrapolated to zero time; for instance, in one case the resistances of the solution in the cell were 1975, 1940, and 1920 ohms, respectively. Hence, at zero-time the resistance was 2010 ohms and the constant $1{\cdot}72 \times 10^{-4}$.

v =	221	442	884	1768
λ =	67·2	80	89·5	106·5
α =	0·177	0·211	0·236	0·280
$K \times 10^4$ =	1·72	1·27	0·824	0·614

There is thus an undoubted diminution of the constant with dilution, in the direction usually observed in the case of acids of medium strength, although 2 : 6-dinitroquinol is not sufficiently strong to be included in this class, which might, however, include the strongest of the acids investigated. In the case of 2 : 6-dinitroquinol, we suspect that the anomalous behaviour is connected with the transition into the second, or red, quinonoid form, for, at the p_H produced by the dissociation of the compound itself in water, this transition would have proceeded to a considerable extent. Pending an explanation, we have adopted a mean constant of 1×10^{-4}, $p_K = 4{\cdot}0 \pm 0{\cdot}2$, for comparison with the other compounds.

3 : 5-*Dinitropyrocatechol.*—This compound, as previously described (J., 1925, **127**, 2499), appears as bright yellow crystals, m. p. 164°. The conductivity of the solutions did not alter on standing in contact with the electrodes. Three series of readings gave :

At v =	890	1010	1010	1780	2020	2020	3560	4040	4040
λ =	149·5	162·5	160·0	190	204	200	228	243	243·5
$K \times 10^4$ =	2·88	3·17	3·09	2·80	3·10	2·92	2·54	2·8	2·8

The mean value of K is $2{\cdot}9 \times 10^{-4}$, $p_K = 3{\cdot}54$.

2 : 4-*Dinitroresorcinol.*—2 : 4-Dinitrosoresorcinol, prepared according to the method of Fitz (*Ber.*, 1875, **8**, 631), was treated with cold concentrated nitric acid (Kostanecki and Feinstein, *Ber.*, 1888, **21**, 3121) in a freezing mixture to minimise the formation of styphnic acid, any of which was removed by shaking with a large quantity of water. The nitro-compound appeared as light yellow crystals, m. p. 142°. The solution was quite stable in contact with the electrodes. Two series of measurements were made, in each of which a distinct diminution of the constant with increasing dilution was observed. Since this is by far the strongest acid of the series, we consider that this diminution may be due to the same causes as that found in the case of acids of medium strength.

	First series.						Second series.				
v =	190	380	760	1520	3040	6080	240	480	960	1920	7680
λ =	129	162	200	236	262	265	141·5	177	215	248	273
$K \times 10^4$ =	9·22	8·43	8·47	6·74	5·05	4·70	9·29	8·47	7·73	6·44	2·69

In accordance with the usual practice, we have excluded values

obtained at a degree of primary ionisation greater than 0·5 ($v > 700$). The mean value of K is $8{\cdot}85 \times 10^{-4}$, $p_K = 3{\cdot}05$.

The compound is colourless in acid solution, and full yellow from about p_H 6·65. There is no further colour change in more strongly alkaline solution up to p_H 12. The colorimetric degrees of transformation were investigated by the methods which are described in the two former papers (*loc. cit.*). The values were found, however, to vary with the p_H of the standard buffer solution containing the partly transformed compound, thus

At p_H =	3·69	3·37	4·2
p_K =	4·09	3·85	4·3

None of the other compounds investigated shows such variations. The colorimetric constant can therefore only be roughly defined as $3{\cdot}9 \pm 0{\cdot}4$—the mean of many determinations at various concentrations. The colour change is very gradual; thus no difference in colour between solutions of p_H 4·77 and 5·07, each containing 8 drops of $M/20$-solution of the compound (in alcohol), can be detected by visual matching.

4 : 6-*Dinitroresorcinol.*—This compound, prepared as already described (*loc. cit.*, 1925), forms yellow prisms, m. p. 214·5°. It is the least soluble of all the compounds investigated. The solutions were quite stable when in contact with the electrodes. The bridge settings were not quite so accurate at these high dilutions and resistances. The last value was not used in calculating the constant, since the corresponding degree of ionisation was 0·68.

v =	2560	5180	5180	10,360
λ =	163	198	188	257
$K \times 10^4$ =	1·22	1·09	0·94	1·39

The mean value of K is $1{\cdot}05 \times 10^{-4}$, $p_K = 3{\cdot}98$.

The solubility of the compound was found to be 0·0781 g. per litre by means of a conductivity titration, using a method which we hope to describe in a further communication.

The mobility of the dinitro-anion was determined by means of the monosodium salt. An $N/61{\cdot}9$-solution ($v_1 = 61{\cdot}9$) was diluted in steps of 2, the corresponding values of λ_1, etc., being treated by the well-known formula derived from the graph of λ and $\sqrt[3]{C}$ in order to obtain λ_0 (Kohlrausch, "Das Leitvermögen der Elektrolyte").

λ_1	λ_2	λ_4	λ_8	λ_{16}	λ_{32}
68·4	72·1	74·9	76·75	78·6	79·9

Hence $\lambda_0 = 2\lambda_8 - \lambda_1 = 85{\cdot}1$, etc.; the mean value was 85·0. The same results were also treated by the method of Ferguson and Vogel (*Phil. Mag.*, 1925, **50**, 971). In the equation

$$\log \delta\lambda = n \log C - \log B(1 - r^n),$$

in which C is the concentration, $\delta\lambda$ the difference in λ brought about by the dilution in the common ratio "r" (in this case 2), the constants n and B were found to be $n = 0{\cdot}437$, $B = 90{\cdot}9$. Hence λ_0 from the individual values of $\delta\lambda$ was 83·08 (82·8—83·2). The compound therefore behaves quite normally like a salt of a strong base and a strong acid. For several reasons we have preferred the value of λ_0 as given by the usual method. Combining this with the limiting mobility of $Na^{\cdot} = 51$, we find that of the anion to be 34, and that of the free monobasic acid 381.

Nitroquinol.—The sample consisted of dark red crystals, m. p. 128° (*loc. cit.*, 1924). The solutions, like those of dinitroquinol, changed in conductivity on standing in contact with the electrodes. Dilutions were therefore made outside the cell, and measurements were taken quickly. The two values of λ refer to two experiments at each dilution. The conductivity can be restored to nearly its original value by passing hydrogen over the electrodes.

$v =$	127	248	254	496	508
$\lambda =$	4·2 (4·74)	6·07 (6·31)	5·7 (7·25)	9·88 (10·2)	7·06 (7·74)
$K \times 10^6 =$	0·981	1·13	0·92	1·41	0·701

The values in brackets are given as showing the variability introduced by a slight delay in taking measurements. The constant is calculated from the lowest values of λ in each case. The mean constant is $1{\cdot}01 \times 10^{-6}$, $p_K = 6{\cdot}0$.

3-*Nitropyrocatechol.*—This was prepared by a modification of the method of Weselsky and Benedickt (*Monatsh.*, 1882, **3**, 386). The mixture of the 3- and 4-isomerides with unchanged pyrocatechol was distilled with steam. The distillate, containing the pyrocatechol and the 3-isomeride, was extracted with ether. The residue from this extraction was further extracted with boiling light petroleum. The 3-isomeride was obtained as bright yellow needles, m. p. 86°. Solutions kept in contact with the electrodes change in conductivity: the change is accelerated by passing oxygen and retarded by passing hydrogen. The precautions already mentioned were taken.

	First series.				Second series.	
$v =$	65·4	130·8	261·6	523·2	184	736
$\lambda =$	4·15	6·08	7·42	10·3	6·1	17·4
$K \times 10^6 =$	1·87	1·99	1·50	1·45	1·45	3·01

The mean value of K is $1{\cdot}88 \times 10^{-6}$, $p_K = 5{\cdot}73$.

The compound is colourless in acid solution, and full yellow at p_H 7·8—10·0. At higher values of p_H, there is a second change, to red-brown, becoming purple at about p_H 13—14. The colorimetric constants were determined by the methods already described:

$${}_1K = 1 \times 10^{-5},\ p_{K_1} = 4{\cdot}95;\ {}_2K_c = 0{\cdot}93 \times 10^{-11},\ p_{K_2} = 11{\cdot}03.$$

4-*Nitropyrocatechol.*—The method of Weselsky and Benedickt gives a product mixed with tarry matter. A more satisfactory method is that of Benedickt (*Ber.*, 1878, **11**, 362). The product when recrystallised from hot benzene is light brown, m. p. 173°. The conductivity of the solutions increased when they were in contact with the electrodes; the lower value of λ was therefore used in calculating the constants.

v =	48·1	51·5	96·2	192·4	384·8
λ =	1·51 (1·77)	1·72	1·97 (2·14)	2·25 (2·49)	5·22 (6·00)
$K \times 10^7$ =	3·33	4·05	2·83	1·85	5·02

The mean value of K is $3{\cdot}52 \times 10^{-7}$, $p_K = 6{\cdot}45$.

The compound is faintly yellow even in acid solution. It changes to red and ultimately to purple with increasingly alkaline solutions.

The constant of the first colour change was determined as already described. The second colorimetric constant was determined by comparison of a tube containing 5 drops at p_H 7·25 (full yellow) behind one containing 5 drops at p_H 13·76 (red) with one containing 10 drops, which matched when p_H was adjusted to 10·96. In another experiment, 8 drops of the solution of 4-nitropyrocatechol in a known p_H (10·64), were matched by 2 drops (in red solution) plus 6 (in yellow). The mean constants are $K_1 = 2{\cdot}8 \times 10^{-6}$, $p_{K_1} = 5{\cdot}56$; $K_2 = 1{\cdot}1 \times 10^{-11}$, $p_{K_2} = 10{\cdot}96$. An $M/20$-alcoholic solution was used.

2-*Nitroresorcinol.*—The method of preparation and the determination of the colorimetric constants have already been described (*loc. cit.*, 1925). The compound appeared as bright red crystals which melted sharply at 83·5°. Since the compound and its sodium salt are quite stable in solution, the latter was used in the determination of the mobility of the mononitro-anion, in the manner described above. Solutions were diluted in the cell, each dilution being two-fold, and the initial dilution, corresponding to λ_1, being 33·8.

λ_1	λ_2	λ_4	λ_8	λ_{16}	λ_{32}
66·2	69·7	72·9	75·9	77·1	78·8

Hence $\lambda_0 = 2\lambda_8 - \lambda_1 = 85{\cdot}6$, etc., the mean of the values of λ_0 being 84·9.*

* The degree of hydrolysis is inappreciable at all dilutions except the highest (v = *ca.* 1000). Taking K as $1{\cdot}6 \times 10^{-6}$, we find by the usual formula that the degree of hydrolysis is $2{\cdot}24 \times 10^{-3}$. The difference between λ_0 of sodium hydroxide and the sodium salt of the acid is $192 - 33{\cdot}5 = 158{\cdot}5$. Therefore, if these two electrolytes were equally dissociated, the repression of the hydrolysis would diminish the value of λ by

$$(2{\cdot}24 \times 10^{-3} \times 158{\cdot}5) \times 78{\cdot}8/85 = 0{\cdot}33.$$

Hence $\lambda_{32} = 78{\cdot}47$ and $2\lambda_{32} - \lambda_4 = 84{\cdot}05$.

The graph of λ against $\sqrt[3]{C}$ gives λ_0 as 84—85, and we use 84·5 as the most probable value. Hence the mobility of the anion is 33·5, and λ_0 of the free acid is 380·5. The conductivity of the acid remained constant when the solutions were kept in contact with the electrodes.

	First series.		Second and third series.			
v =	700	1400	288	349	576	1152
λ =	12·5	17·8	7·85	8·5	11·45	15·75
$K \times 10^6$ =	1·65	1·67	1·53	1·48	1·65	1·56

The mean value of K is $1{\cdot}59 \times 10^{-6}$ ($p_K = 5{\cdot}80$), which is only about $\frac{1}{10}$ of that found by Bader ($1{\cdot}29 \times 10^{-5}$).

The preparation showed all the usual criteria of purity, however, and the solutions were made up with the usual precautions.

4-Nitroresorcinol.—4-Nitrosoresorcinol, prepared according to Henrich (*Ber.*, 1902, **35**, 4193), was oxidised with alkaline hydrogen peroxide (Borsche and Berkhout, *Annalen*, 1904, **330**, 106). In order to obtain any yield at all, it is essential (*a*) that the hydrogen peroxide should be not weaker than 3%, and (*b*) that the solution should be kept alkaline as long as possible, *i.e.*, after the reaction is over it must be kept boiling for at least ½ hour and concentrated to a convenient bulk, then acidified, and extracted with ether. The product after recrystallisation from hot water is the semi-hydrate, yellow crystals, m. p. 82°. It may be quickly dehydrated at 70° giving the anhydrous compound, m. p. 115°.

	First series.		Second series.		
v =	69	138	186	372	744
λ =	3·11	4·37	5·56	7·35	11·08
$K \times 10^6$ =	0·98	0·97	1·16	0·99	1·11

The mean value of K is $1{\cdot}04 \times 10^{-6}$ ($p_K = 5{\cdot}98$), which agrees fairly well with Bader's value, $1{\cdot}2 \times 10^{-6}$.

The compound is colourless in acid solution, and completely yellow between p_H 9 and 10. There is no further change in colour in more alkaline solution. The mean value of the first, and only, colorimetric constant is $K_1 = 1{\cdot}55 \times 10^{-9}$, $p_K = 8{\cdot}81$.

Discussion of Results.

It was not expected that the constants of compounds which undergo tautomeric changes would be as uniform as those of normal electrolytes; these changes are probably the cause of the "drifts" which were found in several cases. The irregularities which are found in some cases have been already traced to irreversible or only partly reversible changes brought about by the catalytic activity of the electrodes. The constant of the somewhat similar, although less sensitive, *p*-nitrophenol has been found by Holleman (*Rec.*

trav. chim., 1902, **21**, 432) to vary between 6·1 and 7·3 × 10^{-8}, while Hantzsch gives 9·6 × 10^{-8}. We have tested the constants over all available dilutions. In Table I the first dissociation constants are represented by K_e in order to distinguish them from the colorimetric constants—first, $_1K_c$; second, $_2K_c$, and third, $_3K_c$. The compounds have been arranged in each group as far as possible in the order of diminishing first dissociation constants, K_e. Some of these, however, can be regarded as practically identical, in view of the probable errors mentioned above. The mononitrodihydric, like the mononitromonohydric, phenols are about equal in strength, but the dinitro-compounds, like the dinitrophenols, show a considerable difference in this respect. It is, however, in the relation between K_e and the K_c values that both mono- and di-nitro-dihydric phenols show the greatest individuality: so much so that a single conductivity measurement, combined with a colorimetric determination in a solution of known p_H would serve to distinguish each compound quite clearly.

In Table I, the constants of the nitrophenols are given for comparison, the values of K_e being due to Holleman (*loc. cit.*) and those of K_c to Michaelis and Gyemant (*Biochem. Z.*, 1920, **109**, 166). The fourth, fifth, and sixth columns give the constants of the tautomeric changes into the yellow, then the red, and purple forms (if any). The figures in the third column assign each compound to its predominant tautomeric form (Ph. = phenolic; Qu. = quinonoid) and attempt to define its strength as an acid dissociating in this form (K_e').

The experimental constants summarise the equilibria between the tautomeric forms, HM_1 and HM_2, and the products of their dissociation. In the equations, HM_1 stands for the phenolic acid (Ph.), HO·R·NO_2, and HM_2 for the quinonoid or *aci*-form (Qu.), O:R:NO·OH:

$$K_e = \frac{[H^\cdot][M'_1 + M'_2]}{[HM_1 + HM_2]} \quad \text{and} \quad K_c = \frac{[H^\cdot][HM_2 + M'_2]}{[HM_1 + M'_1]} \ *$$

* K_e and K_c are the "apparent" constants, due to the two forms present together, and obtained by electrometric and colorimetric measurements, respectively. Experimental results show that these measurements do in many cases give "mass-action" or Ostwald constants, which do not vary more than those obtained in the case of some of those acids having no tautomeric forms. The expressions for K_e and K_c do not, however, imply constancy unless there are other constants regulating the equilibria between the tautomeric forms, as has been shown by Noyes (*J. Amer. Chem. Soc.*, 1910, **32**, 815; see also Prideaux, "Theory and Use of Indicators," p. 129, Constable, 1917). The drift in the case of some constants may be due to the fact that the equilibria between the tautomeric forms do not obey the law of "mass" or concentration action. We have not yet been able to devise a method of testing this hypothesis.

TABLE I.

Compound.	K_e, as p_K.	K_e', as p_K.	${}_1K_c$, as p_K.	${}_2K_c$, as p_K.	${}_3K_c$ as p_K.

* $a = 0{\cdot}4 \quad 0{\cdot}5 \quad 0{\cdot}7 \qquad p_{K_e}' = 3{\cdot}21 \quad 3{\cdot}24 \quad 3{\cdot}47.$

† $a = 0{\cdot}177 \quad 0{\cdot}211 \quad 0{\cdot}236 \quad 0{\cdot}280 \qquad p_{K_e}' = 2{\cdot}96 \quad 3{\cdot}13 \quad 3{\cdot}43 \quad 3{\cdot}64.$

Thus the constant K_c measures the tendency of the compound to undergo the tautomeric change under the influence of diminishing hydrogen-ion concentration, whether this change takes place in the undissociated molecule or in the ion. The constant K_e contains the molecules and ions which take part in the dissociation of the first hydrogen ion from both the tautomeric forms. Although neither of the two true dissociation constants can be deduced from K_e by a rigid algebraic proof, yet by taking into account numerical relations, on the assumption that the colorimetric constant gives correctly the relative amount of coloured form, $HM_2 + M'_2$, the true dissociation constants of HM_1 or HM_2 may be obtained. The following is an outline of the reasoning and calculations by which these true constants (column 3 in Table I) were derived.

Where K_e is much greater than K_c, it is practically identical with the true dissociation constant of the phenolic acid. On the other hand, where K_e is much less than K_c, it is practically identical with the true constant of the quinonoid acid. Where $K_e = K_c$, the original Ostwald theory of indicators must be used, since ionisation proceeds *pari passu* with tautomeric change. Where K_e and K_c are of the same order, but not too close to one another, the true constants may be calculated as described below. The

limiting ratios of K_e to K_c at which such calculations become necessary will depend on the accuracy with which the original constants are defined by the experimental work.

If $K_e \gtrless 100K_c$, K_e is the constant of the phenolic acid, for even at a degree of ionisation $\alpha = 0{\cdot}8$, the amount of the coloured tautomeride is negligible. In the case of the mononitro-compounds, the degree of ionisation does not exceed 0·05 at the highest dilutions investigated. In the case of the dinitro-compounds, we have not, in determining the constants, taken into account degrees of ionisation exceeding 0·5, since, according to the usual estimate, the secondary ionisation of a dibasic acid may begin to be appreciable at this degree of primary ionisation.

Even at much lower ratios of K_e/K_c, the true constant of the phenolic acid, K'_e, is not far from the observed constant, K_e. The correction of K_e to K'_e will be greatest if all the quinonoid tautomeride is present as ion, and we will make this assumption. The total ion concentration is $M'_1 + M'_2$ and this is equal to $M'_1 + x$, if x is the degree of transformation (of total compound) into M'_2. Suppose that the ratio K_e/K_c is 20, and that the conductivity is determined at a degree of dissociation of 0·25; then

$$(1 - x)/x = [H^+]/K_c \quad . \quad . \quad . \quad . \quad . \quad (1)$$

in which x is the degree of colour change, and

$$(1 - \alpha)/\alpha = [H^+]/K_e \quad . \quad . \quad . \quad . \quad . \quad (2)$$

in which α is the degree of ionisation.

Therefore, on the above assumption,

$$[H^+] = K_e(1 - \alpha)/\alpha = 3K_e \text{ and } x = 1/[1 + 3K_e/K_c) = 1/61$$

Also $$3(M'_1 + 1/61) = (1 - M'_1 - 1/61),$$

therefore $M'_1 = 0{\cdot}233$, and the true constant of HM_1, $K'_e = 0{\cdot}233[H^+]/0{\cdot}75$

or $$K_e' = 0{\cdot}93K_e; \text{ since } K_e = 0{\cdot}25[H^+]/0{\cdot}75.$$

Correction of the Constant of the Phenolic Acids.—When the ratio K_e/K_c is still lower, the observed constant may be corrected for the presence of the ion of the quinonoid form. From the conductivity results we select one or more values of α. Then $p_H = p_{K_e} + \log \alpha/(1 - \alpha)$. By introducing the corresponding value of $[H^+]$ into the equation $\log (1 - x)/x = p_{K_c} - p_H$, the value of x is obtained.

Now since $x = M'_2$, $M'_1 = \alpha - x$, and $HM_1 = 1 - \alpha$,

therefore $$p_{K'_e} = p_H - \log (\alpha - x) + \log (1 - \alpha) \quad . \quad . \quad (3)$$

Correction of the Constants of the Quinonoid Acids.—If K_c is greater than K_e, the observed electrolytic dissociation is mainly that of the

quinonoid form. The most natural assumption, and that which requires the largest correction of the observed constants, is that all the ion consists of M'_2, the remainder of the quinonoid form being present as HM_2. The true constant K'_e of this form can be determined by a simple calculation. Selecting a degree of transformation x (*e.g.*, 0·8), we calculate the corresponding value of $[H^+]$ from equation (1) above. Then substitute this in equation (2), and calculate α and hence also $x - \alpha$ from the equation $\log (1 - \alpha)/\alpha = p_{K_e} - p_H$.

Thus in the case of 3-nitropyrocatechol, when $x = 0{\cdot}8$, $p_H = 5{\cdot}55$, $\alpha = 0{\cdot}402$ at this p_H, and $x - \alpha = 0{\cdot}398$. Hence

$$p_{K'_e} = p_H + \log (x - \alpha)/\alpha = 5{\cdot}54 \quad . \quad . \quad . \quad (4)$$

In calculating α from equation (2) in cases where K_e shows a trend, that value of p_{K_e} is used which corresponds according to the conductivity results to *each* value of α. In these cases, the corrected constant also shows a trend.

Orientation and Polarity.—The orientation of the compounds tabulated can be regarded as exerting influence upon (1) the strengths of the phenolic acids, (2) the strengths of the quinonoid acids, and (3) the colorimetric constants of the tautomeric changes. The two principal aspects of orientation which have received most attention are (*a*) the propinquity of substituting groups, the well-known effects of which have long been systematised without any hypothesis as to mechanism; and (*b*) the alternation of substituting groups, the effect of which is intelligible on the electronic theory of valency.

It should be possible to explain the order of the constants which represent (1), (2), and (3) in a quantitative manner, by the principles (*a*) and (*b*). The residual charges, detected by Lewis's method in the electronic formulæ for $\cdot NO_2$ (Lowry, *Trans. Faraday Soc.*, 1923, **18**, 285), cause it to act as a key radical in maintaining the polarity of a conjugated system. The nitrogen atom, on account of its mixed bond in $\cdot NO_2$ ($O{=}N{\dashrightarrow}O$), assumes a virtual positive charge and confers a virtual negative charge on the carbon atom to which it is attached, and this by alternation of the mean directions in which the electrons oscillate or vibrate, strengthens the virtual negative charges on the carbons in the 3- and 5-positions and weakens those in the 2-, 4-, and 6-positions.

Thus when a hydroxyl group is attached to the 3- or 5-position, weaker phenolic acids should result than when it is attached to the 2-, 4-, or 6-position. There might also be a reciprocal effect of the hydroxyl group on the nitro-group, which will become evident when the $\cdot OH$ becomes $:O$. Our results seem to show that the effect of

·NO·OH on :O, and reciprocally, is similar to that of $\cdot NO_2$ on ·OH; so that factors (*a*) and (*b*) act in the same sense on the quinonoid as on the phenolic acids. These effects may first be illustrated by the nitro- and dinitro-phenols.

o-Nitrophenol, in which factors (*a*) and (*b*) are both at a maximum, has a slightly higher constant than *p*-nitrophenol, in which (*b*) is favourable but (*a*) is less so (Holleman, *loc. cit.*). Both are higher in Table I than *m*-nitrophenol, in which (*b*) is unfavourable. The greater tendency to tautomeric change in the *o*- and *p*-compounds is shown by the dissociation of the ortho-compound largely as a quinonoid substance, and of the meta-compound in the phenolic direction. In the case of *p*-nitrophenol, dissociation and tautomeric change are almost parallel.

In the case of the dinitrophenols also, it is remarkable how close the colorimetric lies to the dissociation constant in those cases where both are known. The order of the constants agrees on the whole with the alternate polarity theory. In the strongest, 2 : 6-dinitrophenol, (*a*) and (*b*) are at a maximum; in the 2 : 4-compound (*b*) is favourable and (*a*) not so favourable. In 2 : 3-dinitrophenol, the strengthening effect of the 2-nitro-group is somewhat weakened by the opposing effect of the 3-nitro-group. In the 2 : 5-compound, the opposing effect of the second nitro-group is more marked as the hydroxyl group is exposed to it more directly. In the 3 : 4-, the nitro-group opposing the dissociation is nearer to the hydroxyl than that which favours it. In the 3 : 5-, both nitro-groups alternate incorrectly. It must be noted that the "opposition" of a nitro-group which alternates incorrectly is really only a smaller enhancing effect, since all dinitro-phenols are stronger acids than mononitro-phenols, owing, no doubt, to the more numerous chances for the formation of the quinonoid molecule *whatever* the position of the second nitro-group.

In contrast to the nitrophenols, the nitro-dihydric phenols show the most varied relations between first dissociation and colorimetric constants.

The Mononitro-compounds.—K_c is greater than K_e in the case of 2-nitroquinol, 2-nitroresorcinol, 3- and 4-nitropyrocatechols, 3 : 5-dinitropyrocatechol, and 2 : 6-dinitroquinol, which therefore dissociate chiefly or wholly as quinonoid acids; whilst K_e is greater than K_c in the case of 4-nitro-, and 2 : 4- and 4 : 6-dinitroresorcinol, which therefore dissociate chiefly or wholly as phenolic acids.

The first dissociation constants of the mononitro-compounds are of the order 1×10^{-6}, the constant thus being increased about 10-fold by the introduction of a second hydroxyl group into the molecule of *o*-nitrophenol. The nitro-group is in the ortho-position

to at least one hydroxyl group, *i.e.*, condition (*a*) is favourable, in all the compounds except 4-nitropyrocatechol, which has a distinctly lower constant than the others. One might perhaps expect 3-nitropyrocatechol to be a weaker acid than the 4-nitro-isomeride, instead of *vice versa*. The position of the second hydroxyl group appears, however, to have only a slight effect on the constant. Regarding the first four compounds in this series as derivatives of *o*-nitrophenol, we see that the effect of the second hydroxyl group in decreasing the constant $p_K = 7{\cdot}17$ (*i.e.*, increasing the constant K_c) of *o*-nitrophenol increases in the order 4 = 5, 3, 6. The order of increasingly favourable alternating effect (which agrees with the increase of constant in the order, *o*-, *m*-, and *p*-, in the case of mononitrophenols and some other compounds) is 4, 6, 5, 3. The order of increase in the case of the dihydroxybenzoic acids (with one hydroxyl group ortho to the carboxyl group) is 5, 4, 6, 3 (Lehfeldt, "Electrochemistry," Longmans), which is identical with the order required by condition (*a*) above, *i.e.*, mere propinquity without alternation. The dissociation of the carboxyl group would appear to be more powerfully affected by propinquity, (*a*), and that of the ·NO·OH group by alternation, (*b*), where the two principles are in opposition.

The Dinitro-compounds.—It was considered surprising by Bader (*loc. cit.*), in view of the negative character of hydroxyl, that dinitroquinol should be a weaker acid than 2 : 6-dinitrophenol. This may perhaps be explained as being due to a diminution of the negative polarity of the carbon attached to the ·NO·OH group by the opposing positive polarity of the carbon attached to the 4-hydroxyl group. 2 : 4-Dinitroresorcinol, in which the alternate polarities are in tune, is a stronger acid than 2 : 4- or even than 2 : 6-dinitrophenol.

Comparing the constants of the dinitro- with those of the corresponding mononitro-compounds, there is seen to be an increase in K (decrease in p_K of 1·5—3 units). The polarity of the second nitro-group always enhances that of the first, since the list examined includes only *m*-dinitro-compounds.

The order of the corrected constants is the same as that of the mononitro-compounds from which they are derived :

3-Nitropyrocatechol > 2-nitroresorcinol > 2-nitroquinol = 4-nitroresorcinol *
3 : 5-Dinitropyrocatechol > 2 : 4-dinitroresorcinol = 2 : 6-dinitroquinol > 4 : 6-dinitroresorcinol

* The meta-dinitro-derivative of 4-nitropyrocatechol has not been examined.

The tendency to undergo tautomeric change is measured by the colorimetric constants. The order of these is different from that

of the dissociation constants, and is nearly the same in the dinitro-compounds as in the mononitro-compounds from which they are derived. Thus it is apparently the orientation of one nitro-group in relation to the two hydroxyl groups which determines the number of tautomeric changes and the p_H at which they occur.

Order of $_1K_c$.

* 2-Nitroresorcinol > 2-nitroquinol > 3-nitropyrocatechol > 4-nitropyrocatechol > 4-nitroresorcinol,
2 : 6-Dinitroquinol > 3 : 5-dinitropyrocatechol > 2 : 4-dinitroresorcinol > 4 : 6-dinitroresorcinol †

* The constant is too high to be measured.
† The constant is rather uncertain.

To the second and third colorimetric constants given in our previous communication have now been added all those which can be determined. The nitroresorcinols do not give second constants, with the single exception of the 2-isomeride which undergoes its first change of colour at an exceptionally low p_H, whilst the change of the 4-isomeride occurs at an exceptionally high p_H. The second changes (half-way) to the red or brown forms occur at p_H's from 4 to 6 units lower than the changes (half-way) to the yellow form. The order of the second constants is very similar to that of the first:

$_1K_c$ | 2-N.R. > 2 : 6-N.Q. > 2-N.Q. = 3 : 5-N.C. > 2 : 4-N.R. > 3-N.C. > 4-N.C. > 4-N.R.
$_2K_c$ | 2 : 6-N.Q. > 2-N.R. > 2-N.Q. > 3 : 5-N.C. > 3-N.C. = 4N.C.

The only compounds which undergo the third change, to purple, are nitroquinols and nitropyrocatechols (but not 4-nitropyrocatechol); those in the latter class, however, only show this change in such strong alkali that p_{K_3} could not be determined. The order of the third constants is nearly the same as that of the second:

$_2K_c$ | 2 : 6-N.Q. > 2-N.Q. > 3 : 5-N.C. > 3-N.C. = 4-N.C.
$_3K_c$ | 2 : 6-N.Q. > 2-N.Q. > 3 : 5-N.C. > 3-N.C. —

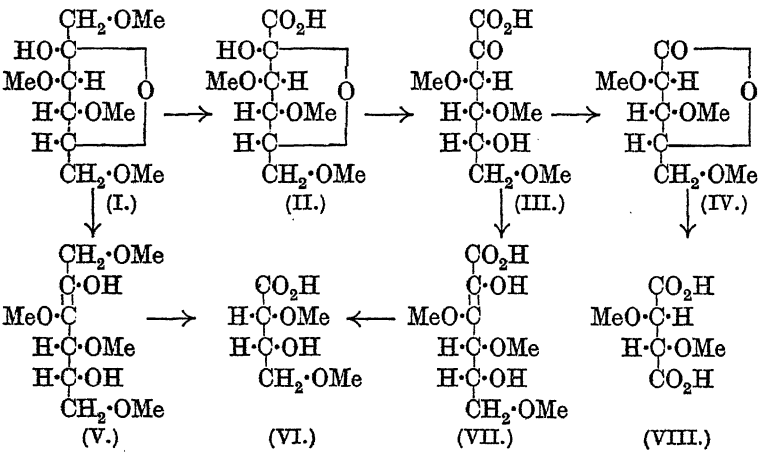
UNIVERSITY COLLEGE,
NOTTINGHAM.

[*Received, April 20th*, 1927.
Revised, June 20th, 1927.]

CCCVIII.—*The Constitution of the Disaccharides. Part XV. Sucrose.*

By JOHN AVERY, WALTER NORMAN HAWORTH, and EDMUND LANGLEY HIRST.

THE normal variety of *d*-fructose has now been brought within the generalisation that hexoses and pentoses tend to exist ordinarily as amylene-oxide forms (Haworth and Hirst, J., 1926, 1858;



Haworth, Hirst, and Learner, this vol., p. 1040). This development has necessitated the abandonment of the butylene-oxide formula generally current for the normal sugar and latterly supported by the experiments of Irvine and Patterson (J., 1922, **121**, 2696), and has in consequence introduced many uncertainties into the reasoning by which the constitution of the more labile γ-isomeride of fructose was deduced. This consequence was indicated in the papers by two of us referred to above.

It will be seen on reference to the papers by Haworth and Linnell (J., 1923, **123**, 294) and by Haworth and Mitchell (*ibid.*, p. 301) that the inferences drawn from the experimental work therein recorded were based on the appropriation of the butylene-oxide structure for normal fructose. The consideration of a butylene-oxide structure for γ-fructose derivatives was for this reason excluded, the conclusion being drawn that "the choice of a constitution for the tetramethyl γ-fructose derived from methylated sucrose appears to be limited to one of the following forms: ethylene oxide, propylene oxide, amylene oxide." This later work on *n*-fructose has therefore rendered uncertain and insecure the arguments by means of which an amylene-oxide structure for tetramethyl γ-fructose has been deduced, and it was decided to take the present opportunity to review the whole position in the light of the experience gained in determining the constitution of other sugar derivatives. It has become evident in the meantime that, owing to the peculiar nature and extent of the isomerism in the sugar group, it is necessary to withhold the application of structural formulæ unless the substance under investigation has been transformed by well-defined methods into products which can be compared with or further degraded to give simple and crystalline reference compounds of definitely verified structure, such as the simple tartaric and hydroxyglutaric acids. In the earlier experiments (Haworth and Linnell, *loc. cit.*; Haworth and Mitchell, *loc. cit.*) the oxidative degradation products were, with few exceptions, liquid distillates and an extended examination of these substances has now yielded crystalline derivatives of such a nature that the structure of the tetramethyl γ-fructose from which they originated may be clearly deduced.

The experiments now to be described have involved a repetition of the work previously recorded on the oxidation of tetramethyl γ-fructose (I) by nitric acid and by alkaline permanganate, with the result that the accuracy of these experimental data has been substantiated, and proof has been obtained that in almost every case the products described, although liquids, were essentially homogeneous.

Oxidation of tetramethyl γ-fructose with either dilute or concen-

trated nitric acid leads, after esterification with ethyl alcohol, to the isolation of an ethyl ester giving C, 50·4; H, 7·8; OMe, 47·6, which agree reasonably well with either of the formulæ $C_{11}H_{20}O_7$ or $C_8H_{14}O_5$. This ethyl ester reduces Fehling's solution on warming, undergoes profound decomposition in the presence of hot alkali, and contains a reducing hydroxyl group which can be methylated to give a stable, non-reducing substance, the behaviour of which towards alkali is now normal. Owing to this behaviour with alkali, the quantitative hydrolysis of the ethyl ester gave figures which were higher than those calculated for $C_{11}H_{20}O_7$ and agreed with those required by a substance $C_8H_{14}O_5$; but, although the recorded analytical data and the behaviour during titration are in better agreement with the lactone formula $C_8H_{14}O_5$, originally proposed by Haworth and Linnell, yet this compound must now be recognised, for the following reasons, as the ethyl ester, $C_{11}H_{20}O_7$, of the lactol acid $C_9H_{16}O_7$ (II).

On methylation of this product, the higher homologue was obtained which was characterised by its conversion to a crystalline amide, m. p. 99—100°, identical with that previously described by Haworth, Hirst, and Nicholson (this vol., p. 1517). The relationship between the methyl ester obtained by these authors and the ethyl ester now described is thus demonstrated. The degradation of the lactol acid by means of alkaline permanganate yielded a hydroxymethoxy-acid which was isolated in the form of its methyl ester. In the experimental section the detailed analysis of this is described, and it is shown that the main product is occasionally accompanied by an impurity which substantially enhances the methoxyl and titration values. Specimens of the ester gave analytical figures which corresponded closely with those recorded by Haworth and Linnell

for their final esterified oxidation products, whilst others corresponded more nearly to methyl hydroxydimethoxybutyrate.* By treatment with methyl-alcoholic ammonia, each of them gave, in yield varying from 60—87%, the crystalline amide, m. p. 104—105°, of a hydroxydimethoxybutyric acid (VI), proof being thus afforded that the latter acid was the essential constituent. The same product was also obtained by direct oxidation of tetramethyl γ-fructose with alkaline permanganate (compare Haworth and Mitchell, *loc. cit.*), and the identity of the hydroxydimethoxybutyric acid from both these sources was demonstrated by the conversion of each specimen into the same crystalline amide. Methylation of the ester gave a methyl trimethoxybutyrate, which was characterised through the corresponding crystalline amide, m. p. 58—59°.

Under certain conditions, the above hydroxydimethoxybutyric acid appeared to lose the elements of water and give a hygroscopic anhydride, which has been described previously as a lactone by Irvine and Patterson (J., 1922, **121**, 2699) and by Haworth and Mitchell (*loc. cit.*). Sufficient evidence is not yet available, however, to enable a final choice to be made between the formulation of this anhydride as a lactone or a lactide (see footnote).

The application of the Weerman test (*Rec. trav. chim.*, 1917, **36**, 16) as a method for characterising α-hydroxy-acids by the action of sodium hypochlorite on their amides, indicated that the hydroxydimethoxybutyric acid under examination did not belong to this class, and the attempted oxidation of the free acid by means of nitric acid led to the recovery of the material unchanged, thus proving that the free hydroxyl group did not occupy a terminal γ-position in the chain. These indications pointed provisionally to the recognition of the hydroxydimethoxybutyric acid as a β-hydroxy-acid.

A complete verification of these results was secured, and a simple and direct proof of the structure of these substances and of γ-fructose derivatives was attained, by the degradative oxidation of the lactol acid $C_9H_{16}O_7$ (II) by means of barium permanganate in acid solution. Under conditions which required careful control, one

* The reason for this variability of composition becomes clear when it is recognised, as will appear later in this paper, that we were handling a β-hydroxy-acid. The parent substance of this product, β-hydroxybutyric acid, has been fully investigated by McKenzie (J., 1902, **81**, 1402), who has observed the readiness with which it passes into an anhydride form and into crotonic acid by loss of water. If in the present case a dimethoxycrotonic acid were formed, this would lead under the conditions employed to methoxymalonic acid, and ultimately to its methyl ester. We are at present studying the various forms of hydroxydimethoxybutyric acid, obtained synthetically from dimethoxyacetoacetic ester.

atomic proportion of oxygen was absorbed for each molecule of lactol acid, and a yield of nearly 50% of crystalline *d*-trimethyl γ-arabonolactone (IV) was obtained. We were able to recognise this compound with certainty, since we were in possession of the corresponding *l*-isomeride of the lactone (Baker and Haworth, J., 1925, **127**, 365; Haworth and Nicholson, J., 1926, 1899; Drew, Goodyear, and Haworth, this vol., p. 1244), and the properties of the two specimens are given for comparison :

	d-Trimethyl γ-arabonolactone.	*l*-Trimethyl γ-arabonolactone.
M. p.	32—33°	33°
$[\alpha]_D$ (initial) in water.....	+44·5°	−44·2°
$[\alpha]_D$ (after 20 days)	+25·5°	−25·2°

We have confirmed the structure assigned to these lactones, wherein the methyl groups are allocated to the positions 2, 3, 5, by effecting their further oxidation with nitric acid. The *d*-trimethyl γ-arabonolactone originating from tetramethyl γ-fructose gave *l*-dimethoxysuccinic acid (VIII), identified as the crystalline methylamide and also as the amide, and these crystalline derivatives were compared directly with specimens which were specially prepared from *l*-tartaric acid (see later papers by Haworth, Hirst, and Learner and by Haworth and Jones).

The reaction between the lactol acid and acid permanganate is thus typical of the behaviour of either α-ketonic acids or ketol-acids which are potentially α-ketonic in nature (compare Ohle, *Ber.*, 1927, **60**, 1165), leading to the formation of a carboxylic acid containing one carbon atom less in the chain. Since the substance isolated in the present instance has been proved definitely to be 2 : 3 : 5-*d*-trimethyl arabonic acid, it follows immediately that the original lactol acid must have contained methyl groups in positions 3, 4, and 6. The oxide linking present in the lactol acid and also in tetramethyl γ-fructose must connect the carbon atoms in positions 2 and 5. Tetramethyl γ-fructose has therefore a γ- or butylene-oxide structure, and the lactol acid, $C_9H_{16}O_7$, is seen to have the constitution provisionally applied to it by Haworth and Hirst (1926). Similarly the hydroxydimethoxybutyric acid (VI) is recognised as 2 : 4-dimethyl *d*-erythronic acid.

The recent views we have expressed (Haworth, Hirst, and Nicholson, *loc. cit.*) relating to the structure of tetramethyl γ-fructose, resting on the analogy with other γ-sugars and on the ease of transformation of γ-fructose derivatives into furan bodies (see also Bergmann, J., 1923, **123**, 1277), are thus finally supported by the experimental results herein outlined. It follows that this sugar is now to be recognised as 1 : 3 : 4 : 6-tetramethyl fructose, and since

this derivative arises from the hydrolysis of methylated sucrose, the constitutional formula (IX), which we have applied in recent papers to sucrose, receives additional support and confirmation.

(IX.)

EXPERIMENTAL.

Oxidation of Tetramethyl γ-Fructose with Nitric Acid (d 1·42). *Isolation of the Ethyl Ester of the Lactol Acid* $C_9H_{16}O_7$ (II).—A mixture of tetramethyl γ-fructose (10 g.) and concentrated nitric acid (70 c.c.; *d* 1·42) was cautiously heated on the water-bath until at 70° a vigorous reaction ensued with evolution of nitrous fumes. The reaction was kept under control by cooling at intervals, and the temperature of the mixture was gradually raised to 93°. The reaction appeared to be complete after 1½ hours. Water was then added to the cooled solution and the nitric acid was almost entirely removed by distillation at 50—60°/13 mm., the usual precautions being observed to avoid undue heating during the concentration. This procedure was many times repeated and finally the product was taken down to a syrup. At this stage, absolute ethyl alcohol was added and distilled from the product to remove water. The syrupy residue was dissolved in 200 c.c. of absolute ethyl alcohol, containing 6 g. of hydrogen chloride, and boiled gently under reflux for 9 hours. Thereafter, the mineral acid was neutralised with silver carbonate, the solution filtered, and the solvent evaporated. The syrupy residue distilled without decomposition :

Fraction 1, at bath temperature up to 125°/0·1 mm.; 2·2 g., $n_D^{16°}$ 1·4500.

Fraction 2, at bath temperature 130—135°/0·1 mm.; 7 g., $n_D^{14°}$ 1·4520.

Fraction 3, at bath temperature 150°/0·1 mm.; 0·5 g., $n_D^{14°}$ 1·4564. Fraction 2, which showed $[\alpha]_D^{24°}$ + 25·8° in water (*c* = 2·7), gave the following analytical data—Found : C, 50·35; H, 7·75; OMe, 47·6. $C_{11}H_{20}O_7$ requires C, 50·0; H, 7·6; OMe, 47·0. $C_8H_{14}O_5$ requires C, 50·5; H, 7·4; OMe, 48·9%. This material reduced Fehling's solution on warming and gave coloured decomposition products when heated with aqueous alkali. As stated on p. 2310, this product consisted essentially of the ethyl ester, $C_{11}H_{20}O_7$, of the

lactol acid, $C_9H_{16}O_7$ (II). *Titration.* 0·269 G. required 13·5 c.c. *N*/10-sodium hydroxide (on heating for ½ hour at 90°). Calc., for $C_{11}H_{20}O_7$: 10·2 c.c.; for the lactone, $C_8H_{14}O_5$: 14·2 c.c.

Methylation and Amide Formation.—A specimen of the above product (Fraction 2) was treated with Purdie's reagents for 5½ hours. A syrup which remained colourless when heated with aqueous alkali and which did not reduce Fehling's solution was obtained, distilling at 12 mm. from a bath heated at 155—160°. This showed $[\alpha]_D^{23°}$ + 3° in water (c = 1·07). *Titration.* 0·1048 G. required 4·2 c.c. *N*/10-sodium hydroxide for hydrolysis and neutralisation.

The methylated product was dissolved in methyl alcohol, saturated with dry ammonia, and cooled in ice, and the mixture was kept for 4 days. Removal of the solvent in a vacuum gave a crystalline product (yield above 60%), m. p. 99—100° (from light petroleum); $[\alpha]_{5461}^{21°}$ — 83° in water (c = 0·98). A specimen of the crystalline amide was mixed with the specimen of the amide $C_{10}H_{19}O_6N$, obtained by Haworth, Hirst, and Nicholson (this vol., p. 1517) from the corresponding methyl ester, and the m. p. showed no depression.

Oxidation with Alkaline Permanganate.—The product (2·5 g.) isolated from the process of oxidation with nitric acid as described above (Fraction 2) was treated at 70° with 2*N*-potassium hydroxide (20 c.c.) and with *N*-potassium permanganate (88 c.c.), the latter being gradually added with frequent shaking. In working up the product the alkali was neutralised with mineral acid in presence of ice, and after removal of the precipitated manganese oxides the filtrate was made slightly alkaline by means of potassium carbonate and evaporated (water-bath) to small bulk. Thereafter the whole of the water was removed in a high vacuum, yielding a white, solid mass. Preliminary experiments showed that no advantage was to be gained by extracting the solid with organic solvents. It was therefore dissolved in water and the organic acid liberated by acidifying with mineral acid. The water was then removed in a high vacuum, and the white mass extracted with chloroform. This extract yielded a syrupy organic acid which was esterified with methyl-alcoholic hydrogen chloride. The liquid ester distilled under 0·07 mm. from a bath heated to 100°, and showed $[\alpha]_D^{20°}$ + 19° (in water, c = 0·96) and $n_D^{17°}$ 1·4400; yield 0·8 g. (Found : C, 46·3; H, 7·9; OMe, 49·2. $C_7H_{14}O_5$ requires C, 47·2; H, 7·9; OMe, 52·2%). *Titration.* 0·0946 G. required 5·2 c.c. *N*/10-sodium hydroxide for hydrolysis and neutralisation (Calc. for $C_7H_{14}O_5$: 5·3 c.c.).

This product has been obtained on several occasions under similar experimental conditions to those outlined above, and the

physical properties and analyses of these specimens are tabulated below:

(*a*) $n_D^{17^\circ}$ 1·4400, $[\alpha]^{20^\circ}$ + 19°, C, 46·3; H, 7·9; OMe, 49·2%; (*b*) $n_D^{19^\circ}$ 1·4410, $[\alpha]_D^{19^\circ}$ + 22·4°, OMe, 54·9%; (*c*) $n_D^{13·5^\circ}$ 1·4390, OMe, 48·8%; (*d*) $[\alpha]_D^{20^\circ}$ + 21·8°, C, 46·75; H, 7·8; OMe, 61·2%; (*e*) n_D 1·4421, $[\alpha]_D$ + 31°, C, 47·8; H, 7·2; OMe, 60%.

The analyses of (*a*) and (*d*) were made independently by Fein-Chemie, G.m.b.H., Tübingen. These products correspond with that obtained by Haworth and Linnell (*loc. cit.*, p. 301), who quote C, 48·4; H, 7·2; OMe, 59·7%. It was evident that all these products were mixtures containing a variable quantity of a substance giving high methoxyl and titration values, and this factor is referred to in the footnote on p. 2311. That each of these specimens was essentially, however, methyl hydroxydimethoxybutyrate was demonstrated by treating them with methyl-alcoholic ammonia. This led to the isolation of the crystalline amide described below in yields from 60—87%, the largest yield being obtained from the specimen (*a*).

Hydroxydimethoxybutyramide was isolated as described above as crystals, m. p. 104—105° (from petroleum); $[\alpha]_{5461}^{19^\circ}$ + 37° in water (c = 1·05), and $[\alpha]_D^{19^\circ}$ + 33° [Found: C, 44·2; H, 8·0; N, 8·7; OMe, 36·2. $C_4H_7O_2N(OMe)_2$ requires C, 44·2; H, 8·0; N, 8·6; OMe, 38·0%].

Oxidation of Tetramethyl γ-Fructose with Alkaline Permanganate.—In general the method described by Haworth and Mitchell (J., 1923, **123**, 306) was followed, except that the product was isolated as the methyl ester as described in the earlier paragraph above. The ester distilled from a bath heated to 130° under 13 mm., and showed $n_D^{14^\circ}$ 1·4413. This material corresponded exactly with the specimens (*a*)—(*e*) described above, and gave on treatment with methyl-alcoholic ammonia a crystalline amide, m. p. 104—105°, identical in all respects with that described above as hydroxydimethoxybutyramide.

Hydrolysis.—A specimen of the above methyl ester was hydrolysed with dilute hydrochloric acid (5%) during 4½ hours at 80°. After the usual process of isolation, the product was distilled from a bath heated to 125° under 0·04 mm., and was obtained as a colourless, hygroscopic syrup having acid properties, but which did not crystallise on preserving in a vacuum over phosphoric oxide for several days. A further purification was effected by fractional distillation, and the substance remained as a colourless syrup. This appeared to be identical with the product obtained by Haworth and Mitchell (*loc. cit.*) and Irvine and Patterson (*loc. cit.*, p. 2699), and described as the lactone of hydroxydimethoxybutyric acid.

The observations now to be recorded indicate, however, that the product may have been a lactide of a β-hydroxy-acid.

Experiments on the Determination of the Structure of the Hydroxydimethoxybutyric Acid.—(a) *Weerman reaction on the amide.* Weerman's method (*loc. cit.*) for the characterisation of α-hydroxy-acids depends on the interaction of the amides of these acids with sodium hypochlorite, this reagent forming sodium *iso*cyanate with such amides but not with those of other hydroxy-acids. The qualitative test applied for the presence of sodium *iso*cyanate is the addition of hydrazine hydrate, followed by the addition of benzaldehyde, which leads to the isolation of benzalsemicarbazone. An alternative method is the addition of semicarbazide, which in presence of sodium *iso*cyanate forms crystalline hydrazidicarbonamide. When the test was applied to the hydroxydimethoxybutyramide which we had prepared during the present work, a negative result was obtained, indicating that this amide was other than an α-hydroxy-compound. Control experiments were carried out with gluconamide, trimethoxyglutaramide and acetamide, and only in the case of gluconamide was a positive result obtained, as should be the case.

(b) *Attempted oxidation with nitric acid.* The above result indicated that the related acid must be either a β- or a γ-hydroxy-acid. In the latter case the hydroxyl group would be in the terminal position as a $-CH_2\cdot OH$ group, which should be characterised by its ease of oxidation to a carboxyl group. When the substance was digested, however, with nitric acid (*d* 1·2) during 6 hours at 70—100°, it gave a product which, on conversion into the methyl ester, was identical with the original material, thus proving that no oxidation had taken place. This conclusion was verified by conversion of this ester into the crystalline hydroxydimethoxybutyramide, m. p. 104—105°. It became evident, on the basis of these results, that the hydroxydimethoxybutyric acid under examination was probably a β-hydroxy-acid.

(c) *Methylation of the ester.* The specimen (*a*) described previously, and consisting essentially of methyl hydroxydimethoxybutyrate, was methylated with Purdie's reagents, and the product on distillation showed $n_D^{12°}$ 1·4282; $[\alpha]_D^{21°}$ + 19° in water ($c = 1·04$). *Titration.* 0·1006 G. required 5·25 c.c. of *N*/10-sodium hydroxide for hydrolysis and neutralisation (Calc. for $C_8H_{16}O_5$: 5·24 c.c.). Found: C, 49·7; H, 6·5; OMe, 62·3. Calc.: C, 50·0; H, 8·3; OMe, 64·6%.

This product was identified as methyl trimethoxybutyrate by conversion into the crystalline amide. The trimethoxybutyramide separated from light petroleum as colourless needles, m. p. 58—59°,

$[\alpha]_D^{18°}$ + 40·5° in water (c = 1·09 (Found: C, 47·7; H, 8·5; N, 7·7; OMe, 49·7. Calc.: C, 47·5; H, 8·5; N, 7·9; OMe, 52·5%).

Confirmatory Proof of the Constitution of Tetramethyl γ-Fructose. Isolation of Crystalline d-2 : 3 : 5-*Trimethyl Arabonolactone by Degradative Oxidation of the Lactol Acid*, $C_9H_{16}O_7$.—The ethyl ester, $C_{11}H_{20}O_7$, of a lactol acid, $C_9H_{16}O_7$, was described as Fraction 2 on p. 2313. Preliminary experiments showed that the desired stage of oxidation by means of acidified permanganate was completed when one atomic proportion of oxygen had been absorbed. The details of the procedure are as follows: The material of Fraction 2 (3·2 g.) was hydrolysed during 3 hours at 90° with 60 c.c. of 2·5% hydrochloric acid. The solution was neutralised with silver carbonate, and the silver removed from the filtrate with the aid of hydrogen sulphide. The filtrate from the silver sulphide was evaporated, and the free lactol acid, $C_9H_{16}O_7$, was collected as a syrup, which was dissolved in 110 c.c. of water and mixed with 40 c.c. of *N*-sulphuric acid. Thereafter, a solution of barium permanganate (4%) was added very slowly until the required amount had been admitted, the reaction being conducted at room temperature. An excess of barium hydroxide solution was then added, followed by the admission of carbon dioxide to precipitate the excess of barium hydroxide. At this stage, the precipitated salts were removed by filtration, and to the solution, which contained the soluble barium salt of an organic acid, the equivalent of dilute sulphuric acid was added. The filtrate obtained after removal of barium sulphate was now evaporated under diminished pressure, and yielded a syrup which crystallised spontaneously when cold (yield 1 g.). The crystalline compound distilled under 11 mm. from a bath at 145°, and the distillate solidified instantly (yield 0·75 g.).

Extraction of this crystalline product with light petroleum left a minute quantity of residual oil which darkened in the air. From the solution in light petroleum, needles or shining plates crystallised according to the conditions of cooling (m. p. 32—33°; yield 0·6 g.); $[\alpha]_D$ + 44·5° in water (c = 0·712)—this initial value decreased during 18 days to the constant value + 25·5° (Found: C, 50·2; H, 7·7; OMe, 47·6. Calc. for $C_8H_{14}O_5$: C, 50·5; H, 7·4; OMe, 48·9%). *Titration.* 0·0512 G. required 2·7 c.c. *N*/10-sodium hydroxide for neutralisation, the substance behaving during titration as a lactone.

This product corresponds to *d*-trimethyl γ-arabonolactone, and in the theoretical section it is shown that the rotation values are equal and opposite to those of the *l*-isomeride, whilst the m. p. is identical.

A similar oxidation was carried out with the corresponding methyl

ester of the lactol acid, $C_{10}H_{18}O_7$ (compare Haworth, Hirst, and Nicholson, *loc. cit.*). In this example, the experiment was modified by omitting isolation of the free acid, inasmuch as control experiments indicated that the alcohol liberated on hydrolysis of the ester was not appreciably oxidised under the experimental conditions employed. The methyl ester (8·9 g.) was heated for 2½ hours at 85° with *N*/2-sulphuric acid (104 c.c.). Barium permanganate equivalent to one atomic proportion of oxygen was then admitted to the cold solution, which had been diluted to a volume of 500 c.c. by the addition of a further 100 c.c. of *N*/2-sulphuric acid and water. The product was isolated in the manner already described, and weighed 4·1 g., of which 3·0 g. were collected as a distillate under 11 mm. from a bath at 145°. This distillate crystallised immediately when cold. A similar portion of an oily by-product was again noticed. The recrystallised *d*-trimethyl γ-arabonolactone, m. p. 33°, weighed 2·6 g.

It should be added that qualitative tests conducted with the ethyl or methyl esters dissolved in acidified permanganate solution showed that the reaction proceeded slowly until hydrolysis of the ester had taken place. Oxidation then proceeded rapidly at room temperature. The oxidation proceeds smoothly and is accompanied by practically no change in the rotation value of the solution.

We wish to thank the Education Committee of the Durham County Council for the award of a Research Exhibition to one of us (J. A.).

CCCIX.—*The Tautomerism of Amidines. Part VII. Methylation of Benzenyl-*p*-nitrodiphenylamidine.*

By CLIFFORD CHEW and FRANK LEE PYMAN.

THE alkylation by alkyl salts of open-chain amidines, in which one of the nitrogen atoms is attached to an aryl group and the other to a non-aryl (hydrogen or alkyl) group, yields as main products compounds alkylated on the arylamine nitrogen atom, together with small quantities of the isomeric alkyl derivatives. For example, benzenylphenylmethylamidine (I or II) gives with methyl iodide methylphenylamidobenzenylmethylimidine (III) in 62% yield, and dimethylamidobenzenylphenylimidine (IV) in 4% yield (Pyman, J., 1923, **123**, 367).

In previous papers (Pyman, J., 1923, **123**, 3359; Forsyth and Pyman, J., 1926, 2502) one of us has expressed the view that results

of this kind are due, not to the feebler basicity of the arylamino-group as compared with the alkylamino-group, as some previous

(I.) $CPh(:NPh)\cdot NHMe \rightleftharpoons CPh(:NMe)\cdot NHPh$ (II.)

(III.) $CPh(:NMe)\cdot NMePh$ $\qquad$ $CPh(:NPh)\cdot NMe_2$ (IV.)

investigators have supposed, but to the tendency of the aryl group to attract the double linking into the αβ-position. Thus, it was thought that benzenylphenylmethylamidine reacted in the form (I) to a much greater extent than in the form (II), owing to the influence of the phenyl group in the anilino-residue, and consequently gave (III) to a much greater extent than (IV), since the alkylation of open-chain amidines with alkyl salts leads to the attachment of the alkyl group to the nitrogen atom which is doubly linked to carbon (Pyman, J., 1923, **123**, 3359). Evidence that the structural effect is of greater importance than the relative basicities of the nitrogen atoms has been given in the papers quoted, and further evidence in favour of this view is afforded by the results of the present investigation.

Benzenyl-p-*nitrodiphenylamidine* (V or VI) gave on methylation with methyl iodide *benzenylmethylphenylamido*-p-*nitrophenylimidine* (VII) in 28·8% yield, and *benzenylmethyl*-p-*nitrophenylamidophenylimidine* (VIII) in 24·9% yield, together with 8·8% of unchanged material. Now, in benzenyl-*p*-nitrodiphenylamidine both nitrogen

(V.) $CPh(:NPh)\cdot NH\cdot C_6H_4\cdot NO_2 \rightleftharpoons CPh(:N\cdot C_6H_4\cdot NO_2)\cdot NHPh$ (VI.)

(VII.) $CPh(:N\cdot C_6H_4\cdot NO_2)\cdot NMePh$ $\qquad$ $CPh(:NPh)\cdot NMe\cdot C_6H_4\cdot NO_2$ (VIII.)

atoms are attached to phenyl groups, and the structural effect of the phenyl groups is thus balanced, but the two nitrogen atoms, which are present as anilino- and *p*-nitroanilino-residues respectively, differ considerably in basicity, for aniline has $K = 4{\cdot}6 \times 10^{-10}$ and *p*-nitroaniline $K = 1 \times 10^{-12}$. The results of the methylation thus show that the marked disparity between the yields of the two methyl derivatives, which is always observed when arylamine and alkylamine residues are in competition for a methyl group, has disappeared here on the elimination of the structural effect of a phenyl group attached to only one of the nitrogens, in spite of a considerable difference between the basicities of the two amino-residues. Further, it is noteworthy that the isomeride isolated in rather larger quantity is that in which the methyl group has become attached to the more basic nitrogen atom. This agrees with the results of alkylating open-chain amidines such

as benzenylmethylamidine, $NMe{:}CPh{\cdot}NH_2 \rightleftharpoons NHMe{\cdot}CPh{:}NH$, in which neither of the nitrogen atoms is attached to a phenyl group (Pyman, *loc. cit.*). The constitutions of the two methylated amidines (VII) and (VIII) were determined by synthesising them from the appropriate methylated amines, and in the course of this work various known methods for the preparation of amidines have been compared, and are referred to below.

EXPERIMENTAL.

Benzenyl-*p*-nitrodiphenylamidine was prepared by several of the available methods.

A. After Gerhardt (*Annalen*, 1858, **108**, 214). Benzanilide-iminochloride (53 g.) and *p*-nitroaniline (33 g.) in dry ether (1 l.) were kept for 4 days. The deposit (22 g.; m. p. 165—195°) was dissolved in hot alcohol (300 c.c.) and kept; the crystals (7·5 g.; m. p. 245—250°) which separated were dissolved in hot alcohol (150 c.c), and when the solution was basified with ammonia, the amidine separated (5·5 g.; m. p. 183°; yield 7%).

B. After Sen and Ray (J., 1926, 646). Benzanilide (10 g.), *p*-nitroaniline (7 g.), and phosphorus trichloride (170 g.) were heated under reflux for 4 hours in an oil-bath at 120—130°, and the amidine was isolated in 15% yield (2·38 g.; m. p. 180—182°).

C. After Hill and Rabinowitz (*J. Amer. Chem. Soc.*, 1926, **48**, 732). Benzanilide (10 g.), *p*-nitroaniline (7 g.), phosphorus trichloride (7 g.), and sodium-dried benzene (44 c.c.) were heated for 5 hours at 100°; the amidine was obtained in 8% yield (1·33 g.; m. p. 182°).

D. After Hill and Cox (*ibid.*, p. 3214). This proved to be by far the best method. To a well-cooled suspension of phosphorus pentachloride (11 g.) in sodium-dried benzene (50 c.c.), benzanilide (10 g.) was added, followed by *p*-nitroaniline (7 g.), and the mixture heated under reflux for 3 hours on the water-bath. The solvent was distilled off, the residue was well ground with aqueous ammonia, and the paste filtered. The precipitate was thoroughly extracted by grinding with cold alcohol and water, and the residue was crystallised from alcohol, the amidine being isolated in 61% yield (9·1 g. of m. p. 182—183° + 0·75 g. of m. p. 179—180°). In a repetition of this experiment with 40 g. of benzanilide, the amidine was isolated in 75% yield (48·7 g.; m. p. 182°).

Benzenyl-p-nitrodiphenylamidine (V or VI) crystallises from alcohol in long, lemon-yellow needles, m. p. 184° (corr.) (Found: C, 71·8; H, 5·1. $C_{19}H_{15}O_2N_3$ requires C, 71·9; H, 4·5%). It is insoluble in hot or cold water or in chloroform, but moderately soluble in hot alcohol or ether. On grinding the base with concentrated

hydrochloric acid, a colourless, crystalline *hydrochloride*, m. p. 261°, is obtained, from which the amidine can be regenerated by treatment with ammonia. This hydrochloride is very sparingly soluble in hot water, and when boiled with alcohol containing hydrochloric acid yields *p*-nitrobenzanilide (m. p. crude, 194°; purified, 199°; mixed with a known specimen of m. p. 200°, 200°). In an attempt to prepare a picrate from the amidine and picric acid in hot alcohol, *p*-nitrobenzanilide was again deposited.

Benzenylmethylphenylamido-p-*nitrophenylimidine* (VII).—*p*-Nitrobenzanilide-iminochloride (9 g.), which had been completely freed from hydrogen chloride by keeping in an evacuated desiccator over sodium hydroxide, and monomethylaniline (3·5 g.) in dry ethereal solution were kept over-night, and the solvent distilled. The residue was extracted with hot 2% hydrochloric acid (250 c.c.), which left crude *p*-nitrobenzanilide undissolved (7·2 g.; m. p. 190°; mixed m. p. with a known specimen, 195°). The extract deposited a further 0·26 g. of the same compound on cooling, and the filtrate from this was basified and extracted with ether. The ether residue (3·65 g.) was separated by means of light petroleum into monomethylaniline (1·18 g.; b. p. 193°) and crude amidine (2·3 g.; m. p. 120—128°; yield 19%). It is essential to free the iminochloride from hydrogen chloride before attempting the condensation with monomethylaniline, for otherwise the amidine is not formed. Consequently, it is not surprising to find that this amidine cannot be prepared by the method of Hill and Cox.

Benzenylmethylphenylamido-p-*nitrophenylimidine* crystallises from alcohol in pale yellow plates, which in thin layers have a silvery lustre, m. p. 138° (corr.) (Found: C, 72·5; H, 5·4; N, 12·8. $C_{20}H_{17}O_2N_3$ requires C, 72·5; H, 5·1; N, 12·6%). It is insoluble in hot or cold water, chloroform, or benzene, moderately soluble in cold alcohol, and readily soluble in ether or hot alcohol. The *picrate* separates from alcohol in yellow plates, m. p. 206° (corr.). It is almost insoluble in water or cold alcohol, and explodes when heated in a flame. The *hydrochloride* and *hydriodide* separated from water as gums which could not be crystallised.

Benzenylmethyl-p-*nitrophenylamidophenylimidine* (VIII) could not be isolated from the products of interaction of benzanilideiminochloride (free from hydrogen chloride) with *p*-nitromonomethylaniline in cold or hot dry ether, but was readily prepared by the method of Hill and Cox. Benzanilide (5 g.) was added to a well-cooled suspension of phosphorus pentachloride (5·5 g.) in sodium-dried benzene (25 c.c.). After thorough shaking, *p*-nitromonomethylaniline (3·8 g.) was added, and the mixture heated under reflux for 3 hours on a steam-bath. The solvent was distilled off, and the

residue extracted several times with hot water (1 l. in all), which left very crude benzanilide (0·85 g.; m. p. 140°) undissolved. On being cooled, the extract deposited a yellow product (2·25 g.; m. p. 140—170°) which gave on crystallisation from alcohol the amidine hydrochloride (0·75 g.; m. p. 218—220°), the mother-liquors containing *p*-nitromonomethylaniline. The filtrate from the yellow product was basified with ammonia and extracted with ether, which removed an orange syrup (5·25 g.). This was mixed with concentrated hydrochloric acid and a little alcohol, and filtered from more amidine hydrochloride (3·8 g.; m. p. 216—219°). A further small quantity of this was obtained from the filtrate, and all crops were combined and crystallised from alcohol, 2·78 g. of the pure salt being obtained (yield, 29%).

Benzenylmethyl-*p*-nitrophenylamidophenylimidine was obtained as a pale yellow syrup, which did not crystallise. It is insoluble in cold or hot water or in chloroform, but readily soluble in alcohol or ether. It yields well-crystallised salts. The *hydrochloride* crystallises from alcohol in colourless, rhombic prisms, containing 1EtOH which is not lost at 100°, and melts and effervesces at 226° (corr.) (Found: C, 64·0; H, 5·9. $C_{20}H_{17}O_2N_3,C_2H_6O,HCl$ requires C, 63·9; H, 5·8%). It is sparingly soluble in cold water, moderately soluble in cold alcohol, and very readily soluble in hot alcohol. The *hydriodide* crystallises from alcohol in pale yellow, anhydrous, rhombic prisms, m. p. 225° (corr.) (Found: C, 52·3; H, 4·5. $C_{20}H_{17}O_2N_3,HI$ requires C, 52·3; H, 3·9%). It is very sparingly soluble in cold water, alcohol, or acetone, but readily soluble in hot alcohol or acetone. The *picrate* crystallises from alcohol in yellow needles, m. p. 194° (corr.). It is sparingly soluble in hot water or cold alcohol, but readily soluble in hot alcohol.

*Methylation of Benzenyl-*p*-nitrodiphenylamidine by Methyl Iodide.*—Benzenyl-*p*-nitrodiphenylamidine (35 g.) and methyl iodide (35 c.c.) were heated under pressure for 3 hours at 100°. The partly crystalline product was mixed with acetone, and crude benzenylmethyl-*p*-nitrophenylamidophenylimidine hydriodide (13·8 g.; m. p. 220°) was collected. The filtrate was concentrated, basified with ammonia, and extracted with ether. The ether residue (27·3 g.) was crystallised from alcohol (220 c.c.), which deposited benzenylmethylphenylamido-*p*-nitrophenylimidine (10·2 g.; m. p. 136°) on keeping for 1 hour, whilst the filtrate deposited crude benzenyl-*p*-nitrodiphenylamidine (4·1 g.; m. p. 163°) on keeping over-night. The final mother-liquor was evaporated to a syrup and mixed with concentrated hydrochloric acid (10 c.c.) and a little acetone, whereupon benzenyl-*p*-nitrodiphenylamidine hydrochloride (0·43 g.; m. p. 249°) separated. The filtrate from this was deprived of acetone,

dissolved in dilute hydrochloric acid, and mixed with sodium iodide, crude benzenylmethyl-*p*-nitrophenylamidophenylimidine hydriodide (0·71 g.; m. p. 197°) being then deposited. The filtrate was basified and extracted with ether, which gave a semi-solid residue (10·3 g.). This was crystallised from alcohol and gave crude *p*-nitromonomethylaniline (0·82 g.; m. p. 150°), but no other crystalline material could be isolated from the filtrate. When the various crude products were purified by the methods described earlier in this paper, benzenylmethyl-*p*-nitrophenylamidophenylimidine hydriodide was obtained in 24·9% yield (11·36 g. of m. p. 225° + 0·76 g. of m. p. 224°), benzenylmethylphenylamido-*p*-nitrophenylimidine in 28·8% yield (9·71 g. of m. p. 138° + 0·37 g. of m. p. 137°), and benzenyl-*p*-nitrodiphenylamidine was recovered unchanged in 8·8% yield (2·67 g. of m. p. 181° + 0·41 g. of m. p. 178°).

CCCX.—*Low-temperature Oxidation at Charcoal Surfaces. Part IV. The Active Areas for Different Acids and their Relative Rates of Oxidation.*

By WINIFRED MARY WRIGHT.

IN previous communications (J., 1925, **127**, 1347; 1926, 1813, 3182), it was demonstrated that the surfaces of charcoals containing both iron and nitrogen could be differentiated by the method of selective poisoning into areas of different catalytic activities for the oxidation of oxalic acid. Whilst it was shown that these areas were differentiated in respect of their structure (the Fe–C–N, Fe–C, and C–C areas), of the rates of oxidation, and of the temperature coefficients of the oxidation processes on the areas, the method of estimating the total active carbon area from the amount of amyl alcohol absorbed only gave a maximum value for the fraction of the surface which was active. It is unlikely that the amyl alcohol is adsorbed preferentially only on the most active area if this is already covered with oxalic acid. It is also improbable that one amyl alcohol molecule is attached to but one carbon atom of the underlying surface. Since the active carbon area, even in very active promoted charcoals, greatly exceeds the more active areas

of the promoted iron and iron–nitrogen patches, it was suggested by Dr. E. K. Rideal that it might be possible to determine both the adsorption of the poison and the displacement of the acid effected on this area.

Two specimens of charcoal were employed, Merck's blood- and Kahlbaum's sugar-charcoal; each charcoal was powdered to pass an 80-mesh sieve and heated for 2 hours at a low red heat in silica crucibles before use. The amyl alcohol content of the aqueous oxalic acid–amyl alcohol solutions employed was determined by the drop-weight method, and the oxalic acid content by titration with permanganate as previously described. The results obtained are shown in Table I.

* This was a hard brittle charcoal (unlike the soft charcoal used in Part I of this series).

It is clear from these data that the amyl alcohol is by no means preferentially adsorbed in the presence of oxalic acid, but that the number of mols. of amyl alcohol required to desorb one mol. of oxalic acid depends both on the relative concentrations of the two adsorbents and on the nature of the adsorbate. Since with blood-charcoal, at the concentration (0·025*M*) giving the maximum oxidation velocity, 6 mols. of the alcohol only displace 1 mol. of the acid, the adsorption of the former does not give a trustworthy means of estimating the active area.

A search for a more efficient poison was made. Saturated solutions of diphenyl ether, *tert.*-butyl *p*-aminobenzoate, allyl *p*-aminobenzoate, octadecyl acetate, and hexadecylcarbamide were tried, but none of these reduced the rate of oxidation of oxalic acid by more than 70%. Solutions of dibromoacetic acid, ethylene dibromide, saponin, and sodium palmitate were also used; of these the soap was most efficient, giving 75% poisoning, but owing to its colloidal nature it was unsuitable for estimating the active areas. Ethylene dibromide, though very slightly soluble, gave 50% poisoning. A saturated solution of ethylene dibromide in aqueous ethyl alcohol (4% alcohol) gave 93% poisoning with oxalic acid, but further addition of alcohol gave an increased oxygen-uptake, owing to some secondary effect. A few determinations of displacement of oxalic acid by this substance were made, and from the degree of poisoning the active areas were calculated, but these results are untrustworthy owing to the unknown effect of alcohol on the oxidation velocity.

An attempt was made to poison the charcoal for the oxidation of *M*-formic acid by the addition of salts. Silver nitrate, copper sulphate, and aluminium chloride in *N*/100- and *N*/10-solutions were tried, but none of these gave more than 15% poisoning.

Finally, a saturated solution of caproic acid (0·046*N*) was found to be a fairly effective poison of the charcoal for the acids investigated. Its absorption was determined by the drop-weight method.

The results of poisoning Kahlbaum's sugar-charcoal with caproic acid for the oxidation of four acids are given in Table II. [Contrary to our previous results (Part I, p. 1353), we find that formic acid is readily oxidised in the absence of impurities.]

Caproic acid is clearly a more selective poison than any material hitherto examined. We note that 2 mols. of both aminoacetic acid and formic acid, 1·5 mols. of malonic acid, and 1 mol. of oxalic acid are displaced on the adsorption of 1 mol. of caproic acid, from which we may deduce the relative areas of these molecules on adsorption. These small values are somewhat surprising, if, as is frequently assumed to be the case, caproic acid is adsorbed with its chain parallel or attached to the underlying carbon atoms. It appears that 1 mol. of caproic acid can displace only two carboxyl groups (compare formic, aminoacetic, and oxalic acids). In every case, complete poisoning would be obtained when $3{\cdot}1 \times 10^{-4}$ g.-mol. (mean value of *A*) of caproic acid is adsorbed per g. of charcoal.

The total carbon area active for oxidation is thus identical for all the four acids investigated on this particular charcoal, whilst the rates of oxidation of the various acids at their respective maxima

M = Concentration for maximum rate of oxidation (g.-mol. per litre).
X = Acid adsorbed on unpoisoned charcoal (g.-mol. per g. of charcoal).
k = Reaction velocity on „ „ (c.c. O_2 per g. of C per hr.).
P = % Poisoning.
d = Acid displaced for P % poisoning (g.-mols. per g. of C).
a = Caproic acid adsorbed for P % poisoning (g.-mols. per g. of C).
D = Acid displaced for complete poisoning (g.-mols. per g. of C).
A = Caproic adsorbed „ „ „ („ „ „).

(D and A are calculated on the assumption that the degree of poisoning is proportional to the amount of acid displaced, or of poison adsorbed, although the results show that this is not strictly accurate.)

* These were poisoned with saturated ethylene dibromide in 4% aqueous alcohol. Malonic and aminoacetic acids were not poisoned readily by this substance.

are by no means identical. We may attempt a revaluation of the active area per g. of charcoal from these data. The total specific area of the charcoal, as determined by the saturation point of methylene-blue (see Part I), is 185 sq. m. per g. Since there is some doubt as to whether the methylene-blue method actually gives the total area, owing to the inability of the large molecules of the dyestuff to penetrate into the micropores of the charcoal, the surface saturation point of oxalic acid was determined from the adsorption isotherm.

From Table I, it is noted that 37×10^{-4} g.-mol. is adsorbed per g. from a 0·75M-solution; the adsorption isotherm is inconveniently flat near the maximum, but we may assume the maximum to be at *ca.* 40×10^{-4} g.-mol. per g.

The area of the adsorbed oxalic acid molecule is unknown, but, regarding it as equal to that of two expanded carboxyl groups, we obtain 50 Å. per mol., giving an area of 1212 sq. m. per g., or some seven times greater than that given by the methylene-blue method. The amount of oxalic acid displaced on complete poisoning by caproic acid is $3{\cdot}5 \times 10^{-4}$ g.-mol. per g., or 8·75% of the total

surface is effective; on poisoning with ethylene dibromide, $1{\cdot}4 \times 10^{-4}$ g.-mol. per g. is displaced, or 3·5% of the total surface is effective, when the oxalic acid is employed as a means of evaluating the total area. These values are considerably smaller than those given previously where methylene-blue was employed. They are probably more accurate, in that the amount of poison adsorbed agrees closely with the amount of acid displaced, the poison being very much more preferential in its action than amyl alcohol.

Experiments with Promoted Charcoal.—An active promoted charcoal was prepared from sugar, carbamide, and ferric chloride, and the rates of oxidation of the four acids were determined on specimens of this charcoal. The oxidations due to the presence of the Fe–C–N and Fe–C areas were determined in the manner previously described by poisoning with solutions of potassium thiocyanate and potassium cyanide. The relative rates of oxidation of the four acids on the unpoisoned promoted charcoal are:

Acid.	C.c. of O_2 per g. per hr.	Relative rate.	Relative rate on sugar-charcoal.
Aminoacetic	1·2	1	1
Malonic	0·74	0·6	2
Formic	4·4	3·6	2·5
Oxalic	5·3	4·4	3·4

It will be noted that malonic acid is oxidised relatively slowly on the promoted charcoal. It was found also that there was no appreciable alteration in its rate of oxidation on the addition of either potassium cyanide or potassium thiocyanate, an indication that the promoted areas in the charcoal are not effective in oxidising this acid. The final product of oxidation of malonic acid (see Part I) is glyoxylic acid, and it is probable that hydroxymalonic acid is formed as an intermediate oxidation product. This hydroxy-acid may poison the iron in the presence of oxygen by the formation of a complex similar to that formed by ferrous salts with hydrogen peroxide in Fenton's test for hydroxy-acids. The transient purple of this test can indeed be obtained on application of Fenton's reagents to a solution of malonic acid which has been agitated with charcoal in the air for some hours. The two breaks in the velocity–poisoning curves indicative of the presence of two promoted areas (compare Pt. III) could be obtained with both aminoacetic and formic acids, and show that these acids, like oxalic acid, oxidise at different speeds on the three types of surface (the Fe–C–N, Fe–C, and C–C areas) present in the charcoal.

It was found difficult to obtain accurate values for the effective areas of these promoted areas for formic and aminoacetic acids, since the iron is slowly extracted from the charcoal in the presence

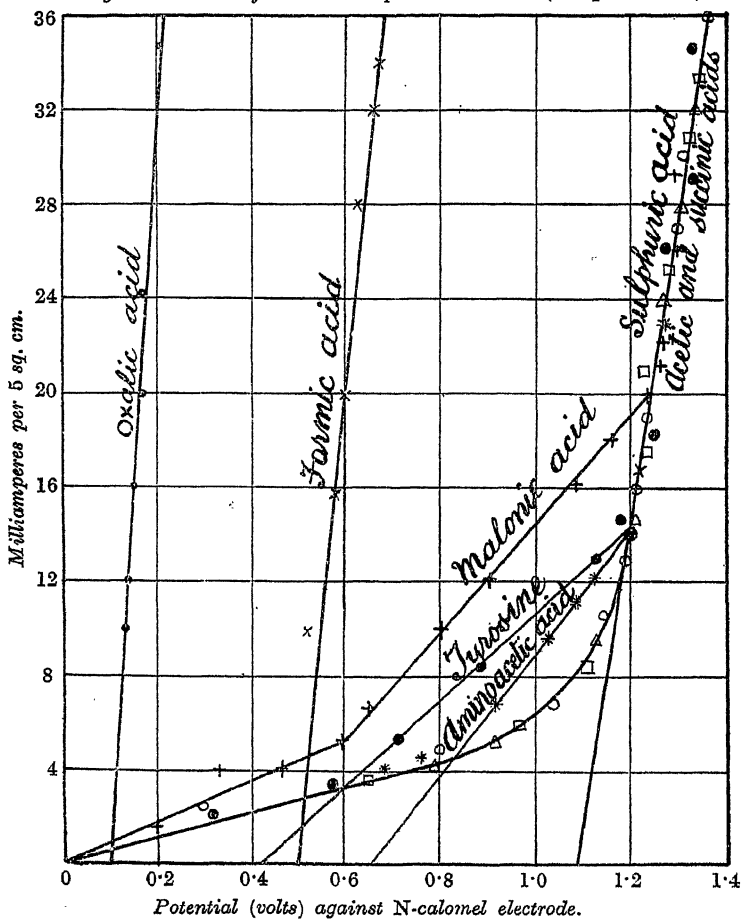
of these acids. The approximate values are given in the following table :

Acid.	Velocity (c.c. of O_2 per g. per hr.) on Fe–C–N area.	Fe–C area.
Aminoacetic	1·08	0·009
Formic	3·90	0·042
Oxalic	4·37	0·049

The relative areas were found to be 9·1 sq. m. per g. for the Fe–C area and 5·5 sq. m. per g. for the Fe–C–N area. It will be noted that the relative rates of oxidation for the acids on the promoted Fe–C–N area are not widely different from those on the sugar-charcoal, and although the experimental error is much greater on account of the small velocities observed, a similar sequence in velocities is noted on the Fe–C area. We may conclude that the active patches on such charcoals are definite in extent and possess the property of oxidising a number of different acids, and that the difference in speed of reaction for different acids is to be attributed to the ease of reaction of the acid with the excited oxygen. This is probably present on the surface of the charcoal in the form of a peroxide which may be desorbed from the surface by excess of acid.

That the ease of oxidation of these fatty acids in aqueous solution follows the same sequence as the reaction velocity of catalytic oxidation at charcoal surfaces was demonstrated by measuring the depolarising capacity of solutions of these acids. These were determined by electrolysis between a small platinum cathode and a large, smooth platinum anode of an $N/5$-solution of sulphuric acid which was also N with respect to the acid under investigation. With the aid of a normal calomel electrode, salt junction, and Wheatstone bridge, the anode potential could be determined for various current densities at 25°. The curves obtained for the various acids are depicted in the figure.

It will be seen that neither acetic nor succinic acid exerts any appreciable depolarising action on the anodic evolution of oxygen, and neither of these acids is oxidised at observable rates with the charcoals hitherto examined by us ; on the other hand, the depolarising powers of oxalic, formic, and aminoacetic acids fall in the order of their rates of oxidation on charcoal surfaces. Tyrosine, a substance readily oxidised at charcoal surfaces, is included for comparison.



Summary.

The oxidation rates and the effects of poisoning with caproic acid on charcoal surfaces have been examined for formic, oxalic, malonic, and aminoacetic acids. It is found that the amounts

of poison absorbed required to inhibit the oxidation of these acids are identical. The effective catalytic area is found by this method to be about 4—8% of the total surface. With the exception of

FIG. 1.

malonic acid, all these acids oxidise more rapidly on the promoted Fe–C–N and Fe–C areas than on pure charcoal. The poisoning of the promoted charcoal in the case of malonic acid is attributed to the hydroxy-acid formed as an intermediate oxidation product.

The velocities of oxidation at their respective maximum rates are shown to follow the order of depolarisation for oxygen liberated at a platinum electrode.

CAMBRIDGE. [*Received, May 3rd,* 1927.]

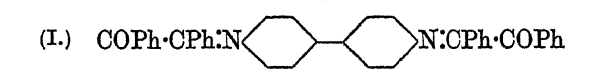
CCCXI.—*Orientation Effects in the Diphenyl Series. Part IV. The Reduction of Bandrowski's and of Strakosch's Dinitrobenzidines, and the Condensation of the Products with Benzil. The Nitration of 2-Nitrodiacetylbenzidine and of 4:4′-Dibromodiphenyl.*

By RAYMOND JAMES WOOD LE FÈVRE, DANIEL DONALD MOIR, and EUSTACE EBENEZER TURNER.

IT was recently shown (Le Fèvre and Turner, J., 1926, 1759) that Cain's supposed 3:3′-dinitrobenzidine (Bandrowski's dinitrobenzidine) was the 2:3′-derivative, but, as was then fully realised, one difficulty still remained in connexion with the supposed identity of the two quinoxalines obtained by Cain and later by Brady and McHugh (J., 1923, **123**, 2047) by condensation with benzil of the tetra-amines derived from Bandrowski's and Strakosch's dinitrobenzidines. In view of the difficulty of purifying Bandrowski's compound (compare Le Fèvre and Turner, *loc. cit.*), an obvious explanation of the above facts was that the quinoxaline obtained from the Bandrowski material actually was derived from the Strakosch product, present as an impurity in the specimens of Bandrowski's dinitrobenzidine used for reduction.

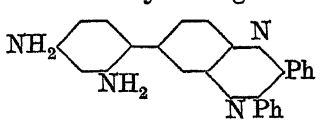
We hesitated to advance this as a solution of the problem in the light of the conclusions of Brady and McHugh, but, in view of the fact that the Bandrowski's dinitrobenzidine prepared by Le Fèvre and Turner (*loc. cit.*) had m. p. 236—237°, *i.e.*, higher than that given by previous workers, we have carefully re-investigated the compounds concerned. We find that, in spite of the difficulties mentioned above, Bandrowski's dinitrobenzidine, *melting at* 233°, does, on reduction, followed by treatment with benzil in glacial acetic acid, give, as the most readily isolable product, a quinoxaline which is undoubtedly identical with that derived normally from 3:3′:4:4′-tetra-aminodiphenyl, and that therefore the initial Bandrowski's dinitrobenzidine must have contained some 3:3′-dinitrobenzidine.

There is a very marked difference in the behaviour of the two



tetra-amines when treated with benzil. With that derived from Strakosch's dinitrobenzidine, a copious precipitate is obtained, but with that derived from Bandrowski's dinitrobenzidine (m. p. 233°, or a little lower), only a *small quantity* of precipitate results. The smallness of the yield was not mentioned by previous authors, and the foregoing explanation was therefore not suspected. The amount of Strakosch's dinitrobenzidine necessary to depress the m. p. of pure Bandrowski's dinitrobenzidine from 236—237° to 233° has been estimated, by examining artificial mixtures, as 2—3%. Such a proportion is in approximate agreement with the yields of quinoxaline obtained from various samples (see Experimental).

During the progress of this work, Hodgson (J., 1926, 2384) showed that some 3 : 3′-dinitrobenzidine was *formed* during the nitration of diphthalylbenzidine, but he did not attempt to demonstrate the presence of the 3 : 3′-isomeride in what has always been called Bandrowski's dinitrobenzidine, *i.e.*, a compound melting in the neighbourhood of 233°.

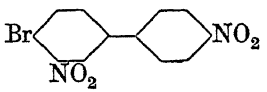


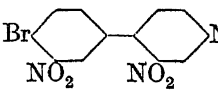
Methods previously described (Brunner and Witt, *Ber.*, 1887, **20**, 1024; Brady and McHugh, *loc. cit.*) for the reduction of Bandrowski's dinitrobenzidine proved unsatisfactory, but it was readily effected by iron powder, water, and ferric chloride.

Brady and McHugh showed that the two tetra-amines behaved very differently towards nitrous acid. A marked contrast was also observed when each was warmed in dilute acetic acid solution with acetic anhydride. In one case (2 : 3′ : 4 : 4′), bunches of white needles slowly separated from a purple solution, whilst in the other case there was immediate formation of an iridescent cream-coloured paste of minute needles. The compounds formed were the expected *tetra-acetyl* derivatives.

It was shown (Le Fèvre and Turner, J., 1926, 2476) that Cain's benzidine–benzil condensation product was dibenzoylbenzylidenebenzidine (I). 2 : 3′ : 4 : 4′-Tetra-aminodiphenyl (Bandrowski's tetra-amine) would therefore be expected to condense rapidly with

(I.) 

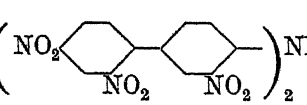


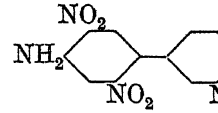


benzil in cold glacial acetic acid solution to give (II), which should condense further with benzil only at higher temperatures. We

(II.) 

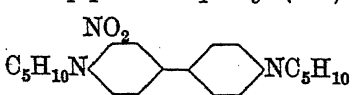
find that (II) is soluble in cold acetic acid, and that on heating the solution in which it is formed it undergoes further condensation



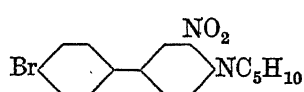


with production of what is evidently a mixture of the two benzoylbenzylidene derivatives and the dibenzoylbenzylidene derivative corresponding with (I).

Although we have improved upon the usual process for obtaining Bandrowski's dinitrobenzidine, we attempted to prepare the corresponding tetra-amine without recourse to the parent dinitrobenzidine. 4-Bromo-4′-nitrodiphenyl was nitrated to give 4-*bromo*-3 : 4′-*dinitrodiphenyl* (III) which on further nitration gave 4-bromo-2′ : 3 : 4′-trinitrodiphenyl (IV) (Le Fèvre and Turner, J., 1926, 2041). Small quantities of the latter compound were readily convertible into 2′ : 3 : 4′-*trinitro*-4-*aminodiphenyl*, but the large-scale conversion proved unsatisfactory. The reduction of the trinitroamine was accordingly not fully investigated.



(III.)   (IV.)



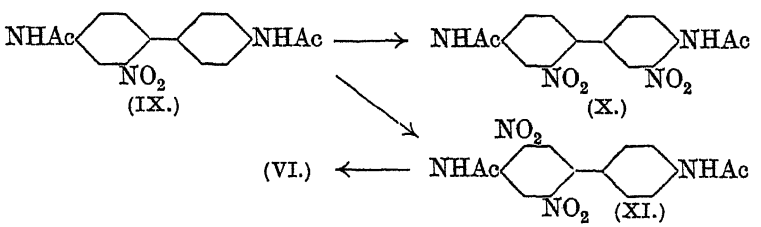
When (IV) was dissolved in boiling nitrobenzene, and dry ammonia was passed through, a bright yellow substance was obtained, apparently 4 : 4′-*bis*-op-*dinitrophenyl*-2 : 2′-*dinitrodiphenylamine* (V). The results of similarly treating other compounds containing reactive halogen atoms are recorded in the experimental part.

When attempting to prepare 2 : 3′-dinitrobenzidine from 2-nitrodiacetylbenzidine (Le Fèvre and Turner, *loc. cit.*), we observed that an impure product occasionally results, apparently owing to overnitration. We have now obtained from such products, by application of the method used for preparing Bandrowski's dinitrobenzidine from diphthalylbenzidine, the sparingly soluble *sulphate* of 2 : 5 : 3′-*trinitrobenzidine* (VI), the constitution of which is proved

(V.)   (VI.)

by its conversion by the perbromide method into 4 : 4′-*dibromo*-2 : 5 : 3′-*trinitrodiphenyl*, this in turn being identified by its ready conversion into a *di*piperidino-compound, *viz.*, 2 : 5 : 3′-*trinitro*-4 : 4′-*dipiperidinodiphenyl* (VII).

(VII.)

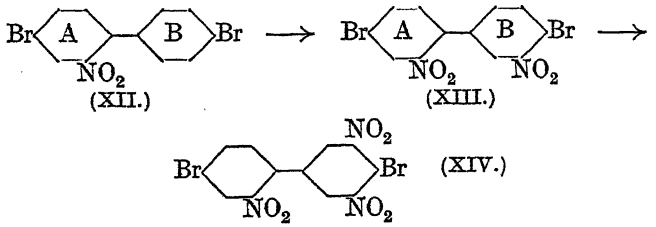


(VIII.)

Lellmann (*Ber.*, 1882, **15**, 2838) had previously isolated by overnitration of dibromodiphenyl a trinitro-derivative, having a m. p.

some 70° lower than that of the above compound. Lellmann's compound is, however, the isomeric 4 : 4′-*dibromo*-2 : 3′ : 5′-*trinitrodiphenyl* (XIV), since 4-*bromo*-2 : 3′ : 5′-*trinitro*-4′-*piperidinodiphenyl* (VIII) is formed from it with great readiness.

Comparison of the results now obtained with those previously recorded (this series) appears to show that, amongst the examples studied, the *op*- directive influence of groups decreases in the order NHAc > *p*-NHAc·C_6H_4 > *p*-Br·C_6H_4 > Br, the first being very powerful. In the light of this, it is possible to discuss the complete nitration of 2-nitrodiacetylbenzidine (IX) and of 4 : 4′-dibromo-2-nitrodiphenyl.



The former is now known to give as the main product 2 : 3′-dinitrodiacetylbenzidine (X), but since it has been shown (Bell and Kenyon, J., 1926, 2705) that 4-acetamidodiphenyl nitrates in position 3, *i.e.*, in the nucleus containing the acetamido-group, it would not be surprising, particularly in view of the now established powerful directive effect of this group, if some of the isomeric 2 : 5-compound (XI) were also formed. Further nitration of a

mixture of (X) and (XI) would only be expected to affect (XI). We have actually found that (X) is unaffected by fuming nitric acid at 25°, *i.e.*, under conditions more drastic than those under which the trinitro-compound (VI) was originally formed. The nitration of 2-nitrodiacetylbenzidine, therefore, in all probability proceeds in accordance with the scheme outlined above.

The nitration of 4 : 4′-dibromo-2-nitrodiphenyl has previously been shown (Dennett and Turner, J., 1926, 476) to be controlled entirely by the bromine atom in the ring B (XII), since nucleus A is rendered ineffective owing to the presence of the nitro-group : 4 : 4′-dibromo-2 : 3′-dinitrodiphenyl is therefore quantitatively produced. In the further nitration of this compound, each nucleus will be as ineffective upon the other as was A in (XII); that is, entry of the third nitro-group will be controlled only by the nitro-group and bromine atom present in the nucleus attacked. In nucleus B (XIII) these groups will both favour nitration in position 5, whilst in A (XIII) they have antagonistic influences. Nitration

therefore occurs in B, with formation of the above 4 : 4′-dibromo-2 : 3′ : 5′-trinitrodiphenyl (XIV).

EXPERIMENTAL.

Preparation of 2 : 3′-Dinitrobenzidine.—The following modification of the usual process is more satisfactory, particularly as regards yield: Powdered diphthalylbenzidine (270 g.) was slowly dissolved in 1800 c.c. of fuming nitric acid (*d* 1·5), the temperature not being allowed to rise above 10°. After 15 minutes, the mixture was poured on 5 kg. of crushed ice, the resulting light yellow precipitate being washed first with boiling water and then with hot methylated spirit (yield, 350 g.).

For hydrolysis, 270 g. of the above product, previously dried at 100°, were dissolved in 1200 c.c. of concentrated sulphuric acid, and the solution was heated at 135—140° for 20 minutes. After being cooled, the acid solution was poured into 5 l. of water, the temperature not being controlled. The precipitate first formed redissolved as the temperature rose, and the nearly clear solution, after filtration, deposited long, yellow-brown needles when cooled. These were collected and crystallised from dilute sulphuric acid (1 : 4 by vol.). The crystals so obtained were ground with aqueous ammonia, and the red base (m. p. 225°) was filtered off. One crystallisation from phenol–alcohol gave a definitely crystalline specimen, m. p. 233°. Two further crystallisations raised the m. p. to 234—235°, and to 236—237° (uncorr.), respectively, the final product being pure 2 : 3′-dinitrobenzidine.

Melting Points of Mixtures of 2 : 3′- and 3 : 3′-Dinitrobenzidines.—The specimens of the two bases used had m. p. 243—244° and 281—282° (corr.) respectively. A mixture containing 90% of 2 : 3′-base and 10% of 3 : 3′-base shrank at about 224°, showed definite signs of melting at 233°, and ran to a liquid at 237°; one containing 94·8% of 2 : 3′- and 5·2% of 3 : 3′ base reached the same three stages respectively at 226°, 236°, and 238·6°; and the 97·6–2·4% mixture at 238°, 239·9°, and 241·4°. The above figures were obtained by the use of a completely immersed, short-stem standard thermometer. The corresponding uncorrected figures,

taken simultaneously with an ordinary thermometer, were: 218°, 227°, 231°; 220—221°, 229°, 232°; and 232°, 233°, 235°, respectively.

Reduction of Bandrowski's Dinitrobenzidine.—Preliminary experiments showed (1) that the tetra-amine is readily soluble in water, and (2) that the solution rapidly oxidises in the air. The following procedure was therefore adopted: 100 G. of iron powder were thoroughly wetted with 100 c.c. of water at 100°; 10 g. of 2 : 3′-dinitrobenzidine were then added, and the whole was well mixed. On the addition of a little ferric chloride, reduction proceeded vigorously, and was completed by ½ hour's heating with continuous stirring. Water was added, and the tetra-amine obtained in clear aqueous solution by filtration. Evaporation of this in a current of carbon dioxide (*a*) gave 2 : 3′ : 4 : 4′-tetra-aminodiphenyl as a purplish solid.

Reduction of Strakosch's Dinitrobenzidine.—10 G. of the dinitrobenzidine were shaken in a litre flask with 150 c.c. of methylated spirit until in fine suspension. 200 C.c. of water were added, followed by 70 g. of sodium hyposulphite, and the mixture was heated on the boiling water-bath for an hour. During this time, the colour changed from red to pale grey, and the suspended solid almost completely dissolved. The alcohol was then distilled off, the residue extracted with a mixture of water (150 c.c.) and concentrated hydrochloric acid (150 c.c.), the extract filtered, and the filtrate evaporated to about 2/3 of its original bulk. On cooling, pale brown needles of 3 : 3′ : 4 : 4′-tetra-aminodiphenyl hydrochloride separated. These, after being crystallised from dilute hydrochloric acid, were ground with aqueous ammonia; the liberated base crystallised from a mixture of phenol and alcohol in greyish plates, m. p. about 172—173° (Found: N, 26·5, 26·3. Calc.: N, 26·2%).

Condensation of 2 : 3′ : 4 : 4′*-Tetra-aminodiphenyl with Benzil.*—(a) *In the cold.* The flask in which the evaporation and extraction (*a* above) had been effected was tared, after its contents had been dried, and the soluble material was extracted four times with 10 c.c. of warm glacial acetic acid. Filtration from a considerable quantity of dark-coloured insoluble material enabled the amount of tetra-amine in solution to be calculated (generally of the order of 2 g.). A solution of the required quantity of benzil in cold glacial acetic acid was added to the cooled filtrate. After some minutes, crystallisation could be induced by scratching, but even after 12 hours the amount of greenish-yellow precipitate was quite small. Reduction of 10 g. lots of specimens of Bandrowski's dinitrobenzidine, melting at 225—226°, 233°, and 237° (uncorr.), gave 1·9, 1·1, and 0·0 g. of "quinoxaline" respectively. The crystals appeared as radiating bunches of needles when examined under

the microscope, and melted in the crude state at 292—300°. The product crystallised readily from salicylaldehyde (originally used as a reagent to detect a free amino-group) in long, thin, straw-coloured plates, m. p. 308—309° (uncorr.). Admixture with an authentic specimen of Strakosch's quinoxaline did not depress this m.p. (Cain, Coulthard, and Micklethwait, *loc. cit.*; Brady and McHugh, *loc. cit.*) (Found: N, 10·7. Calc.: 10·0%). The mother-liquors from this crystallisation were dark coloured, indicating that the salicylaldehyde had reacted with the green impurities in the crude quinoxaline (see below).

(b) *At* 100°. In earlier experiments, condensation was attempted using excess of benzil in glacial acetic acid at 100°. In most cases, no precipitation occurred, even on scratching. Dilution with water produced a gummy deposit, from which dilute alcohol extracted a yellowish-green powder, soluble in glacial acetic acid, xylene, benzene, chloroform, and acetone, but obviously a mixture with a m. p. range of about 30°.

A very marked reaction occurred when the product was heated with salicylaldehyde, water being eliminated.

Condensation of 3 : 3′ : 4 : 4′-*Tetra-aminodiphenyl with Benzil.*—To 1 g. of tetra-amine dissolved in 15 c.c. of glacial acetic acid was added a solution of 2 g. of benzil in 5 c.c. of the same solvent. A precipitate was formed suddenly, and this, when viewed under the microscope, appeared as stout needles. Alcohol was added, the solid filtered, re-heated with alcohol, and then dried at 100°. The cream-coloured powder (m. p. crude, 303—306°) separated from salicylaldehyde in straw-coloured plates, m. p. 308° (Found: N, 10·7%). It was very sparingly soluble in glacial acetic acid and acetone, more soluble in benzene, readily soluble in chloroform, and crystallised well from xylene in parallelograms, m. p. 308° (uncorr.), 313° (corr.).

Colour Reactions with Concentrated Sulphuric Acid.—The benzil condensation products derived both from Bandrowski's and from Strakosch's tetra-amines gave nearly identical purplish-red colorations with concentrated sulphuric acid. The colour is clearly due to the quinoxaline structure, and not to the possible presence of benzoylbenzylidene groupings, since αβ-diphenylquinoxaline gave a reddish-orange colour, whilst dibenzoylbenzylidenebenzidine merely dissolved to a normal yellow solution, which after a few minutes set to a white mass of benzidine sulphate. The other colours disappear on the addition of water or on exposure to the air (compare Brunner and Witt, *loc. cit.*).

Preparation of 4-*Bromo*-2′ : 3 : 4′-*trinitrodiphenyl.*—The following method proved more satisfactory than that used in Part III of this

series, as it avoided numerous wasteful crystallisations : An intimate mixture of 100 g. of 4-bromo-4′-nitrodiphenyl and 52 g. of potassium nitrate was slowly added to 300 c.c. of concentrated sulphuric acid at 70—80°. The resulting solution was heated at 90° for ½ hour, then cooled and poured into water. Crystallisation of the resulting precipitate from glacial acetic acid gave 4-*bromo*-3 : 4′-*dinitrodiphenyl* as dull white needles, m. p. 135° (Found : Br, 24·8. $C_{12}H_7O_4N_2Br$ requires Br, 24·8%). A mixture of 8 g. of the latter with 4 g. of potassium nitrate was nitrated in 60 c.c. of concentrated sulphuric acid under the above conditions. The product melted at 176° after one crystallisation from glacial acetic acid.

2′ : 3 : 4′-*Trinitro*-4-*aminodiphenyl*.—4-Bromo-2′ : 3 : 4′-trinitrodiphenyl (3 g.) was heated with saturated alcoholic ammonia (15 c.c.) in a sealed tube at 150° for 8—10 hours. The product was filtered off, dried, and crystallised from glacial acetic acid. It formed yellowish-orange needles, m. p. 192—193° (Found : N, 18·7. $C_{12}H_8O_6N_4$ requires N, 18·4%). This procedure proving very tedious, the following modification was attempted : 20 G. of 4-bromo-2′ : 3 : 4′-trinitrodiphenyl were dissolved in 200 c.c. of boiling nitrobenzene, and a current of dry ammonia was passed through the solution for 2 hours. A yellow solid soon began to separate, and, after cooling, it was collected, washed with benzene, dried, and crystallised from phenol–alcohol, forming bright yellow needles, m. p. 256—257° (Found : N, 17·0. $C_{24}H_{13}O_{12}N_2$ requires N, 16·6%). The analysis and the fact that the substance separates unchanged after being heated with salicylaldehyde prove it to be 4 : 4′-*bis*-op-*dinitrophenyl*-2 : 2′-*dinitrodiphenylamine* (V). Its low solubility in solvents prevented a determination of its molecular weight.

Action of Ammonia upon Boiling Nitrobenzene Solutions of other Halogeno-nitro-compounds.—(*a*) Picryl chloride (10 g.) was dissolved in boiling nitrobenzene (50 c.c.), and ammonia passed in for 2 hours, although solid had begun to separate very soon. The mixture was cooled and the resulting solid was crystallised from glacial acetic acid and identified as trinitroaniline, m. p. 187—188°.

(*b*) 1-Chloro-2 : 4-dinitrobenzene (20 g.), treated similarly (50 c.c. of nitrobenzene), also gave a precipitate, which separated from glacial acetic acid, and had m. p. 180—182°. It was thus 2 : 4-dinitroaniline.

(*c*) 2 : 5-Dichloronitrobenzene (10 g.) dissolved in 25 c.c. of boiling nitrobenzene was apparently unaffected by ammonia.

(*d*) 4 : 4′-Dibromo-2 : 3′-dinitrodiphenyl was partially converted into the corresponding bromo-amino-compound under the above conditions.

Isolation of 2 : 5 : 3′-*Trinitrobenzidine.*—The crude hydrolysis product resulting from a nitration of 70 g. of 2-nitrodiacetylbenzidine was boiled with dilute sulphuric acid, the extract filtered, allowed to crystallise, and the resulting *sulphate* again crystallised from dilute sulphuric acid. It was ground with aqueous ammonia, and the liberated base crystallised three times from phenol–alcohol, dark red needles, m. p. 276°, being obtained (Found : N, 21·6. $C_{12}H_9O_6N_5$ requires N, 21·9%).

The *diacetyl* derivative was a yellow substance, m. p. above 300°.

4 : 4′-*Dibromo*-2 : 5 : 3′-*trinitrodiphenyl.*—A solution of trinitrobenzidine (3·2 g.) in 20 c.c. of concentrated sulphuric acid was diazotised in the usual manner by 1·4 g. of solid sodium nitrite. The solution was diluted by the addition of 100 g. of ice, and filtered; 3 c.c. of bromine dissolved in 12 c.c. of hydrobromic acid were added, and the oily *perbromide* which separated solidified after 15 minutes, and was filtered off. Decomposition by heating with 40 c.c. of glacial acetic acid proceeded smoothly, and gave rise to a cream-coloured, crystalline precipitate of 4 : 4′-*dibromo*-2 : 5 : 3′-*trinitrodiphenyl*, which separated from about 250 c.c. of glacial acetic acid in wads of needles, m. p. 251—252°. The substance reacted readily with piperidine to give the 4 : 4′-*dipiperidino*-compound, which crystallised from rectified spirit in matted needles, m. p. 160° (Found : N, 15·8. $C_{22}H_{25}O_6N_5$ requires N, 15·4%).

Nitration of 4 : 4′-*Dibromo*-2 : 3′-*dinitrodiphenyl.*—When a solution of this compound in nitric acid (*d* 1·5) was allowed to stand, according to Lellmann's instructions, it remained unaffected. 3 G. of the dinitro-compound in 30 c.c. of a mixture (1 : 5 by vol.) of concentrated sulphuric acid and nitric acid (*d* 1·5) were left for 20 hours. Water was then added, and the precipitate extracted with a large bulk of alcohol. The residue crystallised from toluene in colourless needles, m. p. 176—177°, and reacted very vigorously with piperidine, even in the cold, to give the orange-coloured 4-*bromo*-2 : 3′ : 5′-*trinitro*-4′-*piperidinodiphenyl*, which, after being crystallised from much glacial acetic acid, melted at 194° (Found : N, 12·5. $C_{17}H_{15}O_6N_4Br$ requires N, 12·4%).

3 : 4′-*Dinitro*-4-*anilinodiphenyl.*—This substance was obtained by heating 4-bromo-3 : 4′-dinitrodiphenyl with excess of aniline at the b. p. of the latter for 5 minutes. It separated from glacial acetic acid in orange leaflets, m. p. 155—156°.

3 : 2′ : 4′-*Trinitro*-4-*anilino- and* -4-*methylanilino-diphenyl.*—These were readily obtained by heating 4-bromo-3 : 2′ : 4′-trinitrodiphenyl with excess of aniline and methylaniline respectively. The *anilino*-derivative crystallises from glacial acetic acid in orange-red leaflets,

m. p. 190—191°, and the *methylanilino*-derivative from the same solvent in deep red leaflets, m. p. 212°.

Part of the expenses of this investigation were met by grants allocated to two of us by the Chemical Society, and one of us (R. J. W. Le F.) is indebted to the Advisory Committee of the Department of Scientific and Industrial Research for a maintenance grant.

EAST LONDON COLLEGE,
UNIVERSITY OF LONDON. [*Received, July 25th,* 1927.]

CCCXII.—*The Preparation of* 2 : 5-*Dihydroxybenzaldehyde* (*Gentisaldehyde*).

By HERBERT HENRY HODGSON and HERBERT GREENSMITH BEARD.

NEUBAUER and FLATOW (*Z. physiol. Chem.*, 1907, **52**, 375) prepared 2 : 5-dihydroxybenzaldehyde by the oxidation of salicylaldehyde, but the present method with *m*-hydroxybenzaldehyde as initial material gives an improved yield of a less crude product.

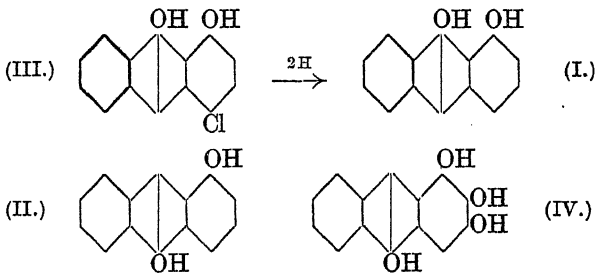
A solution of *m*-hydroxybenzaldehyde (61 g.) and sodium hydroxide (25 g.) in water (400 c.c.), while being vigorously stirred and kept at 30—35°, is treated simultaneously from separate dropping-funnels with aqueous solutions of potassium persulphate (150 g. in 1500 c.c.) and sodium hydroxide (200 c.c.; 40%), the additions being made during 90 minutes at such rates that the mixture is always alkaline. After 36 hours' standing, the deep brown solution is rendered faintly acidic (Congo paper) with concentrated hydrochloric acid, and unchanged *m*-hydroxybenzaldehyde (31 g.) is extracted by ether. The solution is then strongly acidified (350 c.c. of concentrated hydrochloric acid) and heated slowly to 70°, the dark brown, amorphous precipitate (5 g.), which forms gradually, being filtered off. (This substance, which chars above 330°, is almost insoluble in all organic solvents except boiling glacial acetic acid, but readily soluble in aqueous sodium carbonate; it contains the aldehyde group, as shown by formation of a p-*nitrophenylhydrazone* which gives the characteristic magenta colour with alkalis, and invariably constitutes about 40% of the yield.) The 2 : 5-dihydroxybenzaldehyde is extracted from the filtrate by ether, the ether is removed by evaporation, and the residue extracted by benzene; yield 13 g. (m. p. 89—92°). The substance crystallises from benzene in bright yellow needles, containing solvent of crystallisation, which rapidly effloresce at the ordinary temperature, leaving yellow needles, m. p. 98—99° (Tiemann and Müller, *Ber.*,

1881, **14**, 1986, give m. p. 99°). The aqueous solution gives a green colour with ferric chloride and red with sodium hydroxide. Identity was established with 2 : 5-dihydroxybenzaldehyde prepared by Neubauer and Flatow's method (*loc. cit.*), in which the corresponding yield of crude product was 12 g. (m. p. 83—90°). Substitution of ammonium for potassium persulphate, reduction in time of keeping, and oxidation at higher temperatures all produced lower yields.

2 : 5-Dihydroxybenzaldehyde could not be obtained from 2-nitro-5-hydroxybenzaldehyde by reduction, diazotisation, and any variation of decomposition procedure, although Sandmeyer treatment of the diazo-solution afforded 30% yields of 2-chloro- or 2-bromo-5-hydroxybenzaldehyde.

Derivatives. The p-*nitrophenylhydrazone* crystallises from glacial acetic acid in brick-red needles, m. p. 256—257° (decomp.) (Found : N, 15·6. $C_{13}H_{11}O_4N_3$ requires N, 15·4%). The *dibenzoate* separates from alcohol in slender, colourless needles, m. p. 106—107° (Found : C, 72·5; H, 4·1. $C_{21}H_{14}O_5$ requires C, 72·8; H, 4·0%), and is readily hydrolysed by cold 20% aqueous sodium hydroxide. The p-*nitrophenylhydrazone* of the dibenzoate crystallises from glacial acetic acid in fine, orange needles, m. p. 272° (Found : N, 9·0. $C_{27}H_{19}O_6N_3$ requires N, 8·7%).

Methylation in 10% aqueous sodium hydroxide solution with methyl sulphate (2 mols.) gives the dimethyl ether, which crystallises from dilute alcohol in colourless needles, m. p. 51° (Tiemann and Müller, *loc. cit.*, give m. p. 51°), and forms a p-*nitrophenylhydrazone*, red needles, m. p. 216° (Found : N, 14·7. $C_{14}H_{14}O_4N_3$ requires N, 14·6%), from glacial acetic acid. In this methylation a monomethyl ether may be isolated, after extraction of the dimethyl ether, by acidification and steam-distillation; it passes over and remains as a colourless oil with a vanillin-like odour, and gives a blue-black colour with ferric chloride and a bright yellow solution with aqueous sodium hydroxide, both tests being characteristic of 5-methoxysalicylaldehyde (Tiemann and Müller, *loc. cit.*); the p-*nitrophenylhydrazone* crystallises from glacial acetic acid in bright orange needles, m. p. 206° (Found : N, 15·4. $C_{13}H_{12}O_4N_3$ requires N, 15·3%).



The authors thank the Department of Scientific and Industrial Research for a grant to one of them (H. G. B.), and the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD. [*Received, August 6th*, 1927.]

CCCXIII.—*The Determination of the Structure of α-Hydroxyanthranols.*

By ALBERT GREEN.

THE reduction of an α-hydroxyanthraquinone to the corresponding anthranol may occur in two ways: *e.g.*, 1-hydroxyanthraquinone may give 1 : 9-dihydroxyanthracene (I), 1 : 10-dihydroxyanthracene (II), or a mixture of these two.

By the reduction of alizarin 2-methyl ether, Miller and Perkin (J., 1925, **127**, 2684) obtained a mixture of the two possible isomeric anthranols, and were able to assign structures to them by observing the differences in the resistance of the derived benzanthrones to methylation. The use of the benzanthrone condensation in the determination of the structures of reactive substances such as the anthranols has disadvantages: purification of the products is tedious, and the yields are very small. Miller and Perkin (*loc. cit.*) themselves suggest that the poor yields are a result of the anthranols suffering alteration during heating with sulphuric acid for 1 hour at 125—130°. However, in a later paper (Cross and Perkin, this vol., p. 1297) improved methods of effecting the benzanthrone condensation are described.

The present method for deciding whether an anthranol is of type (I) or of type (II) depends on its reaction with thionyl chloride, which takes place at the ordinary temperature. It has been shown (J., 1924, **125**, 1450; 1926, 2198; this vol., pp. 500, 554) that two *ortho*-hydroxyl groups of a phenol always react with thionyl chloride to give a thionyl derivative, but that a similar compound is not given by *meta*- or *para*-dihydric phenols (J., 1926, 1428; this vol., p. 500). In view of the well-established resemblance between reactions shown by certain substituents in the *peri*-position (I) and those of the same groups in the *ortho*-position, it was anticipated that a compound of type (I) would yield a thionyl derivative, whereas one of type (II) would not.

These anticipations were verified by examining, in the first place,

the action of thionyl chloride on two substances of known structure, 1 : 8- and 1 : 5-dihydroxynaphthalene. When the former, in carbon disulphide–pyridine solution, is treated with the theoretical quantity of thionyl chloride it gives 1 : 8-*thionyldihydroxynaphthalene* in quantitative yield. The isomeric 1 : 5-dihydroxy-compound, on the contrary, does not give a thionyl derivative: all the methods of preparation previously described (*loc. cit.*) were used, and in every case the products were complex mixtures which always contained chlorine.

The method was then applied to three anthranols. Two of these, 1-hydroxyanthranol and 4-*chloro*-1-*hydroxyanthranol*, yield thionyl derivatives, and are therefore 1 : 9-dihydroxyanthracene (I) and 4-*chloro*-1 : 9-*dihydroxyanthracene* (III) respectively. In preparing the latter by reduction of 4-chloro-1-hydroxyanthraquinone, it was necessary to avoid over-reduction, which readily led to the replacement of the chlorine atom by hydrogen, with production of 1 : 9-dihydroxyanthracene (I).

The products of four experiments with anthragallol anthranol and thionyl chloride were all complex chlorine-containing mixtures, thus indicating that this anthranol is not 1 : 2 : 3 : 9-tetrahydroxyanthracene—for this would be expected to give a chlorine-free dithionyl derivative, since anthragallol itself yields 2 : 3-thionylanthragallol (J., 1926, 2202)—but is 1 : 2 : 3 : 10-tetrahydroxyanthracene (IV). This conclusion, which is based on negative evidence only, is contrary to that reached by Cross and Perkin (*loc. cit.*).

The anthranols used in this investigation were prepared from the corresponding anthraquinones by the method of Liebermann and Mamlock (*Ber.*, 1905, **38**, 1795), with tin and hydrochloric acid in acetic acid solution as reducing agent. This method was preferred to the more economical one of Breare and Perkin (J., 1923, **123**, 2606), who used a hydrochloric acid solution of stannous chloride, because the products were more easily purified.

The compounds described herein differ from the thionyl derivatives examined previously (*loc. cit.*) in that the thionyl group forms part of a six-atom ring, and is less reactive than one forming part of a heterocyclic structure of five atoms.

EXPERIMENTAL.

Preparation of Materials.—1 : 8-*Dihydroxynaphthalene.* A commercial specimen labelled "pure" contained more than 70% of impurities. The naphthol was eventually obtained pure by two methods: (I) A hot solution of the mixture in acetic anhydride and pyridine, on cooling, deposited practically pure 1 : 8-diacetoxy-

naphthalene. After one recrystallisation from acetic anhydride, this formed small, white plates of constant m. p. 155° (Erdmann, *Annalen*, 1888, 247, 359, gives 147—148°) (Found: $CH_3 \cdot CO$, 35·7. Calc.: 35·3%). The acetyl derivative was hydrolysed by the rapid addition of hydrochloric acid to its solution in hot acetic acid. After removal of some tarry matter by filtration through asbestos, a warm saturated solution of sulphur dioxide was added, and 1 : 8-dihydroxynaphthalene separated as hair-like, white needles, m. p. 144° (Found: C, 74·8; H, 5·1. Calc.: C, 75·0; H, 5·0%). (II) The impurities were very sparingly soluble in cold acetic acid, and were removed by fractional crystallisation. The acetic acid solutions, when diluted with water, yielded the naphthol as small, greyish-white crystals, which, after drying over sulphuric acid, melted at 142—143° (Found: C, 74·8; H, 5·2%). 1 : 8-Dihydroxynaphthalene dissolves in concentrated sulphuric acid with a greenish-gold colour, and its colourless solution in alcohol becomes dark green on the addition of ferric chloride.

The anthraquinones, which were converted into the anthranols, were obtained by the hydrolysis of the purified acetyl derivatives (compare J., 1926, 1431, 2199).

1 : 9-*Dihydroxyanthracene* (1-*Hydroxyanthranol*). This was obtained, by treating the hot acetic acid solution of the diacetate with hydrochloric acid, as faintly yellow, square plates, m. p. 142° (Found: C, 79·9; H, 4·9. Calc.: C, 80·0; H, 4·8%). The diacetate separated from a mixture of acetic anhydride and pyridine in short, pale yellow, six-sided prisms, m. p. 211° (Found: $CH_3 \cdot CO$, 29·3. Calc.: $CH_3 \cdot CO$, 29·3%).

4-*Chloro*-1 : 9-*dihydroxyanthracene* (4-*Chloro*-1-*hydroxyanthranol*). Owing to the ease with which 4-chloro-1-hydroxyanthraquinone was reduced to 1 : 9-dihydroxyanthracene, it was necessary to control the reduction carefully. The addition of hydrochloric acid to the acetic acid solution was stopped as soon as a test portion, added to excess of caustic soda, no longer showed a trace of the red colour of the sodium salt of the hydroxyanthraquinone (about 3 minutes). The solution was then rapidly decanted from the residual tin and cooled. The acetylated product, after recrystallisation from absolute alcohol, yielded 4-*chloro*-1 : 9-*diacetoxyanthracene* as rosettes of faintly yellow, fine needles, m. p. 157° [Found: Cl, 10·7; $CH_3 \cdot CO$, 28·5. $C_{14}H_7O_2Cl(CH_3 \cdot CO)_2$ requires Cl, 10·8; $CH_3 \cdot CO$, 28·2%]. The hot acetic acid solution of these, when treated with hydrochloric acid, deposited 4-*chloro*-1 : 9-*dihydroxyanthracene* as pale greenish-yellow needles of constant m. p. 170—171° (Found: Cl, 14·5; *M*, cryoscopic in naphthalene, 245, 250. $C_{14}H_9O_2Cl$ requires Cl, 14·5%; *M*, 244·5), giving a bright greenish-gold solution

in concentrated sulphuric acid. Its solution in aqueous caustic soda is bright yellow, but on standing in air this is rapidly oxidised to the wine-red solution characteristic of the sodium salt of 4-chloro-1-hydroxyanthraquinone. In alcohol, the anthranol gives a pale greenish-yellow solution which becomes golden-brown on the addition of ferric chloride.

When 3·2 g. of 4-chloro-1 : 9-dihydroxyanthracene were reduced further by the method of Liebermann and Mamlock (*loc. cit.*) during 40 minutes, the product contained less than 1% of chlorine. Its solution in a mixture of warm pyridine and acetic anhydride deposited 2·1 g. of 1 : 9-diacetoxyanthracene, m. p. 208—209°, which after one recrystallisation from the same mixture melted at 210—211°, either alone or mixed with an authentic specimen (Found : $CH_3{\cdot}CO$, 29·6. Calc. : 29·3%).

The thionyl derivatives were prepared by the method adopted for 1 : 2-thionyldihydroxyanthracene (this vol., p. 557).

1 : 8-*Thionyldihydroxynaphthalene* (5·5 g. from 5·3 g. of the naphthol) separated from carbon disulphide in small, pearl-grey crystals, m. p. 97° (Found : C, 58·6; H, 2·9; S, 15·5; *M*, cryoscopic in naphthalene, 218, 210. $C_{10}H_6O_3S$ requires C, 58·3; H, 2·9; S, 15·5%; *M*, 206). It is stable to moisture and a specimen which had stood in air for 9 weeks showed no change in m. p. or in sulphur content. Cold aqueous caustic potash has no appreciable effect on the thionyl compound, but a hot alcoholic solution decomposes it with the production of a pale amethyst colour and the deposition of potassium sulphite. The thionyl compound dissolves in concentrated sulphuric acid with a dull amethyst colour, which changes to the greenish-gold of the naphthol when the solution is heated.

1 : 9-*Thionyldihydroxyanthracene* was obtained (5·0 g. from 4·8 g. of anthranol) from carbon disulphide as pale greenish-yellow plates, m. p. 115° (decomp.) (Found : C, 65·7; H, 3·2; S, 12·7; *M*, cryoscopic in naphthalene, 260, 264. $C_{14}H_8O_3S$ requires C, 65·6; H, 3·1; S, 12·5%; *M*, 256). It gives a greenish-gold solution in cold concentrated sulphuric acid; it is not appreciably soluble in cold caustic soda, but yields a light golden-brown solution on warming. The addition of ferric chloride to its pale yellow solution in alcohol produces no change.

4-*Chloro*-1 : 9-*thionyldihydroxyanthracene* crystallised from carbon disulphide in pale greenish-yellow plates, m. p. 123—124° (decomp.), 4·0 g. of anthranol yielding the same amount of thionyl derivative (Found : S, 11·2; Cl, 12·0; *M*, cryoscopic in naphthalene, 295. $C_{14}H_7O_3ClS$ requires S, 11·0; Cl, 12·2%; *M*, 290·5). The colour reactions are similar to those of 1 : 9-thionyldihydroxyanthracene.

The products obtained by treating 1 : 5-dihydroxynaphthalene with thionyl chloride showed chlorine contents varying from 14 to 22%; those from anthragallol anthranol contained sulphur in amounts varying from 0·7 to 15·6%, and chlorine from 2·1 to 21·5%. In all cases, the reactions and properties of the products pointed to their being complex substances formed by the condensation of several molecules.

The author desires to thank the Research Fund Committee of the Chemical Society for a grant which has defrayed a portion of the cost of this research, and also The British Alizarine Company, Limited, and The Scottish Dyes, Limited, for gifts of materials.

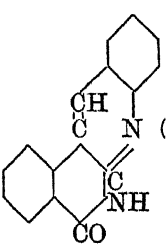
CCCXIV.—*Some Derivatives of* 2 : 3 : 5 : 6-*Dibenzo*-1 : 8-*naphthyridine.*

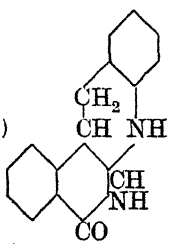
By ROBERT DOWNS HAWORTH and HERBERT SHEPHERD PINK.

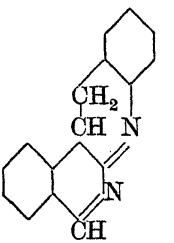


DERIVATIVES of 2 : 3 : 5 : 6-dibenzo-1 : 8-naphthyridine (I) have not been previously described, and a method for their preparation from homophthalimide is now communicated. Dieckmann (*Ber.*, 1914, **47**, 1428) showed that the diethyl ester of homophthalic acid condensed with aldehydes, and homophthalimide is now shown to condense in a similar manner with *o*-nitrobenzaldehyde, giving excellent yields of o-*nitrobenzylidenehomophthâlimide* (II) in pyridine solution in the presence of a trace of piperidine.

(I.)

(II.)





(III.)

This sparingly soluble substance was reduced with stannous chloride in alcoholic solution to 7-*keto*-2 : 3 : 5 : 6-*dibenzo*-7 : 8-*dihydro*-1 : 8-*naphthyridine* (III), which is a pale yellow, very weak base, dissolving in concentrated mineral acids and being precipitated on dilution with water; it possesses marked acidic properties, however, owing to the presence of the *iso*carbostyril

grouping, and on treatment with dilute potassium or sodium hydroxide, bright yellow, sparingly soluble salts were obtained, the *sodium* salt being somewhat more soluble than the *potassium* salt. Owing to the sparing solubility of this ketodibenzodihydronaphthyridine, further reduction was difficult, but zinc dust in glacial acetic acid, saturated with hydrogen chloride, effected reduction to 7-*keto*-2 : 3 : 5 : 6-*dibenzo*-1 : 4 : 7 : 8 : 9 : 10-*hexahydro*-1 : 8-*naphthyridine* (IV), which is devoid of acidic properties, but readily yields a *monohydrochloride* and an amorphous *nitrosoamine*.

(IV.)

(V.)

A similar series of compounds was obtained from the *N*-alkylated homophthalimides, the 8-β-*phenylethyl* and 8-β-*piperonylethyl* derivatives [as (II), (III), and (IV)] being described.

In attempting to reduce the carbonyl group of the ketodibenzodihydronaphthyridine (III), a small yield of a yellow *base*, $C_{16}H_{12}N_2$, was obtained by electrolytic reduction in alcoholic sulphuric acid solution. The same base was, however, more conveniently prepared (in 20% yield) by heating the keto-compound (III) with phosphorus oxychloride and pentachloride at 180° and reducing the unstable chloro-compound with phosphorus and hydriodic acid at 160—170°, the compound (IV) also being formed. The yellow base, $C_{16}H_{12}N_2$, was sparingly soluble in organic solvents and its dilute solutions exhibited an intense violet fluorescence. The two nitrogen atoms are both tertiary in character, since no nitrosoamine or acetyl derivative can be obtained. It is probably 2 : 3 : 5 : 6-*dibenzo*-4 : 9-*dihydro*-1 : 8-*naphthyridine* (V), for it dissolved in hot dilute hydrochloric acid to give a sparingly soluble *monohydrochloride*, and this monoacidic character is in agreement with the amidine structure suggested.

Experimental.

o-*Nitrobenzylidenehomophthalimide* (II).—Homophthalimide (20 g.), o-nitrobenzaldehyde (20 g.), pyridine (100 c.c.), and piperidine (0·5 c.c.) were boiled until homogeneous, and the heating was continued on the water-bath for 2 hours; the solution became

dark red and the product gradually separated on cooling in pale yellow needles, which recrystallised from pyridine in pale sulphur-yellow needles (35 g.), m. p. 236° (Found: N, 9·6. $C_{16}H_{10}O_4N_2$ requires N, 9·5%). o-*Nitrobenzylidenehomophthalimide* is sparingly soluble in the usual organic solvents, and gives a yellow solution in dilute aqueous sodium hydroxide.

o-*Nitrobenzylidene*-N-β-*phenylethylhomophthalimide* was prepared similarly from *o*-nitrobenzaldehyde and *N*-β-phenylethylhomophthalimide; it crystallised from pyridine in yellow needles, m. p. 146° (Found: N, 7·2. $C_{24}H_{18}O_4N_2$ requires N, 7·0%). o-*Nitrobenzylidene*-N-β-*piperonylethylhomophthalimide*, prepared from *o*-nitrobenzaldehyde and *N*-β-piperonylethylhomophthalimide, crystallised from pyridine in yellow needles, m. p. 176° (Found: N, 6·7. $C_{25}H_{18}O_6N_2$ requires N, 6·2%).

7-*Keto*-2 : 3 : 5 : 6-*dibenzo*-7 : 8-*dihydro*-1 : 8-*naphthyridine* (III).—A mixture of *o*-nitrobenzylidenehomophthalimide (II) (15 g.), stannous chloride (40 g.), and ethyl alcohol (200 c.c.) was saturated with hydrogen chloride and heated on the water-bath for 12 hours. After cooling, the tin double compound was collected, digested with excess of potassium hydroxide solution for ½ hour, cooled, and the bright yellow *potassium* salt decomposed by trituration with dilute hydrochloric acid; the resulting *ketodibenzodihydronaphthyridine* was recrystallised from glacial acetic acid, forming very pale yellow needles (12 g.), m. p. 246—247° (Found: C, 77·9; H, 4·1; N, 11·1. $C_{16}H_{10}ON_2$ requires C, 78·0; H, 4·1; N, 11·4%). It is almost insoluble in water, ether, alcohol, acetone, or benzene, slightly soluble in hot chloroform, and soluble in hot glacial acetic acid or pyridine. It dissolves in concentrated hydrochloric acid, but is reprecipitated on dilution. The potassium salt is almost insoluble in water. The *sodium* salt is slightly soluble in hot water, from which it separates in glistening, bright yellow plates (Found: Na, 8·7. $C_{16}H_9ON_2Na$ requires Na, 8·6%); it is also obtained by boiling the ketodibenzodihydronaphthyridine (III) with methyl-alcoholic sodium hydroxide, no further hydrolysis taking place.

7-*Keto*-8-β-*phenylethyl*-2 : 3 : 5 : 6-*dibenzo*-7 : 8-*dihydro*-1 : 8-*naphthyridine* was obtained from *o*-nitrobenzylidene-*N*-β-phenylethylhomophthalimide by reduction with stannous chloride, as described above. It crystallises from acetic acid in almost colourless needles, m. p. 220° (Found: C, 82·1; H, 5·2. $C_{24}H_{18}ON_2$ requires C, 82·3; H, 5·1%). It is a very weak base, and shows no acidic properties. 7-*Keto*-8-β-*piperonylethyl*-2 : 3 : 5 : 6-*dibenzo*-7 : 8-*dihydro*-1 : 8-*naphthyridine* crystallises from glacial acetic acid in pale yellow needles, m. p. 217° (Found: C, 76·0; H, 4·9. $C_{25}H_{18}O_3N_2$ requires C, 76·1; H, 4·6%).

7-*Keto*-2 : 3 : 5 : 6-*dibenzo*-1 : 4 : 7 : 8 : 9 : 10-*hexahydro*-1 : 8-*naphthyridine* (IV).—o-Nitrobenzylidenehomophthalimide (6 g.) or ketodibenzodihydronaphthyridine (III) (6 g.) was dissolved in glacial acetic acid (100 c.c.), saturated with hydrogen chloride, and heated with a large excess of zinc dust for 3 hours on the water-bath. The mixture was diluted with water, made strongly alkaline with ammonia, extracted with chloroform, the solvent removed, and the residue crystallised first from boiling ethyl alcohol and then from methyl ethyl ketone, colourless needles (0·5 g.), m. p. 250°, being obtained (Found: C, 77·4; H, 5·7. $C_{16}H_{14}ON_2$ requires C, 76·8; H, 5·6%). This substance (IV) is more soluble in organic solvents than the dihydro-compound (III). It is insoluble in sodium hydroxide solution, but dissolves in dilute hydrochloric acid; on concentration the *monohydrochloride* separates in colourless needles, which darken at about 225° and decompose at 270° (Found: Cl, 12·3. $C_{16}H_{15}ON_2Cl$ requires Cl, 12·5%). When its solution in dilute hydrochloric acid was treated with sodium nitrite an amorphous *nitrosoamine* gradually separated. This was extracted with chloroform, the extract washed thoroughly with sodium bicarbonate solution, and the solvent removed; the residue gave Liebermann's test for nitrosoamines. The *picrate*, prepared in alcoholic solution, crystallised from glacial acetic acid in small, yellow needles, m. p. 270° (Found: N, 14·6. $C_{22}H_{17}O_8N_5$ requires N, 14·6%).

7-*Keto*-8-β-*phenylethyl*-2 : 3 : 5 : 6-*dibenzo*-1 : 4 : 7 : 8 : 9 : 10-*hexahydro*-1 : 8-*naphthyridine*, obtained by reducing the corresponding dihydro-compound or *o*-nitrobenzylidene-*N*-β-piperonylethylhomophthalimide with zinc dust, as described above, crystallises from ethyl alcohol in colourless needles, m. p. 217° (Found: C, 81·1; H, 6·4. $C_{24}H_{22}ON_2$ requires C, 81·3; H, 6·2%). 7-*Keto*-8-β-*piperonylethyl*-2 : 3 : 5 : 6-*dibenzo*-1 : 4 : 7 : 8 : 9 : 10-*hexahydro*-1 : 8-*naphthyridine* separates from ethyl alcohol in colourless needles, m. p. 211° (Found: C, 75·4; H, 5·7. $C_{25}H_{22}O_3N_2$ requires C, 75·4; H, 5·5%).

2 : 3 : 5 : 6-*Dibenzo*-4 : 9-*dihydro*-1 : 8-*naphthyridine* (V).—The corresponding 1 : 8-dihydroketo-compound (III; 5 g.), phosphorus pentachloride (6 g.), and phosphorus oxychloride (10 c.c.) were heated for 5 hours in a sealed tube at 180°. The oxychloride was removed under diminished pressure, and the solid residue * (7 g.) heated with red phosphorus (1·5 g.) and hydriodic acid (*d* 1·7; 30 c.c.) for 9 hours at 160—170°; the pale greenish-yellow solution, containing long, pale yellow prisms, was diluted with water, boiled, and the sparingly soluble *hydriodide* decomposed by the addition

* The chloro-derivative could not be isolated from this solid residue, as it was rapidly hydrolysed to the keto-compound (III) by water.

of a large excess of ammonia. The base was extracted with chloroform, the extract dried, the solvent removed, the residual solid dissolved in hot dilute hydrochloric acid, filtered, and cooled; the hydrochloride separated in pale orange needles, which were collected, dissolved in water, and decomposed with sodium hydroxide; the resulting yellow base crystallised from ethyl alcohol in pale yellow needles (0·9 g.), m. p. 232° (Found: C, 82·4, 82·8; H, 5·4, 5·5. $C_{16}H_{12}N_2$ requires C, 82·8; H, 5·2%). It is sparingly soluble in ether, light petroleum, or benzene, fairly soluble in hot alcohol, and readily soluble in chloroform, glacial acetic acid, or hot dilute mineral acids. Its alcoholic solutions are almost colourless, with an intense violet fluorescence. The *monohydrochloride* crystallises from water in pale yellow needles which darken at about 240° and gradually decompose at higher temperatures (Found: Cl, 12·9. $C_{16}H_{13}N_2Cl$ requires Cl, 13·3%). The base does not yield a nitrosoamine or acetyl derivative, and could not be further reduced by zinc dust and acids.

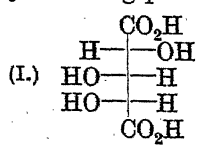
CCCXV.—*New Reference Compounds in the Sugar Group. The Methylamides of* d-, l-, *and* i-*Dimethoxysuccinic Acids and of* l-*Arabo- and* i-*Xylo-trimethoxyglutaric Acids.*

By WALTER NORMAN HAWORTH and DAVID IDRIS JONES.

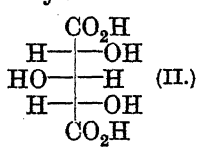
COMPARED with other groups of organic substances, the carbohydrates have hitherto been provided with few fundamental reference compounds which can serve as final standards for the complete identification of the normal and labile forms of sugars through their oxidation derivatives.

The most readily accessible oxidation derivatives of the methylated aldoses are the lactones of the corresponding acids, and most of these lactones are crystalline and give characteristic phenylhydrazides. A lactone of the δ- or amylene-oxide series can be sharply differentiated from the corresponding member of the γ- or butylene-oxide series by reason of its different rate of hydrolysis as revealed by physical methods (Drew, Goodyear, and Haworth, this vol., p. 1237; also forthcoming paper by Carter, Haworth, and Robinson).

The ultimate basis on which the constitution of each of these



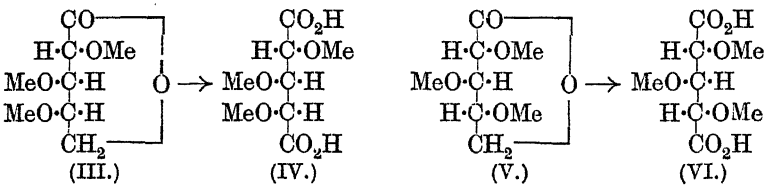
lactones rests is that of the simple dibasic acids to which they give rise on oxidation. Our further study of these lactones by methods of degradative oxidation has revealed the need of a final standard of comparison of these oxidation products with the derivatives of the stereoisomeric forms of tartaric acid and of trihydroxyglutaric acid. Methylated derivatives of these acids do not lend themselves to easy recognition. Crystalline amides of some of these acids have been prepared and examined (Hirst and Purves, J., 1923, **123**, 1352; Hirst and Robertson, J., 1925, **127**, 358) and their physical properties are of some service for the purpose of identification, but inasmuch as these amides melt with decomposition at high temperatures, their utility as standard reference substances suffers by reason of the untrustworthiness of their application in mixed m. p. determinations.



A search for new crystalline derivatives of the stereoisomeric forms of dimethoxysuccinic acid and of trimethoxyglutaric acid has led us finally to adopt as our standards the crystalline methylamides. These substances melt at a definite temperature, solidify on cooling, and then remelt at the same temperature as before, and they undergo no change either of condensation or decomposition at this elevated temperature.

Thus *l*-tartaric acid, prepared by Pasteur's method from racemic acid, was esterified to methyl *l*-tartrate, and methylation by the usual methods gave rise to *methyl* l-*dimethoxysuccinate*. The latter was converted with the aid of pure methylamine into l-*dimethoxysuccinomethylamide*. Similar methods applied to the corresponding *d*- and *i*-tartaric acids furnished the remaining stereoisomeric forms of the above methylamide. Their physical properties are tabulated below for comparison :

	M. p.	$[\alpha]_D$ in water.
d-Dimethoxysuccinomethylamide	205°	+132·6°
l- " " "	205	−131·8
i- " " "	210	Zero



Of the four stereoisomeric forms of trihydroxyglutaric acid, two are most frequently encountered as oxidation products in the sugar group, namely, *l*-arabotrihydroxyglutaric acid (I) and *i*-xylotrihydroxyglutaric acid (II), which are obtained, respectively, from the naturally occurring pentoses, arabinose and xylose :

Both these forms are represented in the cases which we have studied. Thus, *l*-trimethyl δ-arabonolactone (III), prepared from normal methylated arabinose, has been oxidised with nitric acid and

found to give rise almost exclusively to *l*-arabotrimethoxyglutaric acid (IV). Conversion of this into the methyl ester was followed by treatment with methylamine, which gave a quantitative yield of l-*arabotrimethoxyglutaromethylamide*, m. p. 172°, $[\alpha]_D$ + 59·9°. The corresponding amide was similarly prepared. Again, the oxidation of trimethyl δ-xylonolactone (V) gave an almost quantitative yield of *i*-xylotrimethoxyglutaric acid (VI), which was converted into i-*xylotrimethoxyglutaromethylamide*, m. p. 167—168°, and also into the corresponding amide.

The isolation of these products furnishes a proof of the constitution of the two δ-lactones (III and V), and also confirms the amylene-oxide structure of the normal forms of trimethyl arabinose and trimethyl xylose.

Experimental.

d-*Dimethoxysuccinomethylamide.*—Methyl *d*-dimethoxysuccinate having $[\alpha]_D^{18°}$ + 79·9° in methyl alcohol (c = 2·04) (compare Purdie and Barbour, J., 1901, **79**, 973) was prepared from *d*-tartaric acid. The ester was dissolved in dry methyl alcohol saturated with methylamine. The solution was kept for several days, and on concentration yielded long, colourless needles which, recrystallised from light petroleum (b. p. 60—80°), had m. p. 205°; $[\alpha]_D^{15°}$ + 132·6° in water (c = 1·95); yield 90% (Found: C, 47·0; H, 7·8; N, 13·5; OMe, 29·5. $C_8H_{16}O_4N_2$ requires C, 47·05; H, 7·8; N, 13·7; OMe, 30·4%).

Methyl l-*Dimethoxysuccinate.*—A specimen of *l*-tartaric acid [m. p. 167—170°; $[\alpha]_D^{18°}$ − 14·6° in water (c = 3·15)] was prepared by fermentation methods from racemic acid, and esterified in the presence of methyl alcohol containing 3% of hydrogen chloride; yield 95%. The methyl *l*-tartrate was methylated by Purdie's reagents and gave a colourless liquid, b. p. 83°/0·07 mm.; $n_D^{18°}$ 1·4345; $[\alpha]_D^{18°}$ − 78·8° in methyl alcohol (c = 3·12) (0·2340 G. required 22·9 c.c. *N*/10-sodium hydroxide. Calc.: 22·75 c.c.) (Found: C, 46·8; H, 7·0; OMe, 58·3. Calc.: C, 46·6; H, 6·8; OMe, 60·2%).

l-*Dimethoxysuccinomethylamide.*—The methyl *l*-dimethoxysuccinate was dissolved in dry methyl alcohol, saturated with methylamine, and the solution concentrated after 40 hours; a crystalline mass then filled the containing vessel. The *methylamide* was

recrystallised from ethyl acetate; the long needles thus obtained melted at 205°, solidified on cooling, and remelted at the same temperature; $[\alpha]_D^{17^\circ}$ — 131·8° in water ($c = 1{\cdot}61$); yield 82% (Found: C, 46·8; H, 7·7; N, 13·8; OMe, 28·4. $C_8H_{16}O_4N_2$ requires C, 47·05; H, 7·8; N, 13·7; OMe, 30·4%).

The crystalline l-*dimethoxysuccinamide* was also made in the usual way and isolated as colourless needles which became coloured at 250°, dark at 270°, melted at 278°, and decomposed violently at 294°, a behaviour which was identical with that exhibited by the *d*-isomeride (Found: C, 40·8; H, 6·6; N, 15·8; OMe, 33·5. $C_6H_{12}O_4N_2$ requires C, 40·9; H, 6·8; N, 15·9; OMe, 35·2%).

i-*Dimethoxysuccinomethylamide.*—*meso*Tartaric acid was esterified in presence of methyl alcohol and methylated with Purdie's reagents, giving flat plates, m. p. 68°. This specimen of methyl *i*-dimethoxysuccinate was dissolved in methyl alcohol, saturated with methylamine, and the solution kept for 3 days, during which long needles separated, further crops being obtained by concentration. The *methylamide* was recrystallised from ethyl acetate; m. p. 210°; zero rotation in water ($c = 1{\cdot}6$); yield 97% (Found: C, 46·9; H, 8·0; N, 13·6; OMe, 29·8. $C_5H_{16}O_2N_2$ requires C, 47·1; H, 7·8; N, 13·7; OMe, 30·4%).

Oxidation of Trimethyl δ-Xylonolactone.—A specimen of this lactone, m. p. 55° (Haworth and Westgarth, J., 1926, 886) was oxidised with nitric acid (*d* 1·42) by heating the solution in a water-bath at 70—75° for ¾ hour, and thereafter for 3 hours at 90—95°. The removal of the nitric acid was effected in the usual way and the syrupy oxidation product collected, esterified with dry methyl alcohol containing 4% hydrogen chloride, the solution neutralised with silver carbonate, and the solvent evaporated. The liquid product was dissolved in ether, dried, and distilled; b. p. 102—104°/0·09 mm.; n_D 1·4402; the yield was quantitative. That this product was methyl *i*-trimethoxyglutarate was shown by conversion into the crystalline amide (yield over 60%); the crystals turned slightly brown at 195° and melted quickly at 195—198° to a blue liquid. The rotation was zero. Comparison with an authentic specimen of *i*-xylotrimethoxyglutaramide proved its identity.

i-*Trimethoxyglutaromethylamide.* — The above ester was dissolved in methyl alcohol, saturated with methylamine, and kept for 15 hours; crystals then separated, and further crops were obtained by concentration of the solution. The *methylamide* crystallised from ethyl acetate in silky needles, m. p. 167—168°, solidifying and then remelting at 167° (yield 85%). The rotation was zero (Found: C, 48·4; H, 8·4; N, 10·85; OMe, 36·3. $C_{10}H_{20}O_5N_2$ requires C, 48·35; H, 8·1; N, 11·2; OMe, 36·4%).

Oxidation of Trimethyl δ-Arabonolactone.—This lactone (m. p. 45°; $[\alpha]_D^{21°}$ + 179·5° in water) was prepared from crystalline trimethyl β-methylarabinoside as described by Drew and Haworth (this vol., p. 778). The lactone (5 g.) was dissolved in 40 c.c. of nitric acid (*d* 1·42), and the solution heated on the water-bath. The oxidation commenced at 90°, and during a period of 5 hours the evolution of brown fumes was continuous; the reaction then ceased. The nitric acid was removed by dilution with water followed by continuous distillation of the dilute acid at 40°/15 mm.; methyl alcohol was added to, and distilled from, the residue, and the resulting syrup was digested with a solution containing 80 c.c. of methyl-alcoholic hydrogen chloride (3%). Thereafter, the mineral acid was removed by neutralisation with silver carbonate, and the product, a pale yellow syrup (5·8 g.), was distilled, b. p. 105°/0·14 mm.; $n_D^{15°}$ 1·4365; yield 5·25 g. The methyl trimethoxyglutarate showed $[\alpha]_D^{20°}$ + 37·6° in water (*c* = 2·52) and $[\alpha]_D^{18°}$ + 41·2° in methyl alcohol (*c* = 1·31) (Found: C, 47·6; H, 7·3; OMe, 58·35. Calc.: C, 48·0; H, 7·2; OMe, 62·0%). This product (0·5 g.) was dissolved in dry methyl alcohol (6 c.c.), and the solution saturated with dry ammonia. On keeping, a crystalline amide separated, (yield 0·4 g.), m. p. 228—229°. Recrystallisation from methyl alcohol raised the m. p. to 230° (decomp.) (Found: C, 43·7; H, 7·2; N, 13·0; OMe, 40·6%).

l-*Arabotrimethoxyglutaromethylamide.*—Another specimen (0·46 g.) of the preceding ester was dissolved in methyl alcohol (6 c.c.) and saturated with methylamine. After keeping for 3 days at the ordinary temperature the solution was concentrated under diminished pressure and gave crystals (yield 0·45 g.) of the *methylamide.* Recrystallisation from ethyl acetate gave radiating needles (m. p. 172°), solidifying on cooling and remelting at the same temperature; $[\alpha]_D^{18°}$ + 59·9° in water (*c* = 1) (Found: C, 48·3; H, 8·2; N, 10·9; OMe, 35·6. $C_{10}H_{20}O_5N_2$ requires C, 48·35; H, 8·1; N, 11·2; OMe, 36·4%).

[*Received, August 16th,* 1927.]

CCCXVI.—*The Photochemical Oxidation of Alcohols by the Dichromate Ion.*

By EDMUND JOHN BOWEN and CHARLES WILLIAM BUNN.

THE photochemical oxidation of alcohols by the dichromate ion has been studied by Plotnikov (*Z. wiss. Phot.*, 1919, **19**, 40; *Z. Elektrochem.*, 1926, **32**, 13). The aim of the present work was to

obtain measurements under as great a variety of conditions as possible, and to make measurements of the quantum efficiency.

Four lamps were used for different parts of the work: a 1000-c.p. Pointolite lamp, a 1000-watt tungsten-filament lamp, water-cooled, and two quartz–mercury lamps. Copper sulphate solution filters were used to remove infra-red and red radiation, and with the mercury lamps practically monochromatic radiation was obtained with Chance's black glass and cupriammonium sulphate filters.

The reactions were carried out in small quartz cells with plane-polished quartz ends fused on, the cells being fixed in a water thermostat electrically controlled. The energies of the radiations and the absorptions of the solutions were measured with a Moll thermopile calibrated in the usual way with a Hefner lamp.

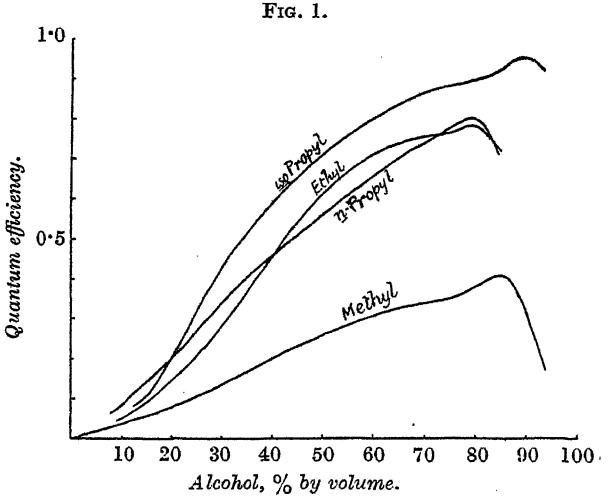
The following two points were established in the first part of the work: (*a*) The chromate ion in neutral or alkaline solution is photochemically quite insensitive towards the alcohols. The results of Plotnikov (*loc. cit.*), that ammonium chromate is photoactive, are to be explained by partial hydrolysis to dichromate.

(*b*) The photochemical reaction between acid dichromate-ion solutions and alcohols leads to aldehyde formation without deposition of a precipitate. (In neutral solutions a precipitate is thrown down.) A series of measurements made with methyl alcohol solutions showed that the photochemical reaction curve obtained from the estimation of formaldehyde by the method of Schulek (*Ber.*, 1925, **58**, 732) was consistently 20% lower than that obtained from the decrease in dichromate-ion concentration. This was shown experimentally to be due to further oxidation of the formaldehyde, and the photochemical reaction may be represented:

$$Cr_2O_7'' + 8H^{\cdot} + 3CH_3{\cdot}OH \longrightarrow 3CH_2O + 2Cr''' + 7H_2O.$$

In later experiments, the reaction was followed only by estimation of the dichromate-ion concentration, potassium iodide being added and the iodine titrated. The thermal reaction was followed at the same temperature, the reactants being contained in a blackened flask, and the true photochemical change was obtained by subtraction of the (small) thermal rate from the total rate in light.

The results of numerous experiments are summarised as follows. The quantum efficiency is independent of the following four factors: (1) light intensity, over a range of 1 : 80; (2) added acid, above a certain limit; (3) dichromate-ion concentration, between $N/10$ and $N/100$; and (4) temperature, between 15° and 50°.



The photochemical reaction curves were determined for a series of alcohol–water mixtures at 15°, the dichromate-ion concentration being maintained at $N/20$ in each mixture, and the acid at $0{\cdot}2N$.

All the curves were linear over a large range of the first part of the reaction, and the slope gave the photochemical rates for the mixtures; these are summarised in Table I, the rates being expressed as the ratio of Cr_2O_7'' ions reduced to quanta absorbed, and plotted in Fig. 1.

FIG. 1.

As a check on these measurements, which were made in the light from a tungsten-filament lamp, filtered through copper sulphate solution, the quantum efficiency for the series of alcohols at concentrations equal to that of maximum rate was measured in monochromatic light from a quartz lamp: At 3666 Å., *Q.E.* of alcohol: methyl 0·45, ethyl 0·86, *n*-propyl 0·86, *iso*propyl 1·00. At 4200 Å. (approx.), ethyl alcohol 0·89. These results agree with the previous ones within the limit of error, if account be taken of the complete

change of apparatus. The whole absorption band of the dichromate ion in the blue and violet region is therefore equally photoactive.

The variation of reaction rate with diminishing acid concentration was investigated and showed a regular decrease, but the results cannot be simply interpreted since the reaction occurs chiefly in the forward layers of the solution, producing variations in acidity throughout the cell. The reactions were also investigated in neutral solution. In this case, a precipitate is thrown down which is not chromium hydroxide, but which is capable of liberating iodine from potassium iodide. Owing to the scattering of the light by the precipitate, the rate falls off rapidly from the beginning of the exposure, and becomes zero when one-half of the total oxidising power of the dichromate solution is utilised. The simplest explanation of this is the formation of chromate:

$$Cr_2O_7'' + 3CH_3{\cdot}OH + H_2O \longrightarrow 3CH_2O + 2OH' + 2Cr(OH)_3.$$
$$2OH' + Cr_2O_7'' \longrightarrow 2CrO_4'' + H_2O.$$

The nature of the precipitate is obscure. Plotnikov has suggested that it is chromium chromate.

Owing to the falling off of the rate with time in the neutral reactions the initial rates for different alcohol–water mixtures were obtained by calculation from the curves. Table II summarises these initial rates, expressed for convenience as the ratio of rates acid/neutral for each mixture:

TABLE II.

Methyl alcohol.		Ethyl alcohol.		*n*-Propyl alcohol.	
Alcohol, % by vol.	Ratio of rates, acid / neutral	Alcohol, % by vol.	Ratio of rates, acid / neutral	Alcohol, % by vol.	Ratio of rates, acid / neutral
30	2·77	20	2·06	15	2·2
50	2·92	30	2·15	30	2·87
70	2·80	40	2·85	50	3·3
80	2·93	50	3·1	70	3·28
82·5	2·89	70	3·2	80	3·08
85	2·62				
87·5	2·50				
90	3·0				

These measurements are not so accurate as those for acid solutions because of the uncertainty in the estimation of the initial rate. Since the ratio is practically constant, the curves for the neutral reactions are almost identical with those for the acid solutions except that the scale is about one-third. It seems that, whatever are the causes of the change in quantum efficiency with alcohol concentration, the same factors operate in acid and neutral solution.

Discussion of Results.

The results for acid solutions seem to point to the conclusion that the true quantum efficiency of the photochemical process is

the decomposition of one dichromate ion and the oxidation of 3 molecules of alcohol per quantum absorbed. The measured quantum efficiency never reaches its true value because disturbing factors cause its diminution in mixtures containing excess of either alcohol or water. The diminution at high alcohol concentrations may be due to the appearance of a new substance, such as an alkyl chromate, since here the thermal reaction becomes very fast. If this is a correct deduction, it is improbable that the reaction really consists of the simultaneous collision of 3 alcohol molecules with an activated dichromate ion; and the simplest assumption is that the real photoactive substance is an alcoholated dichromate ion, *i.e.*, an ion with alcohol molecules attached by co-ordinate links. The diminution on the low alcohol concentration side would then be due to the equilibrium between non-photoactive hydrated dichromate ions and the photoactive alcoholated ions.

Applying the mass law as an approximation for the formation of a hydrate and an alcoholate, we have :

$$\frac{(Cr_2O_7)(H_2O)^n}{(Cr_2O_7,nH_2O)} = K_1; \quad \frac{(Cr_2O_7)(ROH)^m}{(Cr_2O_7,mROH)} = K_2.$$

Putting, for simplicity, $n = m$,

$$\frac{\text{Mol. fraction } H_2O}{\text{Mol. fraction ROH}} \times \sqrt[n]{\frac{\text{(alcoholate)}}{\text{(hydrate)}}} = K,$$

or roughly, at low alcohol concentrations :

$$\frac{\text{Mol. fraction } H_2O}{\text{Mol. fraction ROH}} \times \sqrt[n]{\text{Quantum efficiency}} = K.$$

The following calculations from the experimental data show that $n = 1$ approximately :

Methyl alcohol.

4	26
9·2	43
19·4	27·6

In order to make the hypothesis fit the measurements, therefore, it must be assumed that only one molecule of alcohol or water is attached to each dichromate ion. It is hardly possible to accept this result, as it does not remove the difficulty of the oxidation of 3 molecules of alcohol per quantum absorbed.

An alternative hypothesis is that the activated dichromate ions have a mean "life" and only react if they collide with alcohol molecules during this "life." Applying an approximate equation (Grüss, *Z. Elektrochem.*, 1923, **29**, 144),

$$\text{Quantum efficiency} = 4\pi\sigma^2nct/3v,$$

where v = number of volumes of solution containing one volume of alcohol; n = number of molecules in 1 c.c.; $\sigma = 10^{-8}$ cm.; c = velocity of dichromate ion; t = "life" of activated dichromate ion.

It is significant from the point of view of this hypothesis that the quantum efficiency for all the alcohols is approximately halved at a dilution of 1 : 3; whence $t = 3 \times 10^{-11}$ second.

This time is of the order of that required for an electron shift in a molecule, and is much shorter than the life of the activated molecules of chlorine (Grüss, *loc. cit.*) and iodine (Briers, Chapman, and Walters, J., 1926, 562). The result is not improbable, because the long life of activated halogen molecules may represent the time of recombination of atoms formed after activation. No dissociation of this kind is to be expected with the dichromate ion. The mechanism of the reaction, however, must still be considered to be very imperfectly understood.

CCCXVII.—*Equilibrium in the Systems* $MnSO_4$–K_2SO_4–H_2O *and* $MnSO_4$–$(NH_4)_2SO_4$–H_2O *at* 0°; *also in the System* $CuSO_4$–Na_2SO_4–H_2O *at* 0°, 25°, *and* 37·5°.

By ROBERT MARTIN CAVEN and WILLIAM JOHNSTON.

THE authors have previously shown (J., 1926, 2628), from an investigation of the system $MnSO_4$–K_2SO_4–H_2O at 25°, that at this temperature the double salt is tetrahydrated ($MnSO_4,K_2SO_4,4H_2O$). Since manganese sulphate itself crystallises with $4H_2O$ at 25°, and with $7H_2O$ at 0°, it was decided to investigate the hydration of its potassium double salt at 0°, in the expectation that it might

then be hexahydrated, and thus conform to the general type: $M''SO_4,M'_2SO_4,6H_2O$. Moreover, since manganese ammonium sulphate conforms to this general type, even at 25°, it was decided also to investigate the system $MnSO_4$–$(NH_4)_2SO_4$–H_2O at 0°, and thus to compare the kinds of isotherm obtained in the two cases. Further, this system was investigated at 25° by Schreinemakers (*Chem. Weekblad*, 1909, **6**, 131), and in the present paper his results are compared with those obtained by the authors (*loc. cit.*) for the system $MnSO_4$–K_2SO_4–H_2O at the same temperature.

Also, in order to study the influence of the water of crystallisation of the double salt on the type of isotherm obtained, it was decided to investigate the system $CuSO_4$–Na_2SO_4–H_2O at various temperatures, the double salt in this case always crystallising with $2H_2O$. This system has already been studied by several workers. Diacon (*Jahresber.*, 1866, 61) investigated it at 0°, and his results show that the double salt $CuSO_4,Na_2SO_4,2H_2O$ does not exist at this temperature in contact with solutions of its component salts. Nevertheless, the continuous increase in solubility of each of the two single salts caused by addition of the other salt up to the triple point indicates the presence of a considerable amount of the double salt or its ions in solution. Koppel (*Z. physikal. Chem.*, 1903, **42**, 1) showed that below 16·7° the double salt does not crystallise from a solution of its component salts; and from his results he drew a series of isotherms, showing an increased range of double salt formation above this temperature, which do not seem to be justified. Moreover, these hypothetical isotherms indicate that, from 0° to about 30°, whilst the solubility of sodium sulphate is increased by the addition of copper sulphate, that of copper sulphate is decreased by the addition of sodium sulphate. This conclusion contradicts Diacon's results at 0°. Massink investigated the same system at 20° (*Z. physikal. Chem.*, 1916, **92**, 351),* and showed a short range of double salt formation, with continuous increase of solubility of each of the single salts on addition of the other, up to the corresponding triple point. He gave, however, only one point within the double-salt range.

In view, therefore, of the conflicting and inadequate results of previous workers, the authors felt justified in investigating this system at 0° and 25°; and, since sodium sulphate is decahydrated below 33° and anhydrous above that temperature, they also decided to investigate the system above 33° (at 37·5°), to discover what

* According to an abstract of this paper (*Chem. Weekblad*, 1917, **14**, 756), Massink also investigated the system at 35°. Reference to the original paper shows that 35° is mentioned, but that the results supposed to be obtained at that temperature are missing.

influence the change in hydration of sodium sulphate had upon the isotherm.

EXPERIMENTAL.

The Systems $MnSO_4$–K_2SO_4–H_2O *and* $MnSO_4$–$(NH_4)_2SO_4$–H_2O *at* 0°.

For the manganese–potassium system, solutions of the two salts were made at atmospheric temperature, and various proportions of these solutions were placed successively in a flask, fitted with a stirrer, and kept immersed in a mixture of ice and water. The mixtures were stirred for 3 days before portions of the solutions were separated and analysed. The manganese was estimated volumetrically by the Volhard method, the total sulphate determined, and the potassium sulphate calculated. The same procedure was carried out with the manganese–ammonium system, except that, as the solid phases are known, they were not analysed. The ammonia and total sulphate were determined.

In Table I, the results for the manganese–potassium system at 0° are expressed as g. per 100 g. of solution or of moist solid, and the triangular diagram is used to determine the composition of the double salt (Fig. 1). In Table II, the same results, and those for the manganese–ammonium system at 0°, are expressed as mols. per 1000 g. of water; and these results are then compared graphically by means of rectangular co-ordinates with those previously obtained by Schreinemakers and the authors at 25° (Figs. 2 and 3).

The System $CuSO_4$–Na_2SO_4–H_2O *at* 0°, 25°, *and* 37·5°.

For this system at 0°, the procedure was as above, although only the liquid phases were analysed. Copper was estimated iodometrically, and total sulphate determined. For the systems at 25° and 37·5°, solutions of the two salts were made at temperatures about 15° above those required, and various proportions of the two solutions were placed in a flask, fitted with a stirrer, and kept in a thermostat at 25° ± 0·1° or 37·5° ± 0·1°. The solutions were stirred for 3 days before portions were separated and analysed. The results are expressed in Table III, and in Fig. 4 by means of rectangular co-ordinates, those of Diacon and Massink being also included in the same figure.

Conclusions.

Manganese Double Sulphates.—The following points arise:

1. Manganese potassium sulphate crystallises at 0°, as well as at 25°, with $4H_2O$.

2. Its isotherm at 0° resembles the corresponding isotherm at 25°, except that it shows a more rapid increase in solubility of

manganese sulphate with addition of potassium sulphate up to the triple point. Some difference would be expected, since at 0° the solid phase is $MnSO_4,7H_2O$, whereas at 25° it is $MnSO_4,4H_2O$.

3. The 0°-isotherm of the potassium system differs greatly from that of the ammonium system, the range of double salt formation

in the case of the latter being much the greater. This is traceable to two factors: (*a*) the much greater solubility of ammonium sulphate, (*b*) the fact that the ammonium double salt crystallises with $6H_2O$, whereas the potassium double salt crystallises with $4H_2O$.

4. The 0°-isotherm of the ammonium system resembles the 25°-isotherm, as shown by Schreinemakers's results. Two points, however, should be noted: (*a*) The increase in solubility of manganese sulphate caused by ammonium sulphate at 25° is accentuated at 0° (compare the potassium system at 0° and 25°); (*b*) the decrease in solubility of ammonium sulphate caused by manganese sulphate at 25° is accentuated at 0°.

5. The isotherms for manganese ammonium sulphate, but not for the corresponding potassium salt, closely resemble those for the analogous copper salt (Caven and Mitchell, J., 1924, **125**, 1428).

Copper Sodium Sulphate.—A study of the results for the $CuSO_4$–Na_2SO_4–H_2O system shows a number of interesting points (see Fig. 4):

1. Diacon's results at 0° have been confirmed: there is no formation of double salt, but an increase in solubility of each single salt is caused by the presence of the other.

2. At 25°, the range of double salt formation is fairly wide. The addition of each component increases the solubility of the other up to the corresponding triple point where the double salt begins to crystallise. In the case of copper sulphate, this increase is slight but definite, in agreement with Massink's results, but in contradiction to those of Koppel.

3. At 37·5°, the range of double salt formation is greatly increased. It is to be noted, however, that although copper sulphate still shows a slight increase of solubility in presence of sodium sulphate, sodium sulphate now shows a decrease of solubility in presence of copper sulphate. A change in the form of the isotherm here is to be expected owing to the change of hydration of solid sodium sulphate.

4. The increase in range of double salt formation with rise of temperature is connected with some remarkable relationships seen when the isotherms of different temperatures are compared. Thus, although the solubilities of the single salts at 20° are less than at 25°, the double salt curve at 20°, according to Massink, appears to coincide through part of its course with the corresponding curve of the authors at 25°; and the double salt curve at 37·5°, according to the authors' results, actually falls within the corresponding curve at 25°, and even recedes from it at the sodium sulphate end because of the shortness of the solubility curve of sodium sulphate which has become anhydrous. It is evident, moreover, that the extent of the

double salt curve at 37·5° is connected with the greatly increased solubility of sodium sulphate at that temperature.

5. Thus it is concluded from the authors' results at 25° and 37·5° that the solubility of the double salt decreases with rise of temperature; and it may be supposed that the solubility at 20° is actually slightly greater than that at 25°, although Massink's result compared with the authors' does not show this.

The authors wish to thank the Governors of the Royal Technical College for a Research Assistantship which has enabled one of them (W. J.) to participate in this research.

ROYAL TECHNICAL COLLEGE, GLASGOW. [*Received, August 6th*, 1927.]

CCCXVIII.—*Complex Metallic Ammines. Part IX. The Introduction of Nitrophenol Radicals into Cobaltammine Complexes. Distinctive Behaviour of Mononitrophenoxides.*

By JAMES COOPER DUFF and EDWIN JOHN BILLS.

IN Part VIII (J., 1923, **123**, 561) it was shown that sodium salts of carboxylic acids react with aquopentamminocobaltic nitrate to give acidopentamminocobaltic salts. The sodium derivatives of several nitrophenols have now been found to react similarly with aquopentamminocobaltic nitrate and with bisaquobisethylenediamminocobaltic salts. Mono-, di-, and tri-nitrophenols have been used to examine as far as possible the influence of the number and the orientations of the nitro-groups. The unexpectedly varying nature of the series of compounds obtained is discussed below.

Previously the only nitrophenol which had been found to give cobaltammine derivatives was picric acid. Morgan and King (J., 1922, **121**, 1723) have described the reactions which occur between several cobaltammine salts and certain nitro-dyes. They found that sodium picrate reacts with aquopentamminocobaltic chloride to give aquopentamminocobaltic picrate, and suggested that nitro-dyes such as picric acid and dinitronaphthol do not, in their reactions with cobaltammines, become implicated in the cobalt complex, thus differing noticeably from the *o*-quinoneoxime (nitrosonaphthol) dyes examined similarly by Morgan and Smith (J., 1921, **119**, 704). The latter found that the quinoneoxime radical, although univalent as regards principal valency, functions as a chelate group in the complex, being linked to cobalt through a principal valency (electro-valency) and a residual valency (co-

valency). Morgan and King further suggest (*loc. cit.*) that the lack of residual valency shown by the picrate radical may be taken as evidence corroborating its *p*-quinonoid structure. In no case did they find that the picrate radical became part of the cobalt complex. It has now been found that nitrophenoxide radicals can be induced to form part of the complex, particularly in the tetrammine type. In most cases, the nitrophenoxide radicals were linked through a principal valency, but two outstanding examples have been obtained in which a complete molecule of nitrophenol appears to be implicated in the complex through residual valency.

The mononitrophenoxides have yielded results which indicate a structural difference between *m*-nitrophenol and the *o*- and *p*-isomerides, the quinone structure probably applying to the last two but not to the first. The evidence supports the views of Hantzsch (*Ber.*, 1907, **40**, 330) and of Hewitt, Johnson, and Pope (J., 1913, **103**, 1626) on these compounds.

Conductivity measurements have been used in the present work as the best method available for determining whether a nitrophenoxide radical is within the complex ion or not. It was recorded in Part VIII (*loc. cit.*) that during conductivity measurements with dilute solutions, the platinum-black of the electrodes was capable in the case of compounds of the type $[Co(NH_3)_5X]NO_3$ (X = a dibasic acid radical) of causing internal hydrolysis, changing the acido-salt into an aquo-salt. Examples of this effect have again been encountered (see Experimental), although the compounds concerned are different in type from those in Part VIII. There has also been found in the case of a *p*-nitrophenol derivative (p. 2373) an example where the platinum-black apparently induces the displacement of water from the complex by a nitrophenoxide radical. This is the only case where a fall in the value for μ has been found to occur as the result of the catalytic influence of platinum-black. It should be noted that neither type of change due to the platinum-black requires any current to be passing between the electrodes. As a further check on the value of the conductivity figures those of the corresponding sodium nitrophenoxides are given at the end of this paper.

The Pentammine Compounds.

Sodium mono- and di-nitrophenoxides form alkaline aqueous solutions which complicate the reactions with aquopentamminocobaltic nitrate. In each case there was liberation of nitrophenol and no cobaltammine compound containing *o*- or *m*-nitrophenol could be separated. The reaction in these two cases was nearly quantitatively that of the equation $[Co(NH_3)_5,H_2O](NO_3)_3 + NaO\cdot C_6H_4\cdot NO_2 = [Co(NH_3)_5(OH)](NO_3)_2 + NaNO_3 + HO\cdot C_6H_4\cdot NO_2$.

Sodium *p*-nitrophenoxide, in addition to yielding some free *p*-nitrophenol, gave a fair yield of p-*nitrophenoxopentamminocobaltic* p-*nitrophenoxide* [I; X = *p*-$C_6H_4(NO_2)\cdot O\cdot$].

$[Co(NH_3)_5X]X_2$ (I.) $\quad [Co(NH_3)_5,H_2O]X_3$ (II.) $\quad \left[Co(NH_3)_5X\right]\begin{matrix}X\\OH\end{matrix}$ (III.)

It is of interest that of the three nitrophenols only the *p*-isomeride is capable of combining with the corresponding sodium derivative; this may account for the subsequent production of a pentammino-derivative in this case, and explain the lack of success with *o*- and *m*-nitrophenols. By using the double compound of sodium *p*-nitrophenoxide and *p*-nitrophenol, a better yield of the compound (I) is obtained.

The sodium derivatives of 2 : 4- and 2 : 6-dinitrophenols gave simple aquopentammino-salts [II; X = $C_6H_3(NO_2)_2\cdot O\cdot$]. Sodium picrate yielded *picratopentamminocobaltic picrate* [I; X = $C_6H_2(NO_2)_3\cdot O\cdot$]; its relation to the aquo-picrate prepared by Morgan and King (*loc. cit.*) is considered in the experimental part. When picric acid reacts with carbonatopentamminocobaltic nitrate, two compounds can be obtained. If the carbonato-salt is used in excess, there is produced a basic salt (III), otherwise the normal compound (I) is again obtained.

The two compounds of special interest in this section are those of *p*-nitrophenol and of picric acid (III). Both these undergo a change of conductivity in the Kohlrausch cell with platinised electrodes at the ordinary temperature; this only ceases when an aquo-salt has resulted in each case:

$$[Co(NH_3)_5X]X_2 + H_2O \longrightarrow [Co(NH_3)_5,H_2O]X_3$$

Thus for the *p*-nitrophenol compound μ (for $v = 1024$) changes from 177·7 to 322·5 in 24 hours, accompanied by a colour change, while the stock solution shows but little hydrolysis after 3 months in a stoppered flask. The solutions which have been catalytically hydrolysed in the cell remain permanently hydrolysed.

The Bisethylenediammine Compounds.

The sodium derivatives of all the nitrophenols examined react with bisaquobisethylenediamminocobaltic bromide to give crystalline compounds containing nitrophenol groups. The resulting compounds showed unusual differences. Sodium picrate gave *aquopicratobisethylenediamminocobaltic picrate* (IV; X = picrate radical) and sodium 2 : 4-dinitrophenoxide gave a similar compound (as IV),

whilst the 2 : 6-isomeride yielded a basic salt (V; X = 2 : 6-dinitrophenoxide radical).

(IV.) $\left[\begin{matrix}H_2O\\X\end{matrix}Co\,en_2\right]X_2$ $\left[\begin{matrix}H_2O\\X\end{matrix}Co\,en_2\right]\begin{matrix}OH\\X\end{matrix}$ (V.)

The outstanding results in this section were obtained from the mononitrophenoxides. One circumstance common to all three isomerides was that the resulting cobaltammine compounds contained a molecule of nitrophenol in addition to three nitrophenoxide radicals. The manner in which this nitrophenol molecule occurs in the compound is different in each case. Sodium *m*-nitrophenoxide produced a molecular compound between *bis*-m-*nitrophenoxobisethylenediamminocobaltic* m-*nitrophenoxide* and *m*-nitrophenol (VI; X = *m*-nitrophenoxide radical), in which the latter molecule is outside the complex.

(VI.) $[Co\,en_2\,X_2]X,HX$ $\left[\begin{matrix}X\\HX\end{matrix}Co\,en_2\right]X_2$ (VII.)

From sodium *o*- and *p*-nitrophenoxides it was possible to obtain *nitrophenolnitrophenoxobisethylenediamminocobaltic nitrophenoxide* (VII; X = *o*- or *p*-nitrophenoxide radical). This is a new type of compound because the complete molecule of *o*- or *p*-nitrophenol is linked by residual valency (co-valency) in the same manner as a molecule of water in the case of aquocobaltammine salts. Formula (VII) is supported by the facts that (1) unlike all other compounds in this series, the aqueous solutions of the two salts concerned can be acidified without discharging the yellow or red colour, respectively, of the *p*- or *o*-nitrophenol compound, and (2) the aqueous solutions of these two salts when heated and then cooled and acidified have their colour discharged, yet the heating has caused no change in the values for molecular conductivity. This means that the substances hydrolyse in hot solutions, but only to the extent of having the molecule of nitrophenol displaced by a molecule of water, as in (IX) :

(VIII.) $\begin{matrix}[XCo\,en_2]\,X_2\\ O{=}C_6H_4{=}NO_2H\end{matrix} + H_2O \longrightarrow \left[\begin{matrix}X\\H_2O\end{matrix}Co\,en_2\right]X_2,HX.$ (IX.)

Since the molecule of nitrophenol in the complex is apparently concerned in the colour of the cold acid solution, it would appear reasonable to attribute to this complete nitrophenol molecule in the complex the corresponding *o*- or *p*-quinonoid structure (VIII), especially as the red and yellow colours of the respective compounds correspond to those of *o*- and *p*-quinones. An important point in this connexion is the fact that no free *o*-, *m*-, or *p*-nitrophenol was present at the beginning of the preparation of these compounds. The nitrophenol was liberated in each case during the reaction

between the sodium derivative and the bisaquocobaltammine salt, the probable reaction being as follows :

$$[\mathrm{Co\,en_2\,(H_2O)_2}]\mathrm{Br_3} + \mathrm{NaO{\cdot}C_6H_4{\cdot}NO_2} \longrightarrow \left[\begin{matrix}\mathrm{H_2O}\\ \mathrm{HO}\end{matrix}\mathrm{Co\,en_2}\right]\mathrm{Br_2} + \mathrm{NaBr} + \mathrm{HO{\cdot}C_6H_4{\cdot}NO_2}.$$

The foregoing results suggest that whilst sodium *m*-nitrophenoxide is not quinonoid in structure, yet the *o*- and *p*-nitrophenoxides probably are; and further, when these are decomposed as in the above equation, the newly-liberated nitrophenol has the quinonoid structure and is linked up in this form in the complex in place of water.

Whilst only one cobaltammine compound of this series could be isolated from each of the *o*- and *m*-nitrophenoxides, the *p*-nitrophenoxide was found capable of producing three others in addition to (VII); by use of its addition compound with *p*-nitrophenol, $\mathrm{NaC_6H_4O_3N,C_6H_5O_3N,2H_2O}$, two compounds represented by (IV) and (IX) were obtained by varying the conditions of reaction. In dilute aqueous solution, particularly in the presence of platinum-black, both these compounds undergo change, a nitrophenoxide radical entering the complex and displacing water :

$$\left[\begin{matrix}\mathrm{X}\\ \mathrm{H_2O}\end{matrix}\mathrm{Co\,en_2}\right]\mathrm{X_2,HX} \longrightarrow [\mathrm{Co\,en_2\,X_2}]\mathrm{X,HX} + \mathrm{H_2O}.$$

On attempting to recrystallise compound (IX) from hot water, some nitrophenol is liberated, yet from the solution it is possible to obtain crystals of the molecular compound *bis*-p-*nitrophenoxobisethylenediamminocobaltic* p-*nitrophenoxide*–p-*nitrophenol* (as VI), corresponding to that obtained from *m*-nitrophenol.

Experimental.

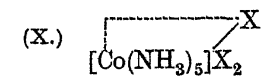
Electrical Conductivity Measurements.—The method of measurement recorded in Part VII (J., 1922, **121**, 453) was adopted. Since most of the compounds were only moderately soluble, measurements were limited to $v = 1024$ and 2048 at 25°, at which temperature all determinations were made. Fresh solutions were made for each. The Kohlrausch cell constant was 0·2117 and the resistances measured did not greatly exceed 5000 ohms. Where conductivity changes due to the platinised electrodes were found, these were checked on new solutions. To find the extent to which change occurred it was usually necessary to leave the cell solution and the stock solution for 24 hours in the thermostat and then redetermine μ for each. No attempt was made to compare the rates at which changes occurred, as it was noted that these only took place in the neighbourhood of the electrodes. Samples of solutions which had

undergone change in this way were kept in closed tubes for 3 months and again examined. In no case had there been any tendency to revert to the original form. With unplatinised electrodes practically no catalytic effect was noticeable.

The Pentammine Series.

The Cobaltammine Reagent.—5 G. of carbonatopentamminocobaltic nitrate, 30 c.c. of water, and 20 c.c. of 2*N*-nitric acid were maintained at 45° until effervescence ceased. The solution was neutralised with 2*N*-sodium hydroxide. For the following compounds, this reagent was mixed at 45° with a solution of the corresponding sodium derivative (3 mols.) in the minimum amount of water. Except in the case of the picrate it was necessary to extract the washed precipitate with alcohol and ether to remove free nitrophenol or dinitrophenol. The product was then crystallised from water at 65°.

Sodium *o*- and *m*-nitrophenoxides produced only a precipitate of free nitrophenol. On addition of sufficient alcohol to retain this in solution, long red needles slowly separated; these were identified by analysis and reactions as hydroxopentamminocobaltic nitrate (see equation, p. 2366).



The following compounds are all easily decomposed by dilute acid or alkali. In the crystalline form and in solution, they begin to decompose at 70—80°.

p-*Nitrophenoxopentamminocobaltic* p-*nitrophenoxide* (as I; with $3H_2O$) was obtained in minute, orange, oblong plates (Found: Co, 9·34; NH_3, 13·76; nitrophenoxide, 67·8; H_2O, 8·21. $C_{18}H_{27}O_9N_8Co,3H_2O$ requires Co, 9·64; NH_3, 13·88; nitrophenoxide, 67·64; H_2O, 8·82%). By the use of the addition compound of sodium *p*-nitrophenoxide and *p*-nitrophenol, the same compound was obtained in better yield (Found: Co, 9·24; nitrophenoxide, 65·77%); $\mu_{1024} = 177{\cdot}7$ and $\mu_{2048} = 189{\cdot}2$; 24 hours later the cell solution had $\mu_{1024} = 322{\cdot}5$ and $\mu_{2048} = 322{\cdot}2$, whilst the stock solution had $\mu_{1024} = 181{\cdot}2$ and $\mu_{2048} = 189{\cdot}4$. The cell solution had become greenish-yellow, whilst the flask solution remained golden-yellow. The solutions were kept sealed for 3 months, and the two cell solutions then had $\mu_{1024} = 340{\cdot}5$ and $\mu_{2048} = 342{\cdot}8$, and the stock solutions $\mu_{1024} = 208{\cdot}4$ and $\mu_{2048} = 245{\cdot}3$. A few minutes in the cell caused a greater change than 3 months in the stock flask.

Aquopentamminocobaltic 2 : 4-*dinitrophenoxide* (as II; with $3H_2O$) was obtained as an orange, sandy, crystalline powder (Found: Co, 7·72; NH_3, 11·11; dinitrophenoxide, 71·88; H_2O, 8·86. $C_{18}H_{26}O_{16}N_{11}Co,3H_2O$ requires Co, 7·71; NH_3, 11·11; dinitrophenoxide, 71·76; H_2O, 9·41%); $\mu_{1024} = 284$ and $\mu_{2048} = 291{\cdot}6$.

Aquopentamminocobaltic 2 : 6-*dinitrophenoxide* (as II) was obtained as an orange-red, microcrystalline powder, only sparingly soluble in water (Found : Co, 8·29; NH_3, 12·20; dinitrophenoxide, 77·68. $C_{18}H_{26}O_{16}N_{11}Co$ requires Co, 8·29; NH_3, 11·95; dinitrophenoxide, 77·21%); $\mu_{2048} = 318{\cdot}4$.

Picratopentamminocobaltic picrate (as I; with $3H_2O$) was obtained in glistening, golden leaflets (Found : Co, 6·53; NH_3, 9·53; picrate, 78·2; H_2O, 6·91. $C_{18}H_{21}O_{21}N_{14}Co,3H_2O$ requires Co, 6·68; NH_3, 9·63; picrate, 77·55; H_2O, 6·12%). The same compound resulted from the reaction between picric acid (3 mols.) and carbonatopentamminocobaltic nitrate (Found : Co, 6·35; NH_3, 9·28; picrate, 76·8%). For conductivity measurements it was difficult to obtain a solution for $v = 2048$ without heating to 60°, and this apparently caused some hydrolysis. At 25°, $\mu_{2048} = 304$, changing in the cell in 2 days to 359·1. In view of this somewhat high value for an acidopentammine salt, the compound described by Morgan and King (*loc. cit.*) was prepared and examined : at 25°, $\mu_{2048} = 288$, changing in 3 hours in the cell to 360, and over-night to 415·3, whilst the stock solution only changed to $\mu_{2048} = 299$; it was noticed that the cell solution had changed from golden-yellow to greenish-yellow. These changes suggest that Morgan and King's compound $[Co(NH_3)_5H_2O]X_3$ is not simply an aquopentammine salt, as they assert. The molecule contains $2H_2O$ less than our compound and differs in appearance, but it can be changed to our picrato-salt by crystallisation from a hot dilute solution of picric acid. A possible explanation may be that in the compound of Morgan and King one of the picrate radicals is linked to the cobalt by residual valency and to the complex by principal valency as in (X). This could account

(X.) 

for the conductivity changes and the conversion by means of picric acid into our compound.

Picratopentamminocobaltic hydroxypicrate (III; with $2H_2O$) was obtained as a brown, microcrystalline powder by stirring powdered picric acid (1 mol.) into a concentrated solution of carbonatopentamminocobaltic nitrate at 60°. The product was recrystallised from water at 60° (Found : Co, 9·09; NH_3, 13·14; picrate, 69·85; H_2O, 5·18. $C_{12}H_{20}O_{15}N_{11}Co,2H_2O$ requires Co, 9·03; NH_3, 13·02; picrate, 69·83; H_2O, 5·51%); $\mu_{2048} = 203{\cdot}3$, changing in the cell in 12 hours to 352·2, while the stock solution remained at 203·3. The cell solution changed in colour from orange to greenish-yellow. After 3 months in a sealed tube, this solution gave $\mu_{2048} = 360$, whilst the stock solution gave 225·6. When the basic picrate was

dissolved in hot dilute picric acid solution, the normal picrato-salt separated on cooling.

Bisethylenediammine Series.

The Cobaltammine Reagent.—5 G. of carbonatobisethylenediamminocobaltic bromide, 30 c.c. of water, and 20 c.c. of 2*N*-nitric acid were maintained at 50° until effervescence ceased. The solution was neutralised with 2*N*-sodium hydroxide. It was freshly made for each of the following preparations.

o-*Nitrophenol*-o-*nitrophenoxobisethylenediamminocobaltic* o-*nitrophenoxide* (as VII; with $1H_2O$) was prepared by mixing the cobaltammine reagent at 50° with 7·5 g. of sodium *o*-nitrophenoxide (3 mols.) in 70 c.c. of water. After alcohol and ether extraction, the product was crystallised from water at 70°, yielding dark red, minute, glistening plates (Found: Co, 7·83; nitrophenoxide, 73·34. $C_{28}H_{33}O_{12}N_8Co,H_2O$ requires Co, 7·86; nitrophenoxide, 73·60%). The aqueous solution is red and changes to a more scarlet tint on addition of dilute mineral acids, with separation of some nitrophenol. The acid solution becomes faintly pink on boiling. A fresh aqueous solution of the compound becomes yellow when immersed in boiling water, and subsequent addition of acid gives only the pink colour of aquocobaltammine inorganic salts. It is inferred from these reactions that a complete molecule of *o*-nitrophenol is within the complex and is only readily replaced by a molecule of water in hot solutions. Dilute alkali causes complete hydrolysis immediately. The compound is appreciably soluble in alcohol and in acetone, but not sufficiently soluble to serve for an accurate estimation of the molecular weight: values obtained ebullioscopically ranged from 780 to 900. $\mu_{1024} = 135{\cdot}6$ and $\mu_{2048} = 142{\cdot}2$. After the latter solution had been heated on the water-bath to change the colour from red to yellow, μ_{2048} became 140·2.

Bis-m-*nitrophenoxobisethylenediamminocobaltic* m-*nitrophenoxide* + m-*nitrophenol* (as VI; with $1H_2O$) was obtained when the cobaltammine reagent at 50° was mixed with 7·5 g. of sodium *m*-nitrophenoxide in 70 c.c. of water. The mixture was filtered at 25° and the solution left over-night. The desired compound was obtained in brownish-red nodules (Found: Co, 7·81; nitrophenoxide, 72·98. $C_{28}H_{33}O_{12}N_8Co,H_2O$ requires Co, 7·86; nitrophenoxide, 73·6%). The aqueous solution is yellow and addition of dilute acid renders it pink, with liberation of all the nitrophenol; $\mu_{1024} = 75{\cdot}7$ and $\mu_{2048} = 71{\cdot}5$. The former value is high because of hydrolysis during the preparation of the solution. After this solution had been heated on the water-bath for 30 minutes, μ_{1024} became 101·5.

p-Nitrophenol was found capable of yielding the compounds A, B, C, D, as follows.

A. p-*Nitrophenol*-p-*nitrophenoxobisethylenediamminocobaltic* p-*nitrophenoxide* (as VII; with $3H_2O$). To obtain this compound it was necessary to use a solution of sodium *p*-nitrophenoxide freshly prepared from the nitrophenol: the use of the crystallised salt resulted in a mixture of A and C. The cobaltammine reagent at 50° was mixed with a solution of 6·5 g. of *p*-nitrophenol in 46·8 c.c. of *N*-sodium hydroxide and 40 c.c. of water. The precipitate, washed with alcohol and ether to remove *p*-nitrophenol, was crystallised from water at 70°. In this way, A was obtained in dark brown microcrystals which assumed a purple shade on dehydration at 90° (Found: Co, 7·30; nitrophenoxide, 69·45; H_2O, 6·72. $C_{28}H_{33}O_{12}N_8Co,3H_2O$ requires Co, 7·50; nitrophenoxide, 70·23; H_2O, 6·87%). The compound is appreciably soluble in alcohol and acetone. The aqueous solution is orange and when acidified retains a yellow colour for several minutes. If the solution is heated, then cooled and acidified, it becomes pink immediately. $\mu_{1024} = 130·2$ and $\mu_{2048} = 139·6$. After the latter solution had been heated for 15 minutes at 90° it had $\mu_{2048} = 125·7$, changing in the cell to 91·0 after 24 hours and 78·8 after 48 hours. This indicates a change from A through C into D (p. 2374). The hydrated salt changes slowly in the solid state, passing into the compound C, since after 4 months it gave aqueous solutions which at once became pink on being acidified. The anhydrous form of the salt is more stable.

B. *Aquo*-p-*nitrophenoxobisethylenediamminocobaltic* p-*nitrophenoxide* (as IV; with $2H_2O$) was obtained as a light brown, crystalline powder when the cobaltammine reagent was mixed at 70° with 15 g. of the double compound of sodium *p*-nitrophenoxide and *p*-nitrophenol in 200 c.c. of water. The precipitate was filtered immediately and free nitrophenol removed by ether extraction (Found: Co, 9·14; nitrophenoxide, 63·83. $C_{22}H_{30}O_{10}N_7Co,2H_2O$ requires Co, 9·11; nitrophenoxide, 63·98%). An aqueous solution is immediately decomposed by dilute acid, a distinction from A. On heating to 80°, the aqueous solution decomposes with separation of *p*-nitrophenol, yet the impure crystals which separate on cooling contain more than three equivalents of nitrophenoxide. There is evidently a tendency for B to pass into the more stable compound C. $\mu_{1024} = 115·8$ and $\mu_{2048} = 122·8$; the latter changes in the cell to 84·3.

C. *Aquo*-p-*nitrophenoxobisethylenediamminocobaltic* p-*nitrophenoxide* + p-*nitrophenol* (as IX; with $1H_2O$) was obtained in orange-brown microcrystals by mixing the cobaltammine reagent with 15 g. of the double sodium salt in 200 c.c. of water at 40°, filtering the solution after 2 hours, and removing free *p*-nitrophenol by ether

extraction (Found: Co, 7·74; nitrophenoxide, 71·34; H_2O, 3·8. $C_{28}H_{35}O_{13}N_8Co,H_2O$ requires Co, 7·68; nitrophenoxide, 71·87; H_2O, 4·68%). In solution, C behaves similarly to B. $\mu_{1024} = 119·5$ and $\mu_{2048} = 118·8$; after 24 hours in the cell $\mu_{2048} = 70·1$ while the stock solution gave $\mu_{2048} = 117·9$. The results support the change of C into D as below.

D. *Bis*-p-*nitrophenoxobisethylenediamminocobaltic* p-*nitrophenoxide* + p-*nitrophenol* (as VI; with $2H_2O$) was obtained from C above by crystallising it from water at 70°, filtering the solution from liberated *p*-nitrophenol, and leaving it over-night; the salt separated in dark brown nodules (Found: Co, 7·73; nitrophenoxide, 71·9; H_2O, 5·23. $C_{28}H_{33}O_{12}N_8Co,2H_2O$ requires Co, 7·68; nitrophenoxide, 71·87; H_2O, 4·68%). The yellow colour of the aqueous solution is changed to pink immediately by dilute acid. $\mu_{1024} = 88·0$ and $\mu_{2048} = 70·1$; the high value for μ_{1024} is due to the fact that the solution had been prepared at 40°.

Aquo-2 : 4-*dinitrophenoxobisethylenediamminocobaltic* 2 : 4-*dinitrophenoxide* (as IV; with $1H_2O$) was prepared by mixing the cobaltammine reagent at 60° with 9·6 g. of sodium 2 : 4-dinitrophenoxide (3 mols.) in 200 c.c. of water. After being washed, finally with ether, the pure compound crystallised from water at 70° in orange-red microcrystals (Found: Co, 7·71; dinitrophenoxide, 70·55; H_2O, 4·13. $C_{22}H_{27}O_{16}N_{10}Co,H_2O$ requires Co, 7·72; dinitrophenoxide, 71·86; H_2O, 4·71%); $\mu_{2048} = 184·1$—it was necessary to warm to 60° to obtain this solution.

Aquo-2 : 6-*dinitrophenoxobisethylenediamminocobaltic hydroxy*-2 : 6-*dinitrophenoxide* (as V) was obtained in brown microcrystals by the analogous method (Found: Co, 10·02; dinitrophenoxide, 63·45. $C_{16}H_{25}O_{12}N_8Co$ requires Co, 10·17; dinitrophenoxide, 63·10%); $\mu_{2048} = 165·7$.

Aquopicratobisethylenediamminocobaltic picrate (IV; with $4H_2O$) was obtained in orange, flat needles from the cobaltammine reagent and 12 g. of sodium picrate in 200 c.c. of water by the method used for the two preceding compounds (Found: Co, 6·16; picrate, 72·7; H_2O, 9·69. $C_{22}H_{24}O_{22}N_{13}Co,4H_2O$ requires Co, 6·18; picrate, 71·77; H_2O, 9·44%). The same compound was produced by the action of excess of picric acid in solution on carbonatobisethylenediamminocobaltic bromide at 60° (Found: Co, 6·32; picrate, 70·84%); $\mu_{2048} = 251·7$, without change in the cell on standing.

Analysis.—In both series cobalt was determined directly as sulphate by heating the compounds with concentrated sulphuric acid. The nitrophenols were estimated by heating with excess of titanous chloride solution and titrating the excess with standard ferric alum solution: in the pentammine series this was done after

precipitation of cobalt with sodium hydroxide, but in the bisethylenediammine series it was necessary to let the titanous chloride reduce both the cobaltic complex and the nitrophenol and subsequently to allow for the cobalt present. No estimation of ethylenediamine was made, since all the compounds in this series were found to yield the green *trans*-dichlorobisethylenediamminocobaltic chloride on evaporation with hydrochloric acid.

As standards for the conductivity values, the following values were determined (at 25°) for the various sodium derivatives of the nitrophenols :

	μ_{1024}.	μ_{2048}.
Sodium *o*-nitrophenoxide	82·0	92·9
Sodium *m*-nitrophenoxide	82·35	92·6
Sodium *p*-nitrophenoxide	86·35	90·0
Sodium 2 : 4-dinitrophenoxide	82·6	90·6
Sodium picrate	82·6	91·6

CENTRAL TECHNICAL COLLEGE,
BIRMINGHAM.

[*Received, July 15th*, 1927.]

CCCXIX.—*The Preparation of some Nitrohydroxybenzaldehydes and the Colour Relationships of their Substituted Phenylhydrazones.*

By HERBERT HENRY HODGSON and HERBERT GREENSMITH BEARD.

MONONITRO-*m*-HYDROXYBENZALDEHYDES were first described by Tiemann and Ludwig (*Ber.*, 1882, **15**, 2043) but correctly oriented by Friedländer and Schenck (*Ber.*, 1914, **47**, 3040), whilst Friedländer and Schreiber (*Ber.*, 1895, **28**, 1382) described the mononitration of *m*-methoxybenzaldehyde, thereby completing previous work by Ulrich (*Ber.*, 1885, **18**, 2571) and Rieche (*Ber.*, 1889, **22**, 2349). Tiemann and Ludwig's α- and β-dinitro-*m*-methoxybenzaldehydes, m. p.'s 155° and 110°, respectively, have not, however, been oriented; this problem, together with an investigation on the di- and trinitro-*m*-hydroxy- and the dinitro-*p*-hydroxy-benzaldehydes, is now dealt with.

Controlled direct dinitration of *m*-hydroxybenzaldehyde proved impracticable, the reaction products containing unchanged material and inseparable mixtures of nitro-compounds. Nitration of 6-nitro-3-hydroxybenzaldehyde gave two dinitro-products, m. p.'s 94° and 106°, whereas nitration of 2- and 4-nitro-3-hydroxybenzaldehydes gave single products melting at 94° and 106°, respectively, which must therefore be the 2 : 6- and 4 : 6-*dinitro-3-hydroxybenzaldehydes*. These could not be methylated by the ordinary methods, but a mixture of 2 : 6- and 4 : 6-*dinitro-3-methoxybenz-*

aldehydes was obtained by the dinitration of *m*-methoxybenzaldehyde at a lower temperature than that employed by Tiemann and Ludwig (*loc. cit.*), and separated by fractional crystallisation from hot benzene, in which the latter is five times more soluble than the former. Confirmation of their constitutions was obtained by nitration of the 6-, 4-, and 2-nitro-3-methoxybenzaldehydes, the first giving a mixture of two products, m. p.'s 157° and 131°, and the other two giving single products, of m. p.'s 131° and 157°, which are therefore 4 : 6- and 2 : 6-dinitro-3-methoxybenzaldehyde, respectively. Tiemann's α-compound (*loc. cit.*) is consequently the 2 : 6-dinitro-isomeride, whereas his β-compound is a mixture of this with the 4 : 6-isomeride.

All three mononitro- and both dinitro-3-hydroxybenzaldehydes give the same trinitrated product, which must therefore be the 2 : 4 : 6-*trinitro-3-hydroxybenzaldehyde*.

Nitration of 3-nitro-4-hydroxybenzaldehyde with pure nitric acid gives 3 : 5-*dinitro-4-hydroxybenzaldehyde*, but if sulphuric acid is present only picric acid is formed. It is noteworthy that the introduction of two nitro-groups into either *m*- or *p*-hydroxybenzaldehyde or their chloro-derivatives (Hodgson and Beard, J., 1926, 2030) gives products which all melt between 90° and 110°.

The facility of decomposition of the *p*-nitrophenylhydrazones of the various nitrohydroxybenzaldehydes appears to depend upon the positions of the nitro-groups in the aldehyde residue, *e.g.*, 2 : 6-dinitro-3-hydroxy- and -3-methoxybenzaldehyde-*p*-nitrophenylhydrazones explode at about 240° and 260°, respectively, whereas the 4 : 6-dinitro-isomerides are stable above 300°.

Colours and Colour-reactions.

The colours of the nitro- and *p*-bromo-phenylhydrazones of the above aldehydes, both as solids and in aqueous and alcoholic alkaline solution, are discussed in relation to positional influences.

Acidic groups in both *o*-positions to the aldehyde radical reduce the depth of colour of the solid phenylhydrazones in a similar way to that found by Chattaway and Clemo (J., 1923, **123**, 3041) for the hydrazine nucleus; thus, the phenylhydrazones of 2- and 3-nitrobenzaldehydes are respectively crimson and deep bright orange, whereas those of the corresponding dichloro-derivatives (2 : 5-dichloro-6-nitro- and -3-nitro-benzaldehydes) are orange-yellow and orange; the introduction of a *p*-nitro-group into the hydrazine nucleus causes a further reduction of colour, *e.g.*, to a pale yellow in the case of 2 : 5-dichloro-6-nitrobenzaldehyde-*p*-nitrophenylhydrazone.

The presence of the hydroxyl group modifies Chattaway and

Clemo's generalisation, for the *p*-nitrophenylhydrazone of 2-nitro-3-hydroxybenzaldehyde is much darker than that of the 6-nitro-isomeride, although the nitro-group is ortho in each case; methylation of the hydroxyl group, however, removes the disturbing effect, the *p*-bromophenylhydrazones of 2-nitro-3-hydroxy- and -3-methoxybenzaldehydes being deep nigre-brown and bright orange, respectively.

Alcoholic solutions of the hydrazones now described obey Chattaway and Clemo's generalisation. The exceptional case quoted by them—the phenylhydrazone of 2 : 5-dichloro-6-nitrobenzaldehyde—is not repeated, however, in the *p*-nitrophenylhydrazone of this aldehyde, which, instead of merely affording the magenta colour characteristic of substituted phenylhydrazones, as would be expected if the exceptional character persisted, now gives a pronounced blue colour, showing that the nitro-group in the aldehyde residue is again functioning in a quinonoid structure.

2 : 5-Dichloro-3-nitrobenzaldehydephenylhydrazone gives the pronounced brown colour with alkalis associated with Chattaway and Clemo's scheme, but the *p*-nitrophenylhydrazone gives a blue and not a magenta colour as expected.

The magenta colours given by *m*-hydroxy- and nitro-*m*-hydroxybenzaldehyde-*p*-nitrophenylhydrazones persist to much greater dilutions than if the hydroxyl group is absent, and that these colours are not due to salt formation alone is shown by the fact that the *m*-nitrophenylhydrazone of the *m*-hydroxyaldehyde gives no colour reaction.

The *p*-bromophenylhydrazones of the nitrohydroxyaldehydes are colourless in aqueous alkaline solution, thus, by contrast with the foregoing, showing that the methine group is far more resistant to quinonoid formation than the imino-group. This same difference is also illustrated by the fact that when aqueous alkaline solutions of benzaldehyde-*p*-nitrophenylhydrazone and *p*-nitrobenzaldehyde-phenylhydrazone are diluted, the colour of the former persists to much greater dilutions (about 400-fold). Differential suppression of colour is shown by the sequence of colour changes (blue, violet, magenta) on dilution of *p*-nitrobenzaldehyde-*p*-nitrophenylhydrazone.

The pronounced colour effects in alcoholic alkaline solutions when a nitro-group is in the para-position in each nucleus suggest a double quinonoid structure (*e.g.*, $OK\cdot NO{:}C_6H_4{:}C{:}N\cdot N{:}C_6H_4{:}NO\cdot OK$), since in a mixture of two singly-quinonoid compounds the magenta of the hydrazine-quinonoid compound would predominate, as it does if a *m*-hydroxyl group is present in the aldehyde nucleus.

Correction.—Hodgson and Beard (J., 1926, 2034) nitrated what was thought to be pure 4-chloro-3-hydroxybenzaldehyde and

obtained what they regarded as the 2- and 6-nitro-derivatives. It is now found that the 4-nitro-3-hydroxybenzaldehyde from which the above chloro-derivative had been prepared contained some of its 2-nitro-isomeride—these two are very difficult to separate—and consequently the resulting chloro-compound was a corresponding mixture. The supposed 4-chloro-6-nitro-3-hydroxybenzaldehyde is now shown to be the 2-nitro-isomeride (by conversion to 2 : 4-dichloro-3-hydroxybenzaldehyde), and the supposed 4-chloro-2-nitro-3-hydroxybenzaldehyde is really the 2-chloro-4-nitro-compound (identified by mixed m. p. and comparison of semicarbazones and *p*-nitrophenylhydrazones).

EXPERIMENTAL.

Nitration of 6-Nitro-3-hydroxybenzaldehyde.—To the aldehyde (10 g.; m. p. 166°) in glacial acetic acid (30 c.c.) solution at 70°, nitric acid (10 c.c.; *d* 1·42) was added during ¼ hour; the mixture was kept for a further ¼ hour and poured into ice water (150 c.c.); and the voluminous mass of crystals (9 g.; m. p. 71—74°) which slowly separated was extracted with boiling water, which removed 2 : 6-dinitro- from the much less soluble 4 : 6-dinitro-3-hydroxybenzaldehyde.

Nitration of 2-Nitro-3-hydroxybenzaldehyde.—2 G. on similar treatment gave only the above water-soluble product (1·8 g.), identified by a mixed m. p. determination and through the *p*-nitro- and *p*-bromo-phenylhydrazones.

Nitration of 4-Nitro-3-hydroxybenzaldehyde.—The above treatment gave unchanged material only; nitration of a sulphuric acid solution by potassium nitrate (1 mol.) gave a mixture of 4 : 6-dinitro- and 2 : 4 : 6-trinitro-3-hydroxybenzaldehydes with unchanged material, whereas excess of potassium nitrate (2 mols.) gave mainly the trinitro-product. If the finely-powdered aldehyde (10 g.) was added gradually to well-stirred synthetic nitric acid (50 g.; 98%) at 5—10°, and the mixture was allowed to attain room temperature before being poured on ice (250 g.), the trinitro-product (3 g.) separated, and the 4 : 6-dinitro-compound (5·4 g.) could be salted out of solution. Identity of the latter with the less soluble product above was established as in the case of the more soluble product.

2 : 6-*Dinitro-3-hydroxybenzaldehyde* is more soluble in the usual solvents than its 4 : 6-isomeride, and crystallises from water in colourless needles, m. p. 94° (Found: N, 13·3. $C_7H_4O_6N_2$ requires N, 13·2%). On exposure to air, it acquires a deep brown colour, whereas its alcoholic solution turns green. The yellow *sodium* and dark orange *ammonium* salts are both very soluble in water, but the silver salt could not be obtained. The p-*nitrophenylhydrazone*, deep

terra-cotta needles which explode at 240—242°, and the p-*bromophenylhydrazone*, similar crystals, m. p. 166—167° (decomp.) (Found: Br, 20·8. $C_{13}H_9O_5N_4Br$ requires Br, 21·0%), were both crystallised from glacial acetic acid.

4 : 6-*Dinitro*-3-*hydroxybenzaldehyde* crystallises from dilute acetic acid in almost colourless needles, m. p. 106° (Found: N, 12·9%). The orange *sodium* and dark orange *ammonium* salts are very soluble in water, but the silver salt could not be prepared. The p-*nitrophenylhydrazone* forms deep reddish-orange needles, which decompose slowly at 282—283°; the p-*bromophenylhydrazone* forms dark crimson needles, m. p. 249—250° (decomp.) (Found: Br, 20·8%).

2 : 4 : 6-*Trinitro*-3-*hydroxybenzaldehyde* is produced when 6-nitro-3-hydroxybenzaldehyde (10 g.) in concentrated sulphuric acid (50 g.) is treated gradually with a mixture of nitric acid (25 c.c.; *d* 1·42) and sulphuric acid (25 c.c.; *d* 1·84) at 70—75°; the cooled mixture is poured on ice (200 g.); the precipitate crystallises from benzene in stout, colourless, hexagonal prisms, m. p. 161—162° (decomp.) (Found: N, 16·7. $C_7H_3O_8N_3$ requires N, 16·3%). The product is much more soluble in water than picric acid. The solutions in alkalis are deep red, although the *sodium* salt crystallises in bright yellow needles. The p-*nitrophenylhydrazone*, dark crimson needles, exploded violently at 228—230°, and the p-*bromophenylhydrazone*, deep olive-green parallelepipeds with metallic lustre, also exploded violently at 218—220° (Found: Br, 18·8. $C_{13}H_8O_7N_5Br$ requires Br, 18·8%). The *azine* was prepared by adding a mixture of hydrazine sulphate (1 g.), sodium hydroxide (3 c.c.; 20%), and water (5 c.c.) to a hot solution of the aldehyde (2 g.) in water (60 c.c.), and separated, on cooling, in bright yellow micro-needles; it is readily soluble in acetic acid (50%) and alcohol, insoluble in benzene and chloroform, and gives red solutions with alkalis; it explodes violently at 150—160°.

2 : 4 : 6-Trinitro-3-hydroxybenzaldehyde was also obtained from 2- and 4-nitro-3-hydroxybenzaldehyde, but the product from the latter was much less pure than in the other cases.

Dinitration of p-*Hydroxybenzaldehyde*.—Mixtures of nitric and sulphuric acids yielded only picric acid, but when 3-nitro-4-hydroxybenzaldehyde (10 g.) was added with stirring to nitric acid (80 g.; 98%) at 5° and the deep red solution was allowed to warm to 10° and then poured on ice (150 g.), a mixture (10 g.) of 3 : 5-dinitro-4-hydroxybenzaldehyde and picric acid was obtained, the latter being eliminated by one crystallisation from glacial acetic acid.

3 : 5-*Dinitro*-4-*hydroxybenzaldehyde* crystallises in colourless needles, m. p. 102—103° (Found: N, 13·1. $C_7H_4O_6N_2$ requires

N, 13·2%), which are moderately soluble in water; the *sodium* salt is pale orange. The p-*nitrophenylhydrazone*, deep orange microcrystals, slowly decomposes at 283—284°; the p-*bromophenylhydrazone*, brick-red needles, decomposes rapidly at 242—244° (Found: Br, 20·9. $C_{13}H_9O_5N_4Br$ requires Br, 21·0%); the *phenylhydrazone*, deep maroon needles, has m. p. 203° (Found: N, 18·6. $C_{13}H_{10}O_5N_4$ requires N, 18·5%).

Some Hydrazones of 3-*Nitro*-4-*hydroxybenzaldehyde*.—These were all crystallised from glacial acetic acid. Phenylhydrazone: dark red needles, m. p. 175—176° (slow decomp.) (Schöpff, *Ber.*, 1891, **24**, 3776, gives m. p. 175—176°). p-*Nitrophenylhydrazone*: dull orange needles, m. p. 247—249° (decomp.) (Found: N, 18·7. $C_{13}H_{10}O_5N_4$ requires N, 18·5%). p-*Bromophenylhydrazone*: bright red needles, m. p. 192—193° (Found: Br, 23·6. $C_{13}H_{10}O_3N_3Br$ requires Br, 23·8%).

Nitration of m-*Methoxybenzaldehyde*.—(a) *Mononitration*. Friedländer and Schreiber's conditions (*loc. cit.*), together with Rieche's test (*loc. cit.*) for the end-point of mononitration, gave no solid products until the temperature was allowed to rise to 20°; 40 g. of *m*-methoxybenzaldehyde then afforded 31g. of nitrated product and 15 g. of unchanged material. By the use of 85% nitric acid, however, 30 g. of nitrated products were obtained from 25 g. of aldehyde; when this yield was dissolved in hot benzene (20 g.) 2-nitro-3-methoxybenzaldehyde (11 g.) was deposited on cooling, and the mother-liquor contained some 6-nitro-3-methoxybenzaldehyde. No 4-nitro-3-methoxybenzaldehyde was ever isolated. Tröger and Fromm's statement (*J. pr. Chem.*, 1925, **111**, 217) that the 6-nitro-isomeride is absent has been shown to be incorrect, inasmuch as 6-nitro-3-methoxybenzoic acid has been isolated after oxidation of the foregoing mixture.

(b) *Dinitration*. Tiemann and Ludwig's conditions (*loc. cit.*) gave small yields accompanied by much charring; better results were obtained as follows: *m*-Methoxybenzaldehyde (10 g.) was added gradually to a mixture of potassium nitrate (17 g.) in concentrated sulphuric acid (80 g.) at 0—5°, then poured on ice, and the resulting colourless solid (12·4 g.) was extracted twice with boiling water, which dissolved Tiemann's β-compound (3 g.; m. p. 110—130°) and left the α-compound, which was almost pure 2 : 6-dinitro-3-methoxybenzaldehyde, m. p. 156—157° after one crystallisation from benzene. The β-compound (3 g.) was dissolved in hot benzene (16 g.), which deposited only 2 : 6-dinitro-3-methoxybenzaldehyde on cooling; the mother-liquor contained chiefly the 4 : 6-dinitro-isomeride. The total yields from the above nitration were 80% of 2 : 6- and 20% of 4 : 6-dinitro-3-methoxybenzaldehydes.

Nitration of 6-*Nitro*-3-*methoxybenzaldehyde*.—The aldehyde (10 g.) was added to nitric acid (100 c.c.; 98%) at 20°, kept for ½ hour, and then poured into ice water. The colourless solid (11·5 g.) which separated was fractionally crystallised from benzene and proved to be mainly 2 : 6- (m. p. 157°) with a little 4 : 6-dinitro-3-methoxybenzaldehyde.

Nitrations of 4- *and* 2-*Nitro*-3-*methoxybenzaldehydes*.—These aldehydes (10 g. each) gave almost pure 4 : 6- (10 g.; m. p. 127—131°) and 2 : 6-dinitro-3-methoxybenzaldehydes (11·5 g.; m. p. 152—156°) which melted at 131° and 157° respectively after one crystallisation from benzene.

2 : 6-*Dinitro*-3-*methoxybenzaldehyde* crystallises from benzene in stout, hexagonal prisms, m. p. 157° (Found : N, 12·4. $C_8H_6O_6N_2$ requires N, 12·3%); 5 g. require 60 g. of boiling benzene for complete solution. The p-*nitrophenylhydrazone* forms pale orange, elongated, hexagonal plates, which explode at about 260°, and the p-*bromophenylhydrazone* terra-cotta needles, m. p. 196—197° (decomp.) (Found : Br, 20·0. $C_{14}H_{11}O_5N_4Br$ requires Br, 20·2%). On being boiled with 50 c.c. of 1% potassium permanganate solution, the aldehyde (1 g.) was oxidised to 2 : 6-*dinitro*-3-*methoxybenzoic acid*. This forms colourless needles, m. p. 199° (Found : N, 11 9. $C_8H_6O_7N_2$ requires N, 11·6%), which give a yellow solution in aqueous sodium carbonate with liberation of carbon dioxide.

4 : 6-*Dinitro*-3-*methoxybenzaldehyde* crystallises from benzene in hexagonal prisms, m. p. 131° (Found : N, 12·3. $C_8H_6O_6N_2$ requires N, 12·3%); 5 g. require 12 g. of boiling benzene for complete solution; p-*nitrophenylhydrazone*, terra-cotta needles, m. p. above 300° without explosion (Found : N, 19·5. $C_{14}H_{11}O_7N_5$ requires N, 19·4%); p-*bromophenylhydrazone*, dull red needles, m. p. 254—256° (decomp.) (Found : Br, 20·3. $C_{14}H_{11}O_5N_4Br$ requires Br, 20·2%). Oxidation as above gave 4 : 6-dinitro-3-methoxybenzoic acid, m. p. 188—189° (Giua, *Gazzetta*, 1915, **45**, 352, gives m. p. 186—187°) (Found : N, 11·8. Calc. : N, 11·6%), which liberates carbon dioxide from sodium carbonate, but much less readily than its isomeride above.

Nitration of 2 : 5-*Dichlorobenzaldehyde*.—The method of Gnehm and Banziger (*Ber.*, 1896, **29**, 876) results in 2 : 5-dichloro-6-nitrobenzaldehyde (3 parts) and a second product (1 part) which has now been diagnosed as 2 : 5-*dichloro*-3-*nitrobenzaldehyde* (by conversion into 2 : 3 : 5-trichlorobenzaldehyde); it forms a *phenylhydrazone*, orange needles, m. p. 171°, and a p-*nitrophenylhydrazone*, deep orange needles, m. p. 290—292° (decomp.). On oxidation with alkaline permanganate, 2 : 5-*dichloro*-3-*nitrobenzoic acid* results; this crystallises from glacial acetic acid in colourless needles, m. p.

220° (the 6-nitro-acid has m. p. 143—144°) (Found: Cl, 30·1. $C_7H_3O_4NCl_2$ requires Cl, 30·0%).

2 : 3 : 5-*Trichlorobenzaldehyde* is volatile in steam, has a characteristic pungent odour, is soluble in the usual organic solvents, and crystallises from dilute alcohol in colourless needles, m. p. 56° (the 2 : 4 : 5-isomeride melts at 110—111°) (Found: Cl, 50·0. $C_7H_3OCl_3$ requires Cl, 50·1%). On oxidation with neutral permanganate, 2 : 3 : 5-trichlorobenzoic acid results, m. p. 162° (Cohen and Dakin, J., 1902, **81**, 1331, give m. p. 162°).

Additional Nitrophenylhydrazones used for Comparison Purposes.—All were crystallised from glacial acetic acid. They are tabulated under the heading of the components from which they were prepared.

Benzaldehyde.	Nitrophenylhydrazine.		M. p.
3-Hydroxy-	*o*	Terra-cotta needles	195°
,,	*m*	Deep crimson needles	209—210
,,	*p*	Terra-cotta needles	219—220
6-Nitro-3-hydroxy-	*o*	Deep terra-cotta needles	248—250 (slow decomp.)
,, ,,	*m*	Scarlet needles	257—258 (slow decomp.)
6-Nitro-3-methoxy-	*p*	Terra-cotta needles	281—283
4- ,, ,,	*p*	Saffron needles	257—258
2- ,, ,,	*p*	Curly orange needles	222—223
2 : 5-Dichloro-6-nitro-	*p*	Fine pale yellow needles	269—270 (decomp.)

Additional p-*Bromophenylhydrazones.*—All were crystallised from glacial acetic acid.

Benzaldehyde.		M. p.
6-Nitro-3-hydroxy-	Reddish-brown, hexagonal clusters	214—215°
4- ,, ,,	Crimson needles	179—180
2- ,, ,,	Nigre-brown needles	194—195 (rapid decomp.)
6-Nitro-3-methoxy-	Light crimson needles	235—236
4- ,, ,,	Pale orange needles	177—178
2- ,, ,,	Orange needles	193—194

Persistence of Colour Effects on Dilution.—Test. 0·01 G. of the hydrazone was treated with 15 c.c. of alcoholic potassium hydroxide (10 g. in 75 g. of solution), and the coloured mixture then gradually diluted with water.

(a) *Nitro-group in phenylhydrazine portion only.* The intense magenta-violet colour of benzaldehyde-*p*-nitrophenylhydrazone was not dispersed until 18,000 c.c. of water had been added.

(b) *Nitro-group in aldehyde portion only.* The deep greenish-blue colour of *p*-nitrobenzaldehydephenylhydrazone required only 35 c.c. of water for its dispersion.

Colours produced by Aqueous and Alcoholic Alkalis.—Test. 0·05 G. of hydrazone was treated with 5 c.c. of 10% aqueous or alcoholic potassium hydroxide. The hydrazones are tabulated as in the previous tables.

NOTES.

The Structure of Quinizarin. By ALBERT GREEN.

Two alternative schemes were advanced (J., 1926, 1430) for the reaction between quinizarin and thionyl chloride, the second of which suggested the replacement of a carbonyl oxygen atom by two atoms of chlorine. This is now shown to be improbable, for diacetylquinizarin (4 g.), m. p. 207—208°, after boiling with an excess of thionyl chloride for 2 hours, crystallised in the polymorphic form (3·8 g.), which was free from chlorine and melted, either alone or mixed with an authentic specimen, at 200°.

Although this lack of reactivity on the part of a derivative, in which the probably mobile hydrogens of the hydroxyl groups are replaced, would appear to invalidate the second mechanism suggested for the formation of 10-chloro-1-hydroxy-4 : 9-anthraquinone from quinizarin, it should not be held to dispose of it entirely, since there are many examples of carbonyl groups in free hydroxyanthraquinones showing properties different from those they display in simple derivatives. The *meso*-carbonyl groups influence, and are influenced by, substituents in the α-positions of anthraquinones : *e.g.*, whilst anthraquinone itself yields an oxime only with difficulty, 1-chloroanthraquinone easily gives the oxime; 1-hydroxyanthraquinone cannot be oximated, yet its ethers yield monoximes (Freund and Achenbach, *Ber.*, 1910, **43**, 3251).

Whilst it is clear, therefore, that any deduction from an experimental result obtained with an alkylated or acylated hydroxyanthraquinone should be applied to the hydroxy-compound itself with caution, nevertheless the work described above strengthens the first suggestion (*loc. cit.*), that quinizarin assumes a reactive *ortho*-quinonoid state (1 : 10-dihydroxy-4 : 9-anthraquinone) when it reacts with thionyl chloride to yield 10-chloro-1-hydroxy-4 : 9-anthraquinone. Furthermore, in this reaction only one of the hydroxyl groups is affected, and this affords experimental support

for the suggestion of Perkin (J., 1899, **75**, 433) that, although the two hydroxyls of quinizarin, under suitable conditions, may assume a double quinonoid change, in the case of the second hydroxyl group this change is not readily achieved and is of an unstable nature.

The materials used in this work were purchased from a grant made by the Research Fund Committee of the Chemical Society, whom the author wishes to thank.—THE EDWARD DAVIES LABORATORIES, UNIVERSITY COLLEGE OF WALES, ABERYSTWYTH. [*Received, June 28th*, 1927.]

Solubility of Cupric Sulphide in Alkali Sulphides in Presence of Sulpharsenates. By CHRISTINA DAVIES and ALEXANDER DONALD MONRO.

ALTHOUGH the slight solubility of cupric sulphide in yellow ammonium sulphide is well known, the enhanced solubility in presence of metals of the arsenic group has been little studied. Wohler (*Annalen*, 1840, **34**, 236) and Storch (*Ber.*, 1883, **16**, 2015) have shown that the sulpho-salts of these acids promote the solubility of cupric sulphide, but as no quantitative data were available a further study of the Cu–As system was made.

Solutions of various quantities of arsenic trioxide in hydrochloric acid were diluted and to each was added a solution containing 0·200 g. of copper. The mixture was completely precipitated as sulphide, which was filtered off, washed, and warmed with 50 c.c. of yellow ammonium sulphide [78·47 g. of sulphur and 73·26 g. of ammonia per litre, *i.e.*, approximately $(NH_4)_2S_2$]. The resulting mixture was filtered, and the filtrate treated with hydrochloric acid to precipitate copper and arsenic sulphides. After another filtration the precipitate was treated with warm dilute nitric acid to separate the copper, which, after evaporation with sulphuric acid, was precipitated and weighed as thiocyanate. The following results were obtained :

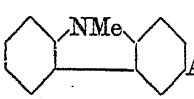
As present (mg.) ...	0	83·3	113·6	253·2	254·5	265·2	349·7	613·5
Cu dissolved (mg.)..	7·8	29·5	34·5	52·0	52·2	53·0	61·0	80·4

The amount of copper dissolved rises steadily with increasing amounts of arsenic until it becomes ten times its original value. This agrees with our observation that it is possible for small amounts of copper in copper–arsenic mixtures to be entirely missed in a qualitative analysis, unless the arsenic group is examined for copper.

A second series was tried in which colourless ammonium sulphide was substituted for yellow ammonium sulphide. No copper was found in the arsenic filtrate. Pure sodium sulphide gave irregular results. With 0·1600 g. of arsenic, 0·0373 g. of copper appeared

in the filtrates, but although two other results gave appreciable dissolved copper, other experiments gave negative results. Qualitative experiments showed that copper sulphide dissolved appreciably in presence of arsenic sulphide, giving unstable solutions from which cupric sulphide was reprecipitated on warming.

A solution of sodium polysulphide (16 g. of sulphur and 120 g. of $Na_2S,9H_2O$ per litre, *i.e.*, Na_2S_2) gave stable solutions containing arsenic and copper. The influence of arsenic was not so great as in the first series of experiments, but was by no means negligible. The results were as follows:



Cu taken, 0·200 g.; 50 c.c. of Na_2S_2 solution.

As (mg.)	0	149·2	237·7	365·5	480·0	620·2
Cu diss. (mg.).....	41·8	48·5	50·7	51·8	52·0	53·0

—UNIVERSITY OF GLASGOW. [*Received, June 25th*, 1927.]

9-*Methylcarbazole*-3-*arsinic Acid and its Reduction Products.* By HAROLD BURTON and CHARLES STANLEY GIBSON.

3-AMINO-9-METHYLCARBAZOLE was prepared from 9-methylcarbazole (Burton and Gibson, J., 1924, **125**, 2501) by nitration in acetic acid solution and reduction of the 3-nitro-9-methylcarbazole by means of tin and hydrochloric acid (Lindemann, *Ber.*, 1924, **57**, 555; Morgan and Read, J., 1922, **121**, 2715). It was characterised by its m. p., 173—174°, and by its acetyl derivative, m. p. 208—209° (Found: C, 75·65; H, 5·65. Calc.: C, 75·6; H, 5·9%). Lindemann (*loc. cit.*) gives m. p.'s 174° and 210°, respectively. On diazotisation in hydrochloric acid solution at the ordinary temperature (compare Morgan and Read, *loc. cit.*) and addition of an alkaline solution of β-naphthol, the deep red 9-*methylcarbazole*-3-*azo*-β-*naphthol* separated. This compound was obtained from its solution in acetic acid in small, deep red needles, m. p. 212° (decomp.) (Found: C, 78·5; H, 5·2; N, 12·1. $C_{23}H_{17}ON_3$ requires C, 78·6; H, 4·9; N, 12·0%).

9-*Methylcarbazole*-3-*arsinic Acid*,  .—A suspension of 3-amino-9-methylcarbazole (19·6 g.) in a mixture of water (250 c.c.) and concentrated hydrochloric acid (25 c.c.) was cooled below 10° and diazotised with sodium nitrite solution. The diazo-solution was then cooled to 0° and neutralised with cold sodium hydroxide solution. The neutralised solution was added gradually with stirring at room temperature to a solution of sodium arsenite (arsenious oxide, 15 g.; sodium carbonate, 24 g.; water, 105 c.c.), to which 10 c.c. of a 10% solution of copper sulphate

previously treated with ammonia had been added. After the addition was complete, the mixture was stirred for 1 hour, boiled, and filtered from tarry matter. The filtrate on acidification deposited the crude acid (10·5 g.); this crystallised from glacial acetic acid in clusters of small, colourless needles, which did not melt below 300° (Found: As, 24·3. $C_{13}H_{12}O_3NAs$ requires As, 24·6%).

9-*Methylcarbazole*-3-*arsenious Chloride*.—A boiling solution of 9-methylcarbazole-3-arsinic acid (5 g.) in alcohol (20 c.c.) and concentrated hydrochloric acid (20 c.c.) containing a trace of iodine was saturated with sulphur dioxide for 10 minutes. On cooling, the crude *chloroarsine* separated as a gummy mass which gradually solidified. It was purified by dissolving it in benzene, adding light petroleum to the hot solution until all the colouring matter was precipitated, and then filtering and cooling it; the chloroarsine separated in small, colourless prisms, m. p. 121—122° (Found: As, 22·6. $C_{13}H_{10}NCl_2As$ requires As, 23·0%).

9-*Methylcarbazole*-3-*arsenious Oxide*.—A solution of the chloroarsine in acetone was treated with ammonia, and the mixture well shaken. The precipitate was filtered off, washed with water until free from chloride, and dried. The *oxide* is insoluble in the ordinary organic solvents. It has m. p. 182—185° (decomp.) (Found: As, 27·3. $C_{13}H_{10}ONAs$ requires As, 27·7%).—Guy's Hospital Medical School (University of London), S.E.1. [*Received, July 26th*, 1927.]

Derivatives of o-*Aminophenylarsinic Acid*. By Harold Burton and Charles Stanley Gibson.

During the course of investigations which have been carried out on heterocyclic arsenic compounds, a number of simple arsinic compounds have been prepared which might be useful to other investigators.

o-*Ethylaminophenylarsinic Acid*, $NHEt{\cdot}C_6H_4{\cdot}AsO(OH)_2$.—Ethyl sulphate (17 g.) was added to a constantly stirred solution of *o*-aminophenylarsinic acid (21·7 g.) in sodium hydroxide solution (45 c.c., 10%), heated on the water-bath, and the clear solution heated for 10 minutes after the initial reaction had finished. The red oil which separated on cooling solidified and was recrystallised from water, forming colourless needles, m. p. 128—129° (yield, 6 g.) (Found: As, 30·7. $C_8H_{12}O_3NAs$ requires As, 30·6%). The *nitroso*-derivative was prepared by adding a solution of sodium nitrite (2·5 g.) to a solution of the acid (2 g.) in dilute hydrochloric acid. The crystalline product (1·7 g.), which gave Liebermann's nitrosoamine-reaction, was recrystallised from water and obtained in colourless needles, m. p. 160° (decomp.) (Found: As, 27·0.

$C_8H_{11}O_4N_2As$ requires As, 27·35%). The *acetyl* derivative (m. p. 187—188°), prepared in the usual way, was readily soluble in water and in the common organic solvents; its *silver* salt was analysed and the acid shown to be dibasic (Found: Ag, 43·0. $C_{10}H_{12}O_4NAsAg_2$ requires Ag, 43·1%).

3-*Nitro*-6-*diethylaminophenylarsinic Acid*,

$$NEt_2 \cdot C_6H_3(NO_2) \cdot AsO(OH)_2.$$

—For the preparation of this acid we required 4-*nitro*-2-*aminodiethylaniline*. This was prepared by the ammonium sulphide reduction of 2 : 4-dinitrodiethylaniline, and the product isolated as the crystalline *hydrochloride*, yellow prisms, m. p. 205—206°. The *benzylidene* derivative formed yellow needles, m. p. 97—98°, from alcohol (Found: C, 68·4; H, 6·6. $C_{17}H_{19}O_2N_3$ requires C, 68·7; H, 6·4%). The base itself was obtained as a red, viscous oil. The hydrochloride was suspended in water, diazotised, and reduced with sodium stannite, giving *p*-nitrodiethylaniline, m. p. 75°.

A mixture of 4-nitro-2-aminodiethylaniline hydrochloride (24·5 g.), water (150 c.c.), and concentrated hydrochloric acid (25 c.c.) was diazotised at 0° with a sodium nitrite solution (7 g.; 20 c.c.). This diazo-solution was added to a stirred solution consisting of sodium arsenite (arsenious oxide, 15 g.; crystalline sodium carbonate, 65 g.; water, 105 c.c.; 5*N*-sodium hydroxide, 40 c.c.) and 10 c.c. of a 10% solution of copper sulphate which had been treated with an excess of ammonia. The mixture was stirred until frothing had subsided and then warmed until all effervescence had ceased. After cooling, it was stirred with decolorising charcoal, filtered, and the filtrate acidified with hydrochloric acid (Congo-red). The acid (5·5 g.) was filtered off and crystallised from a large volume of water, from which it separated in glistening, yellow needles, m. p. 195—196° (decomp.) (Found: As, 23·5. $C_{10}H_{15}O_5N_2As$ requires As, 23·6%).

3-*Nitro*-6-*diethylaminophenylarsenious Chloride*,

$$NEt_2 \cdot C_6H_3(NO_2) \cdot AsCl_2.$$

—3-Nitro-6-diethylaminophenylarsinic acid (3·2 g.), in alcohol (20 c.c.) and concentrated hydrochloric acid (10 c.c.) containing a trace of iodine, was saturated with sulphur dioxide for 30 minutes. On cooling, a yellow, crystalline product separated (3·0 g.); this crystallised from benzene in deep yellow prisms, m. p. 143—144° (Found: As, 22·1; Cl, 20·8. $C_{10}H_{13}O_2N_2Cl_2As$ requires As, 22·1; Cl, 20·9%).

When *o*-ethylaminophenylarsinic acid or its acetyl derivative was reduced under similar conditions, arsenic was eliminated from the molecule.—GUY'S HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON), S.E.1. [*Received, July 26th*, 1927.]

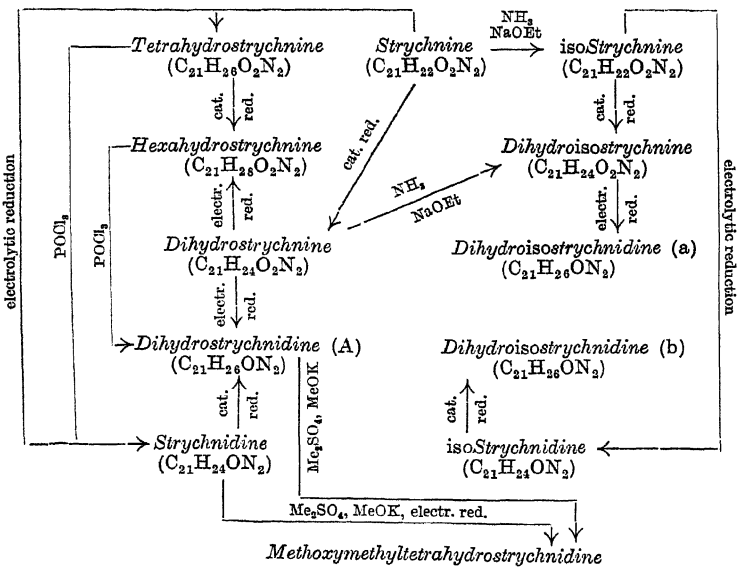
CCCXX.—*Strychnine and Brucine. Part VI. The Catalytic Hydrogenation of Strychnine and Some Derivatives.*

By ALBERT EDWARD OXFORD, WILLIAM HENRY PERKIN, jun., and ROBERT ROBINSON.

THE motive of this investigation was our desire to gain further knowledge of the function of the characteristic groups and of the nitrogen and oxygen atoms in the molecule of strychnine, and we directed our attention in the first place to the question of the unsaturated centres. The results show clearly that strychnine contains one double bond. According to Skita and Franck (*Ber.*, 1911, **44**, 2863), the reduction of strychnine in dilute acetic acid solution by means of hydrogen in presence of palladium (from 1% palladous chloride in presence of gum arabic) yields a dihydrostrychnine, m. p. 209—210°, but the volume of hydrogen stated to have been absorbed is only about half of that theoretically required. Owing to an erroneous calculation of the latter, Skita and Franck considered that the correct amount had been absorbed. Repetition of the experiment under the conditions employed by these authors gave negative results, but under other conditions we obtained *dihydrostrychnine*, $C_{21}H_{24}O_2N_2$, which crystallised well from aqueous methyl alcohol with $2H_2O$, and when anhydrous had m. p. 220—222°. Skita and Franck make no mention of the water of crystallisation, and they state, further, that the catalytic reduction of strychnine under 3 atm. pressure at 70° yields tetrahydrostrychnine, identical with the substance obtained by the electrolytic reduction of strychnine. It is certain, at least, that our dihydrostrychnine could not be an intermediate product in the latter process. Just as strychnine, $C_{21}H_{22}O_2N_2$, by electrolytic reduction yields strychnidine, $C_{21}H_{24}ON_2$, and tetrahydrostrychnine, $C_{21}H_{26}O_2N_2$, by conversion of ·CO·N: into ·CH_2·N: and ·CH_2(OH) + NH:, respectively (Tafel, *Annalen*, 1898, **301**, 301), so, in the same manner, dihydrostrychnine yields *dihydrostrychnidine* (A),* $C_{21}H_{26}ON_2$, m. p. 212—214°, and *hexahydrostrychnine*, $C_{21}H_{28}O_2N_2$, m. p. 197—199°. Furthermore, catalytic reduction of strychnidine gave dihydrostrychnidine (A) and catalytic reduction of tetra-

* Two dihydrostrychnidines, $C_{21}H_{26}ON_2$, have been prepared during the course of our investigations, and we propose to designate by (A) the substance described in the present communication, m. p. 212—214°. The isomeric dihydrostrychnidine (B) melts at 151° and is obtained from strychnidine by reduction with hydriodic acid and phosphorus. An account of the interesting properties of this substance will form the subject of a communication to be published in the near future.

hydrostrychnine gave hexahydrostrychnine, identical with the bases already mentioned. The dehydration of tetrahydrostrychnine to strychnidine is also paralleled by the similar conversion of hexahydrostrychnine into dihydrostrychnidine (A). The further reduction of these substances by hydrogen in presence of catalysts could not be accomplished, and dihydrostrychnine is characterised by its stability towards oxidising agents. It seems certain that the strychnine molecule contains only one double bond, and Tafel's view of the relation of strychnine to strychnidine and tetrahydrostrychnine is amply confirmed. Although, therefore, dihydrostrychnine contains the ·CO·N: group, we have not found it possible to demonstrate this by the preparation of dihydrostrychnic acid, and it is evident that the reduction has stabilised the lactam ring. At one point, we have made a contact with the investigation described in Part IV (this vol., p. 1617), since *dihydrostrychnidine* (A) *methosulphate* yields methoxymethyltetrahydrostrychnidine, m. p. 220°, when it is heated with methyl-alcoholic potassium hydroxide. Methoxymethyltetrahydrostrychnidine was previously obtained by electrolytic reduction of methoxymethyldihydrostrychnidine, m. p. 126° (*loc. cit.*), the product of the action of methyl-alcoholic potash on strychnidine methosulphate. It is evident that the double bond which resists electrolytic reduction in strychnidine may be readily saturated when methoxymethyldihydrostrychnidine is submitted to the same treatment.



The examination of dihydrostrychnine has led us to consider further the important problem of the relation of strychnine to *iso*strychnine. On catalytic reduction *iso*strychnine yields *dihydro*iso*strychnine*, $C_{21}H_{24}O_2N_2,3H_2O$, m. p. 249—251°, and the same substance was more readily obtained from dihydrostrychnine by the action of warm alcoholic sodium ethoxide. This proves that the strychnine–*iso*strychnine isomerism in no way depends on a shift of the double bond, as had previously been assumed, and that the process involved in the conversion of strychnine into *iso*strychnine does not even require the presence of the double bond. All attempts to prepare acetyl and other similar derivatives of strychnine, strychnidine, dihydrostrychnine, and dihydrostrychnidine (A) have failed, but both *iso*strychnine and dihydro*iso*strychnine yield monoacetyl derivatives. There is no evidence of the presence of imino-groups, and since the *acetyliso**strychnine* and *acetyldihydroiso**strychnine* are strong bases, they must be *O*-acetyl derivatives. Hence the interesting fact emerges that the change of strychnine to *iso*strychnine and of dihydrostrychnine into dihydro*iso*strychnine involves the appearance of a hydroxyl group. On the assumption, therefore, that *iso*strychnine contains

the group ·CO·N: (see below), we know that the other groups in the molecule include a tertiary basic nitrogen atom, one double bond, and a hydroxyl group. It is of fundamental importance that *iso*strychnine contains only one double bond because oxygen can only occur as C:O, C·O·C, or C·OH, and if a substance containing a carbonyl or an ether group isomerises with the production of an alcohol the process must be accompanied by the formation of a new double bond or a new ring. Experiment excludes the former alternative and we must therefore accept the latter. On the hypothesis that strychnine contains an ether group, it becomes necessary to assume the occurrence of some such process as the slipping of a bond in pentamethylene oxide with formation of a hydroxy*cyclo*pentane. This does not commend itself as a probable explanation: there are few analogous reactions and we cannot imagine that such a change would be brought about by the agency of sodium ethoxide in warm alcoholic solution. On the hypothesis that strychnine contains a carbonyl group, however, we can readily explain the appearance of a hydroxyl group in *iso*strychnine as due to an intramolecular condensation, :CO + CH: ⟶ :C(OH)·C:. It is interesting that no parallel to the strychnine–*iso*strychnine transformation exists in the strychnidine and tetrahydrostrychnine series (see p. 2407), and this suggests that the ·CO·N: group is directly concerned. If it should be proved in the future that strychnine is a ketone, then an acceptable explanation of the change of strychnine to *iso*strychnine is that expressed in the scheme

$$:CO + \dot{C}H\cdot CO\cdot N: \longrightarrow :C(OH)\cdot\dot{C}\cdot CO\cdot N:$$

These considerations have necessitated the further examination of the reactions of *iso*strychnine. As stated above, it yields an *O*-acetyl derivative, but we have been unable to confirm the statement of Oliveri-Mandalà and Comella (*Gazzetta*, 1923, **53**, 627) that the base gives a crystalline semicarbazone, m. p. 215° (decomp.). In addition we were unable to obtain a phenylhydrazone of *iso*strychnine or a semicarbazone of dihydro*iso*strychnine. The argument presented above, and indeed any theory implying that the hydroxyl group of *iso*strychnine is derived by modification of the function of the cryptic oxygen atom of strychnine (*i.e.*, that oxygen atom not included in the ·CO·N: group), can only be sustained if *iso*strychnine contains the ·CO·N: group of strychnine. In favour of this view we may marshal the facts that *iso*strychnine is a monoacid base, that it exhibits colour reactions of the strychnine type, that it yields *iso*strychnic acid on hydrolysis (Pictet and Bacovescu, *Ber.*, 1905, **38**, 2787; compare p. 2395), although the reverse change has not been accomplished, and that *iso*strychnic acid

exhibits colour reactions of the strychnidine type; nothing is known that is not in agreement with the suggestion that *iso*strychnine contains this group. We have sought further confirmation by studying the electrolytic reduction of *iso*strychnine and of dihydro*iso*strychnine, and have obtained new bases of the strychnidine type, *viz.*, iso*strychnidine*, $C_{21}H_{24}ON_2,1{\cdot}5H_2O$, and *dihydro*iso*strychnidine*, $C_{21}H_{26}ON_2,0{\cdot}5H_2O$, respectively. The latter must be designated *dihydro*iso*strychnidine* (*a*), since an isomeride, *dihydro*iso*strychnidine* (*b*), is obtained by the catalytic reduction of *iso*strychnidine. These bases exhibit many of the characteristics of strychnidine, and their preparation affords strong support to the view that *iso*strychnine contains the cyclic amide grouping.

The following miscellaneous observations are included in this communication. Some further work on the coupling of strychnine derivatives with diazonium salts has been carried out. Reduction of *sulphobenzeneazostrychnidine* gives *aminostrychnidine*, $C_{21}H_{25}ON_3$, and the striking colour reactions of this base establish beyond question that it is p-*aminostrychnidine*, the amino-group being in the para-relation to the nitrogen atom attached to the benzene nucleus in strychnine. It is, for example, convertible into an analogue of toluylene-blue and then into the eurhodine analogous to toluylene-red.

The Schotten–Baumann benzoylation of strychnic acid was

expected to attack the :NH group that this substance is supposed to contain, and although we have isolated a definite product of the correct composition, yet its behaviour suggests that it is the mixed *anhydride* of benzoic and strychnic acids rather than *N*-benzoylstrychnic acid.

In the course of abortive attempts to convert strychnidine and tetrahydrostrychnine into members of the *iso*strychnine series, it was found that on being heated with water in an autoclave at 170—185° each of these bases was partly converted into an oxidation product.

The scheme on page 2392 summarises the relationships of some of the substances discussed above. A more detailed examination of certain of the new bases now described is in progress, and the work is being extended to the brucine series.

EXPERIMENTAL.

Dihydrostrychnine.—All the catalytic reductions described in this communication were carried out in a flask fitted with an efficient stirrer with gas-tight packing. Norite (50 g., previously heated to redness) was added to a solution of palladous chloride (4 g.) in water (400 c.c.) containing a few drops of concentrated hydrochloric acid, and the mixture stirred in hydrogen until no further absorption took place. A solution of strychnine (57 g.) in 50% acetic acid (200 c.c.) was then introduced and agitation continued for 3—4 hours, during which 3,600 c.c. of hydrogen were absorbed (calc. for one double bond: 3,820 c.c.). The filtered liquid was basified with ammonia, whereupon practically pure *dihydrostrychnine* was precipitated in a crystalline condition (yield, 93%). The recovered catalyst may be reactivated by exposure to the air for a day and can be used at least 4 times, but in any one experiment 1 g. of palladous chloride is unable to catalyse satisfactorily the reduction of more than 17 g. of strychnine.

Dihydrostrychnine crystallises from 50% aqueous methyl alcohol in long, silky, colourless needles (Found: C, 68·3, 67·9; H, 7·5, 7·4; N, 7·1; loss at 100°, 9·3; loss at 130°, 9·8. $C_{21}H_{24}O_2N_2,2H_2O$ requires C, 67·7; H, 7·5; N, 7·5; $2H_2O$, 9·7%). The anhydrous base melts without decomposition at 220—222° (Found: C, 75·1; H, 7·1. $C_{21}H_{24}O_2N_2$ requires C, 75·0; H, 7·2%). It dissolves in about 190 parts of boiling water and is sparingly soluble in cold water; it is readily soluble in cold ethyl and methyl alcohols, moderately readily soluble in cold benzene, and sparingly soluble in cold ethyl acetate and in boiling acetone, from which it separates in minute, compact prisms. The substance has a bitter taste similar to that of strychnine. The faintly acid solutions of dihydro-

strychnine develop no coloration on the addition of ferric chloride, and the base does not couple with diazobenzenesulphonic acid. With 60% sulphuric acid (by vol.) and potassium dichromate it gives an intense reddish-purple colour, slowly fading to a brownish-red. Attempts to obtain a semicarbazone of the base were fruitless, and failure also attended an attempt to acetylate it by means of anhydrous sodium acetate and acetic anhydride, the dihydrostrychnine being recovered unchanged and identified by analysis (Found : C, 68·0; H, 7·6; N, 7·5%), by m. p., and by mixed m. p. (220° in each case).

If the base contained the ·CH(OH)· group it should yield a ketone under the conditions used to change codeine into codeinone (Ach and Knorr, *Ber.*, 1903, **36**, 3070). Dihydrostrychnine (5 g.) was dissolved in a cold mixture of concentrated sulphuric acid (3·5 c.c.) and water (31 c.c.); addition of finely powdered potassium dichromate (3 g.) with stirring produced an orange-coloured precipitate, and when the mixture was heated for 20 minutes on the steam-bath a deep brownish-red solution was obtained, from which 4 g. of pure dihydrostrychnine could then be recovered.

Oxidation of the base with potassium permanganate was attempted under the conditions prescribed by Leuchs and Schwabel (*Ber.*, 1913, **46**, 3695) for the oxidation of strychnine. Dihydrostrychnine dihydrate (15 g.), dissolved in chloroform (120 c.c.) and acetone (600 c.c.), was stirred with a little finely powdered potassium permanganate for 1 hour. Oxidation did not occur and the mixture was boiled for 3 hours with gradual addition of potassium permanganate (30 g.), and then for 1 hour longer. The permanganate was destroyed, but 12 g. of dihydrostrychnine were recovered, and the working up of the manganese precipitate gave only a minute amount of a brown syrup that was not further investigated.

Further catalytic hydrogenation of dihydrostrychnine was attempted at 100°, 0·6 g. of palladous chloride being used for 3 g. of the base. No absorption of hydrogen occurred, and the whole of the base was recovered unchanged. Attempts to convert dihydrostrychnine into dihydrostrychnic acid (*e.g.*, by the method used by Tafel, *Annalen*, 1891, **264**, 50, for the conversion of strychnine into strychnic acid free from *iso*strychnic acid) gave either dihydro*iso*strychnine (see below) or an amorphous base melting over a wide range, but in no case was any satisfactory acid product isolated. It may be mentioned here that the catalytic reduction of strychnic acid in dilute acetic acid solution gave dihydrostrychnine in good yield, but in all probability the strychnic acid was first converted into strychnine and then reduced.

Dihydrostrychnine Methosulphate.—A mixture of dihydrostrych-

nine (10 g.), methyl sulphate (6 c.c.), and benzene (120 c.c.) was boiled for 5 minutes, then cooled; the resulting solid crystallised from alcohol in fine, colourless rods, m. p. 322° (decomp.) with previous darkening from 300° (Found : C, 59·1 ; H, 6·4. $C_{23}H_{30}O_6N_2S$ requires C, 59·7 ; H, 6·5%). This derivative is readily soluble in water, but very sparingly soluble in cold alcohol or boiling ethyl acetate or acetone. When it was reduced in aqueous solution by 4% sodium amalgam (under conditions similar to those employed for strychnine methosulphate in experiments that will shortly be reported), no oily base separated and the brownish-red solution was not further investigated. The related *methiodide* was obtained in a similar manner by direct combination of the components. It is moderately readily soluble in water, very sparingly soluble in alcohol, and crystallises from a mixture of these solvents in stellar aggregates of colourless rods, that suffer slight discoloration between 300° and 330° (Found : C, 53·8; H, 5·6. $C_{22}H_{27}O_2N_2I,H_2O$ requires C, 53·2; H, 5·8%).

iso*Strychnine and* iso*Strychnic Acid.*—An attempt to repeat the preparation of the semicarbazone described by Oliveri-Mandalà and Comella (*loc. cit.*) did not succeed, and *iso*strychnine was recovered unchanged (Found : C, 65·5; H, 7·2. Calc. for $C_{21}H_{22}O_2N_2,3H_2O$: C, 65·0; H, 7·2%). No other result was obtained when the sodium hydroxide prescribed by the above-mentioned authors was replaced by a large excess of sodium acetate. When the base (1 g.), together with phenylhydrazine (0·4 g.) and 6% acetic acid (3·5 c.c.), was heated for 3 hours on the steam-bath, the recoverable crystalline base was found to be unchanged *iso*strychnine, m. p. 220°, alone or mixed with an authentic specimen.

The colour reaction of *iso*strychnine with 60% sulphuric acid and potassium dichromate differs somewhat from that of strychnine. It is a not very intense pure violet coloration, fading in a few seconds to a very pale brown. The conversion of *iso*strychnine into *iso*strychnic acid can be accomplished according to Pictet and Bacovescu (*loc. cit.*) by the action of boiling alcoholic sodium ethoxide (concentration not stated) during 6 hours. We find, however, that the yield is very small under their conditions. A mixture of *iso*strychnine trihydrate (4·5 g.) and alcoholic sodium ethoxide (from 0·7 g. of sodium and 7·5 c.c. of alcohol) was heated on the steam-bath for 6¼ hours, giving a deep brownish-red solution that exhibited a green fluorescence. After dilution with water (85 c.c.) and keeping for some hours in the ice-chest, nothing separated and the solution was exactly neutralised with acetic acid. The slimy, red precipitate consisted chiefly of an insoluble pigment

and was extracted with hot water (charcoal); ultimately, colourless, slender needles of *iso*strychnic acid (0·5 g.), m. p. 231° (decomp.), were isolated. The yield was increased to 40% when the hydrolysis was carried out for 11 hours at 60°. This material does not lose weight when heated at 140° for several hours (Found: C, 68·3; H, 7·1. Calc. for $C_{21}H_{26}O_4N_2$: C, 68·1; H, 7·0). We have found that *iso*strychnic acid cannot be reduced by hydrogen in presence of palladinised charcoal in dilute acetic acid solution. It is usually regarded as $C_{21}H_{24}O_3N_2,H_2O$, but the facts suggest that the molecule of water may be constitutionally bound, *e.g.*, by addition to the ethylene linkage. The acid is unchanged by boiling dilute hydrochloric acid and under no conditions has it been reconverted into *iso*strychnine. The colour reactions indicate that the N–CO link has been broken, since they are of the strychnidine type. With ferric chloride in dilute hydrochloric acid solution a red colour develops slowly in the cold, but, on warming, the solution becomes intensely blood-red. Coupling with diazobenzenesulphonic acid occurs in cold dilute acetic acid solution to an azo-compound exhibiting the usual properties. Unlike strychnic acid (see below), *iso*strychnic acid could not be converted into a benzoyl derivative by the Schotten–Baumann method.

O-*Acetyl*iso*strychnine*.—Oliveri-Mandalà and Comella (*loc. cit.*) found that *iso*strychnine, but not strychnine, reacts with magnesium ethyl bromide, yielding a molecular proportion of ethane. They attributed this to interaction of the Grignard reagent with an imino-group in the base; it seems more probable to us that the liberation of ethane is due to the presence of a hydroxyl group in the *iso*-strychnine molecule, and we can recall no evidence indicating that the substance is a secondary base.

A mixture of *iso*strychnine (2 g.), fused sodium acetate (1 g.), and acetic anhydride (6 c.c.) was heated on the steam-bath for 4 hours and considerable darkening occurred. The cooled mass was added to water, and the excess of acetic acid neutralised by sodium bicarbonate. The product was isolated by means of chloroform and crystallised repeatedly from light petroleum, a process which greatly diminishes the final yield. The *acetyl* derivative crystallises in groups of minute, colourless needles, m. p. 133—134° (Found: C, 73·3; H. 6·4. $C_{23}H_{24}O_3N_2$ requires C, 73·4; H, 6·4%); it is readily soluble in most organic solvents and dissolves at once in very dilute acetic acid, the addition of sodium hydroxide then producing a turbidity which soon clears, doubtless as the result of hydrolysis.

*Preparation of Dihydro*iso*strychnine*.—(A) *By the catalytic reduction of* iso*strychnine*. Norite (12 g.) was palladinised (0·5 g. of

palladous chloride in 250 c.c. of water) as already described, and a solution of *iso*strychnine trihydrate (4·9 g.) in a few c.c. of dilute acetic acid was then introduced. The theoretical volume of hydrogen (340 c.c.) was absorbed in 5 hours; absorption then ceased suddenly. The filtered liquid was basified with dilute aqueous sodium hydroxide, a colourless oil being precipitated which solidified after being kept for a long time. The *dihydroisostrychnine* was crystallised from benzene–light petroleum and then several times from water; fern-like bunches of coarse, colourless needles, m. p. 244—246°, were thus obtained (Found: C, 64·7; H, 7·5. $C_{21}H_{24}O_2N_2,3H_2O$ requires C, 64·6; H, 7·7; $3H_2O$, 13·8%).

(B) *By isomeric change of dihydrostrychnine.* Strychnine has been converted into *iso*strychnine in two ways: (1) by heating with water at 170—175° (Pictet and Bacovescu, *loc. cit.*; compare also Leuchs and Nitschke, *Ber.*, 1922, **55**, 3171, and Oliveri-Mandalà and Comella, *loc. cit.*); (2) by heating with methyl-alcoholic ammonia under various conditions (Leuchs and Nitschke, *loc. cit.*). A third method (3) is indicated by the observation of Tafel (*Annalen*, 1891, **264**, 50) that strychnine yields *iso*strychnic acid as well as strychnic acid when it is heated with alcoholic sodium ethoxide at temperatures above 70°. The three processes have been applied to the transformation of dihydrostrychnine.

(1) Dihydrostrychnine (1 g.) and water (25 c.c.) were heated in a sealed tube at 165—185° for 5 hours. Very little decomposition occurred (distinction from strychnine), and the aqueous solution was separated from the gummy residue and kept in the ice-chest. The gum solidified and was found to consist of unchanged material, whilst the solution deposited amorphous material which could be crystallised from water in slender, colourless needles, m. p. 237—238°. This product is slightly impure dihydro*iso*strychnine, as was proved by comparison with specimens prepared by other methods.

(2) This method gave quite good results on a small scale, but an attempt to reproduce the conditions on a larger scale in an autoclave failed completely. A sealed tube containing dihydrostrychnine dihydrate (1·2 g.) and 25 c.c. of methyl-alcoholic ammonia (saturated at 15°) was heated at 120—140° (but not higher) for 48 hours. The tube was opened and the pale yellow liquid evaporated in a vacuum; the residue crystallised from water in colourless needles, m. p. 240—245° (Found: C, 64·8; H, 7·8%).

(3) This is the most satisfactory method of preparation, but the yield is greatly diminished if the operation is carried out on a larger scale. Dihydrostrychnine dihydrate (5 g., finely powdered) was added to an alcoholic solution (20 c.c.) of sodium ethoxide (0·5 g. of sodium), and the mixture heated on the steam-bath

until complete solution had been effected. The deep purplish-red liquid was boiled for 2 minutes, then cooled and maintained at 44—46° for 6 hours. A yellow solid soon began to separate and eventually the liquid became filled with the crystals, forming a thick paste. After being cooled and kept in the ice-chest, the solid was collected, washed with a little alcohol, and dried (2 g., or 40%). Nothing further could be obtained from the alcoholic filtrate, which gave an amorphous precipitate on dilution with water. The base crystallised from water in bunches of colourless needles, m. p. 248—250° (Found: C, 65·1; H, 7·5; loss at 120°, 13·5%). The anhydrous base crystallised from benzene–light petroleum in needles, m. p. 249—251° (Found: C, 74·6; H, 7·2. $C_{21}H_{24}O_2N_2$ requires C, 75·0; H, 7·2%).

The following mixtures had melting points that were higher than those of the lower-melting specimens in each case, the m. p.'s of the specimens being those already quoted above: (A) with (B2), (A) with (B3), (B2) with (B3).

Dihydro*iso*strychnine dissolves in 90—100 parts of boiling water and is sparingly soluble in cold water, cold ethyl alcohol, boiling benzene or acetone; it is moderately readily soluble in boiling ethyl acetate, and readily soluble in chloroform, cold methyl alcohol, and hot ethyl alcohol. It gives no ferric chloride reaction, and addition of potassium dichromate to its solution in 60% sulphuric acid produces an intense purple coloration, persisting for a minute and then fading to a light reddish-brown. Attempts to prepare a semicarbazone were quite unsuccessful, and it was found that the further catalytic hydrogenation of the base at 70° could not be accomplished. There was some evidence, in that a weak Liebermann reaction was observed, that the base gives a nitrosoamine, but the isolated product (Found: N, 6·6%) was the unchanged base. Probably the crude material contained a trace of an ester of nitrous acid resulting from the interaction of the acid with the alcoholic hydroxyl group of the base. The *methosulphate* is a readily soluble gum, but the *methiodide* crystallises from alcohol containing a little water in groups of thick, colourless rods, m. p. 320° (decomp.) with darkening from 310° (Found: N, 6·2. $C_{22}H_{27}O_2N_2I$ requires N, 5·9%). It is sparingly soluble in hot alcohol and readily soluble in cold water.

O-*Acetyldihydro*iso*strychnine*.—A mixture of dihydro*iso*strychnine (1 g.), fused sodium acetate (0·5 g.), and acetic anhydride (3·5 c.c.) was heated on the steam-bath for 3 hours. The product was decomposed by water, the acid neutralised by sodium bicarbonate, and the base extracted by chloroform. After removal of the solvent in a vacuum, the residue crystallised from light petroleum, con-

taining a little benzene, in rods which were recrystallised several times from light petroleum without material alteration of the m. p. The slender, colourless needles thus obtained had m. p. 202—204° (Found: C, 72·9; H, 7·1. $C_{23}H_{26}O_3N_2$ requires C, 73·0; H, 6·9%), and m. p. 190—195° when mixed with dihydro*iso*strychnine. O-*Acetyldihydroisostrychnine* is immediately soluble in dilute acetic acid, and on the progressive addition of sodium hydroxide a turbidity appears and then disappears; on keeping, this solution deposits dihydro*iso*strychnine in needles.

Preparation of Dihydrostrychnidine (A).—(I) *By catalytic hydrogenation of strychnidine.* The reduction of strychnidine could not be accomplished at the ordinary temperature, and under the following conditions it gave good results on a small scale only. A violently agitated mixture of norite (4 g., previously heated to redness) and palladous chloride (0·4 g.) dissolved in very dilute hydrochloric acid (100 c.c.) was allowed to absorb hydrogen, and when no further change occurred a solution of strychnidine (3 g.) in 67% acetic acid (30 c.c.) was introduced and the flask immersed in water at 65° (renewed when it cooled to 50°). After 3½ hours the volume of hydrogen absorbed was 190 c.c. (theory, 210 c.c.) and absorption ceased. The base was precipitated from the filtered liquid by means of sodium hydroxide, and the grey granules were collected and dried in a vacuum (yield, 50%; m. p. 200—209°). The substance, crystallised from methyl alcohol and then from light petroleum, formed small, well-defined, colourless tablets, m. p. 212—214° (Found: C, 78·3; H, 7·9. $C_{21}H_{26}ON_2$ requires C, 78·3; H, 8·1%). When crystallised from methyl alcohol the base forms large, glistening, colourless leaflets (Found: C, 78·6; H, 8·0%). *Dihydrostrychnidine* (A) is not appreciably soluble in boiling water, but it is readily soluble in cold ethyl alcohol, benzene, or carbon tetrachloride; it is moderately readily soluble in hot ethyl acetate, and sparingly soluble in boiling acetone and light petroleum. Unlike strychnidine, it gives only a faint coloration when ferric chloride is added to its solution in an excess of dilute hydrochloric acid; a rose-red coloration develops on warming. If only a trace of hydrochloric acid is present, an intense coloration develops a few seconds after the addition of ferric chloride. As explained in Parts IV and V (this vol., pp. 1595, 1662), this behaviour is closely connected with the strength of the substances as di-acid bases, and is a clear indication that the nitrogen atom joined to the aromatic nucleus is a much stronger basic centre in dihydrostrychnidine (A) than it is in strychnidine. The base is stable to potassium permanganate in cold acetone solution containing a few drops of water, but it is rapidly oxidised if much water is added. It is

unaffected by acetic anhydride and dry sodium acetate at 100°. The base is unacted upon by magnesium phenyl bromide in boiling benzene or by magnesium methyl iodide. It was also recovered unchanged after vigorous treatment with sodium and boiling *iso*amyl alcohol.

(II) *By electrolytic reduction of dihydrostrychnine.* Dihydrostrychnine dihydrate (22 g.), dissolved in a mixture of concentrated sulphuric acid (83 c.c.) and water (100 c.c.), was reduced at a lead cathode (compare Tafel, *Annalen*, 1898, **301**, 302) by a current of 6 amps. at 3·8 volts (current density, 0·09 amp./cm.^{2}). At the end of 3 hours, the liquid in the cathode cell gave no appreciable ferric chloride reaction; at the end of 9 hours both the ferric chloride and Otto reactions were positive; after 18 hours the Otto reaction was very faint; and after 2 hours more it had disappeared. Tafel (*loc. cit.*) found that strychnine was completely reduced (using similar conditions, but with a rather smaller current density and a rotating cathode) in 8 hours, so that dihydrostrychnine is apparently less easily reduced by this method than strychnine is. The liquid was diluted with 3 times its volume of water, and the base precipitated by the cautious addition, with cooling, of potassium hydroxide. The crude product was collected and dried (14 g.). After crystallisation from methyl alcohol and then from light petroleum, pure dihydrostrychnidine (A) was obtained, m. p. 212—214°, unchanged by admixture with a specimen obtained as in (I). The above method is the one that should be adopted for the preparation of the base in quantity.

Dihydrostrychnidine (A) *methosulphate* was obtained under conditions similar to those used for dihydrostrychnine methosulphate (p. 2394). It crystallises from alcohol–light petroleum in rosettes of colourless, pointed needles, m. p. 250° (decomp.) (Found: C, 61·3; H, 7·5; N, 5·8. $C_{23}H_{32}O_5N_2S$ requires C, 61·6; H, 7·2; N, 6·2%). The derivative is readily soluble in water and alcohol and sparingly soluble in most other organic solvents. The salt (2 g.) was heated at 105—115° for 8 hours (reflux) with 40% methylalcoholic potassium hydroxide (22 c.c.). On addition of water, fine, colourless leaflets separated. Complete purification was effected by two crystallisations from methyl alcohol, and the massive, colourless, hexagonal tablets, m. p. 219—220°, were found to consist of methoxymethyltetrahydrostrychnidine (Part IV, this vol., p. 1617). The m. p. was not depressed on admixture with a specimen obtained by the electrolytic reduction of methoxymethyldihydrostrychnidine.

The methiodide. Dihydrostrychnidine (A) (5 g.) was suspended in methyl alcohol (50 c.c.), and methyl iodide (12 c.c.) added; the

base then dissolved completely with little rise of temperature, crystallisation soon commenced, and a sandy precipitate separated. The mixture was boiled for ½ hour and left over-night; the *methiodide* was then collected, washed with methyl alcohol, and dried at 100°. When rapidly heated, it decomposed at about 340—350° to a brown syrup. It is sparingly soluble in boiling water or methyl alcohol and separates from water in striated, arrow-shaped prisms (Found: C, 57·0; H, 6·4. $C_{22}H_{29}ON_2I$ requires C, 56·8; H, 6·5%).

The *methochloride* was obtained by digesting the methiodide with much water and silver chloride for 2 hours and evaporating the filtered solution to a small bulk; a colourless syrup remained which, kept over sulphuric acid in a vacuum desiccator, crystallised to a mass of needles. After contact with porous porcelain, the colourless mass was recrystallised from a few drops of water, and dried over sulphuric acid. It did not then lose weight at 100° (Found: C, 70·7; H, 8·0. $C_{22}H_{29}ON_2Cl$ requires C, 70·8; H, 7·9%). This substance decomposes at about 345° and the aqueous solution gives with hydrochloric acid and ferric chloride a pale pink colour, which gradually becomes deep pink on warming. The solution in dilute sulphuric acid (60%) is coloured intensely brownish-crimson by dichromate. The methochloride (0·5 g.) was heated cautiously in a test-tube over a free flame until decomposition at the high temperature was just complete; the residue crystallised from methyl alcohol (norite) in leaflets, m. p. 212—213°, of dihydrostrychnidine (A). When the methochloride was heated with methyl-alcoholic potassium hydroxide (25%) on the sand-bath until the temperature of the melt reached 125°, the resulting product gave on addition of water a grey mass, which was well washed and left in contact with porous porcelain. This separated from xylene (norite) in leaflets, m. p. 220—222°, and proved to be methoxymethyltetrahydrostrychnidine.

As stated in the Addendum at the end of this paper, these and other properties prove that dihydrostrychnidine (A) methiodide and methochloride are identical with methyl*neo*dihydrostrychnidinium iodide and chloride (Part IV, this vol., p. 1623).

The dimethosulphate and dimethiodide. A solution of dihydrostrychnidine (A) (7 g.) in carefully purified boiling benzene (50 c.c.) was cooled, and freshly distilled methyl sulphate (20 c.c.) added; the solution became warm, clouded, and the monomethosulphate separated as a voluminous crystalline precipitate. On heating on the steam-bath under reflux, the crystals gradually gave place to a gelatinous mass. After the mixture had been boiled for 15 hours and cooled in ice-water, the benzene layer was decanted and the viscid dimethosulphate, which showed no sign of crystallising, was

dissolved in water. The solution was filtered from benzene, neutralised with potash, and heated to boiling, and a large excess of hot sodium iodide solution added. The clear solution soon began to deposit brilliant, arrow-shaped plates of the *dimethiodide*, which were collected, washed, and dried at 100°; m. p. about 285—290° (decomp.) (Found: C, 46·0; H, 5·5. $C_{23}H_{32}ON_2I_2$ requires C, 45·6; H, 5·3%). A further small crop of crystals was obtained on concentrating the mother-liquor; the filtrate gave, on addition of 50% potassium hydroxide solution, only a slight turbidity (compare Part IV, this vol., p. 1594).

The same dimethiodide was obtained when dihydrostrychnidine (A) was heated in a sealed tube with a large excess of methyl iodide alone (compare the preparation of the monomethiodide above) for several hours in the steam-bath, since the old-gold plates which separated had m. p. 285—290° (decomp.) and gave C, 45·2; H, 5·5%. This dimethiodide is very sparingly soluble in boiling methyl alcohol, but dissolves readily in cold and very readily in hot water.

The *dimethochloride*, prepared from the dimethiodide and silver chloride in the usual way, is a hygroscopic syrup.

After this had been heated on the sand-bath with methyl-alcoholic potassium hydroxide (25%) in an open flask until the temperature of the melt was 130°, the cold product gave with water a grey precipitate of methoxymethyltetrahydrostrychnidine and *methyldihydrostrychnidine* (A) in about equal proportions. Owing to the small quantity of material available, the separation of these two substances proved to be difficult. The mixture was dissolved in boiling benzene and the solution was digested with norite and concentrated to a very small bulk. On standing in ice, crude methoxymethyltetrahydrostrychnidine separated. After crystallisation from xylene, it melted at m. p. 220—222°, alone or when mixed with a specimen of the methoxy-derivative obtained as described in Part IV (this vol., p. 1617). The benzene filtrate was evaporated, and the colourless syrup boiled with methyl alcohol; a mass of crystals, m. p. 155—190°, then separated. This crude substance was rubbed with a very little benzene, the small quantity of very sparingly soluble residue, m. p. 220—222°, was filtered off, and the syrup was again treated with methyl alcohol after the benzene had been evaporated. This process was repeated and the substance was then crystallised from methyl alcohol and finally from acetone (Found, in two different preparations: C, 79·0, 78·9; H, 8·5, 8·4. $C_{22}H_{28}ON_2$ requires C, 78·6; H, 8·3%).

Methyldihydrostrychnidine (A) melts not quite sharply at 178—180° and is characterised by being remarkably sparingly soluble in

boiling methyl alcohol or acetone and unusually readily soluble in benzene. It separates from methyl alcohol or acetone in flat needles. A solution in dilute hydrochloric acid gives, on treatment with ferric chloride, an immediate crimson colour, changing to pale brown on warming. The base has unexpectedly little tendency to combine with methyl iodide. When a concentrated solution in benzene was boiled with methyl iodide for several minutes and evaporated, the residue obtained consisted essentially of the unchanged base and separated from methyl alcohol in needles, m. p. 175—177° (Found: C, 78·3; H, 8·2%). The base is readily soluble, without rise of temperature, in methyl iodide and even after 10 minutes' boiling a good deal of uncombined base remains.

Hexahydrostrychnine (*Dihydrotetrahydrostrychnine*).—(A) *Catalytic reduction of tetrahydrostrychnine.* This was carried out as in the cases described already, and the quantities were: palladous chloride (0·8 g.), water (300 c.c.), norite (12 g.), tetrahydrostrychnine (6 g.), 50% acetic acid (60 c.c.). Absorption at the ordinary temperature was very slow (20 c.c. in 1 hour), but at 50—70° the theoretical volume of hydrogen was absorbed in 4 hours. The filtered liquid was made strongly alkaline with potassium hydroxide (cooling necessary), and the slightly pink, granular solid was collected and dried in a vacuum (yield, 60%). The *hexahydrostrychnine* crystallises from ethyl acetate, containing a little light petroleum, in large, rectangular tablets, mostly with facets at the corners, and faintly pink as the result of superficial oxidation. The m. p. of this substance, 197—199°, is thus close to that of tetrahydrostrychnine (200—202°), but a mixture of the two gave a very large depression (Found: C, 74·4; H, 8·2. $C_{21}H_{28}O_2N_2$ requires C, 74·1; H, 8·3%). This base is sparingly soluble in light petroleum and appreciably soluble in boiling water; it is moderately readily soluble in cold ethyl acetate and in boiling benzene, acetone, or carbon tetrachloride, and readily soluble in cold ethyl alcohol or boiling methyl alcohol. Like tetrahydrostrychnine, hexahydrostrychnine gives no coloration with ferric chloride if too much hydrochloric acid is present in the solution, but in the presence of only a trace of acid a brownish-red coloration slowly develops.

(B) *By electrolytic reduction of dihydrostrychnine.* The alkaline solution from which crude dihydrostrychnidine was precipitated (see p. 2400) was exhaustively extracted with chloroform, the red extract separated and dried over sodium sulphate (norite), and the solvent removed, finally in a vacuum at 40°. The residual gum solidified in contact with light petroleum, and this material (5 g. from 22 g. of dihydrostrychnine), after three crystallisations from ethyl acetate containing light petroleum, was obtained in large,

faintly brown, irregular tablets, m. p. 197—199°, alone or mixed with the specimen prepared as described under (A) above.

Evidence was obtained that hexahydrostrychnine yields a nitrosoamine, but the substance could not be fully purified. Similarly, the *diacetyl* derivative, prepared in the usual manner (compare *O*-acetyldihydro*iso*strychnine), was obtained only as a very pale yellow, hygroscopic syrup (Found: N, 6·8. $C_{25}H_{32}O_4N_2$ requires N, 6·6%). It is of interest to note that this substance gives no coloration with ferric chloride, thus indicating the neutralised character of the nitrogen atom attached to the aromatic nucleus. The dehydration of hexahydrostrychnine with formation of dihydrostrychnidine (A), analogous to the conversion of tetrahydrostrychnine into strychnidine, can be accomplished by boiling the substance with ten times its weight of phosphoryl chloride for 4 minutes. The crude base, isolated in the usual way, has m. p. 200—210°, and yields pure dihydrostrychnidine (A), m. p. 212—214°, after one crystallisation from light petroleum.

iso*Strychnidine*.—The electrolytic reduction of *iso*strychnine was effected in the usual apparatus. *iso*Strychnine trihydrate (13 g.), dissolved in a cold mixture of concentrated sulphuric acid (50 c.c.) and water (70 c.c.), was placed in the cathode cell and submitted to a current of 4·4 amps. at 4 volts (current density, 0·065 amp./cm.^{2}) for 20 hours, after which the Otto reaction could no longer be obtained. The base precipitated by means of potassium hydroxide from the diluted solution (with cooling) weighed 9 g., and was repeatedly extracted with much boiling water. On cooling, the solutions deposited tufts of slender, very pale brown needles, m. p. 155—157°, with sintering at 107—118°. The behaviour on heating was not altered by subsequent recrystallisation from water (Found: loss at 105°, 6·9; at 130°, 7·4. Found in anhydrous material: C, 78·7; H, 7·6. $C_{21}H_{24}ON_2,1{\cdot}5H_2O$ requires H_2O, 7·8. $C_{21}H_{24}ON_2$ requires C, 78·8; H, 7·5%). iso*Strychnidine* which had been heated at 110° for an hour was crystallised thrice from light petroleum and formed very light, feathery groups of colourless needles, m. p. 163—168° (slight decomp.) [Found: (A) C, 77·6; H, 7·9%]. Again, the alkaline mother-liquors from the crude *iso*strychnidine were worked up by extraction with chloroform in the usual manner, with the object of determining whether any *iso*tetrahydrostrychnine was formed in the reduction, but the only definite product isolated was one that crystallised from light petroleum in colourless needles, m. p. 165—167°, alone or mixed with the specimen of m. p. 163—168° mentioned above (Found: C, 76·5; H, 7·5. $C_{21}H_{24}ON_2,0{\cdot}5H_2O$ requires C, 76·6; H, 7·7%). The analysis (A) (above) requires a still smaller proportion of

associated water (0·25 mol.). *iso*Strychnidine is easily decomposed on heating, *e.g.*, it is discoloured at 110° after 1 hour, and a possible explanation of our results is that the low m. p. of the product crystallised from water is the result of decomposition occurring during the sintering period, when solvent of crystallisation is being removed. Crystallisation from light petroleum seems to give less fully hydrated modifications, which may melt at higher temperatures as the result of their superior stability. Confirmation of this view was obtained by crystallising a specimen, m. p. 163—168°, from water, whereupon the m. p. fell to 155—157°. *iso*Strychnidine is readily soluble in cold methyl and ethyl alcohols, ethyl acetate, acetone, or chloroform, and in boiling benzene, from which a small proportion crystallises on cooling in elongated, rectangular plates. It is sparingly soluble in light petroleum. In the presence of an excess of dilute hydrochloric acid, it gives no coloration with ferric chloride when cold, and a very pale colour on warming. If only a trace of hydrochloric acid is present, an intense rose-red colour develops in a few seconds. The *methosulphate* crystallises from a mixture of alcohol and light petroleum in minute, elongated, rectangular, nearly colourless prisms, m. p. 200—205° (decomp.) (Found: N, 5·9. $C_{23}H_{30}O_5N_2S$ requires N, 6·3%). When heated with methyl-alcoholic potassium hydroxide, it yielded a resinous base that could not be crystallised and was not further investigated.

*Dihydro*iso*strychnidine* (a).—This base was obtained by the electrolytic reduction of dihydro*iso*strychnine. A solution of this (10·1 g.) in a mixture of concentrated sulphuric acid (50 c.c.) and water (80 c.c.) was submitted to a current of 4 amps. (3·7—4·1 volts), the current density at the lead cathode being 0·07 amp./cm.^{2}. The anode cell contained 20% sulphuric acid. At the end of 21 hours the Otto reaction was no longer exhibited, and the *dihydro*-iso*strychnidine* (a) was isolated as a pale yellow, gelatinous precipitate (8 g.), which, crystallised from acetone and then twice from benzene, formed pale yellow bunches of needles, m. p. 191—192°. A final crystallisation from light petroleum (b. p. 80—100°) did not alter the m. p. (Found: C, 76·5, 75·9; H, 8·6, 8·1; *M*, in camphor by micro-Rast, 301. $C_{21}H_{26}ON_2,0·5H_2O$ requires C, 76·1; H, 8·2%; *M*, 331). On being heated at 110° for 8 hours, the substance lost only 1·0% (theory, 2·7%), and this suggested the possibility that it might be an ether derived from two molecules of the hypothetical hexahydro*iso*strychnine. The molecular-weight determination disposes of this view and makes it necessary to assume that the compound is $2C_{21}H_{26}ON_2,H_2O$, giving $C_{21}H_{26}ON_2$ and $C_{21}H_{26}ON_2,H_2O$ in fused camphor solution. Naturally any water set free would be evaporated at the temperature of fused

camphor, and so would not affect the result. The original alkaline mother-liquor, from which this base was collected, was extracted with chloroform, and the gum remaining after removal of the solvent was purified by solution in ethyl acetate and precipitation with light petroleum, followed by two similar processes, using benzene and light petroleum. The product, m. p. 170—190°, then crystallised from water in tiny, colourless leaflets, m. p. 191—192° (Found: C, 75·6; H, 8·1%). This substance was readily soluble in hot water, and was unaltered by further crystallisation. It thus appeared to differ from the specimen first described, but a mixture of the two specimens had m. p. 191—192°. The base from the first precipitate was boiled with 1000 parts of water, which dissolved only 5% of its weight. On evaporation of the solution, nearly colourless leaflets, m. p. 190°, alone or mixed with the original material, were obtained. In all such cases it is very difficult to determine whether we are observing the behaviour of a mixture of isomerides, or whether it is merely an example of the large influence occasionally exerted by traces of impurity on the solubility properties. The base is readily soluble in methyl alcohol, ethyl acetate, or boiling benzene, it is moderately readily soluble in boiling acetone, and sparingly soluble in boiling light petroleum. It exhibited the usual ferric chloride reaction, and was partly recovered unchanged after boiling with phosphoryl chloride and after treatment with nitrous acid.

Dihydroisostrychnidine (b).—Unlike strychnidine, *iso*strychnidine may be catalytically reduced at the ordinary temperature. The quantities employed were: palladous chloride (0·5 g.), dissolved in water (200 c.c.) and a little hydrochloric acid, norite (7 g.), *iso*strychnidine (2·4 g.), dissolved in a little dilute acetic acid. The volume of hydrogen absorbed in 3 hours was 200 c.c. (theory, 160 c.c.). The filtered liquid was basified with sodium hydroxide, and the gelatinous precipitate collected and boiled with water (800 c.c.). On cooling, the filtered solution deposited copiously small, colourless plates, and these crystallised from water in tufts of slender, colourless needles, m. p. 150°. Further extraction of the crude product yielded nothing. The *dihydroisostrychnidine* (b) was twice recrystallised from light petroleum (b. p. 60—80°), giving spongy clusters of colourless needles, m. p. 151—153° after sintering at 140° (Found: C, 73·9; H, 8·2. $C_{21}H_{26}ON_2,H_2O$ requires C, 74·1; H, 8·3%). This material, evidently a monohydrate, lost 3·6% at 110—120° in 4 hours (theory, 5·3%), but some discoloration occurred. The solubilities, except in water, were similar to those of dihydro*iso*strychnidine (a) and the new base gives a rose-red colour on the addition of ferric chloride, even in an excess

of dilute hydrochloric acid. Our examination of the isomeric dihydro*iso*strychnidines is not complete and we have not yet sufficient data to enable us to advance any suggestions as to the structural or stereochemical differences that may exist between them. Attempts to obtain one or other of these compounds from dihydrostrychnidine (A) were fruitless. Dihydrostrychnidine (A) is quite unchanged when it is heated with water at 180—185° for 6½ hours or with methyl-alcoholic ammonia at 120—145° for 48 hours.

Dioxyhydroxydihydrostrychnidine.—Strychnidine was unaffected by heating with methyl-alcoholic ammonia at 130—140° for 48 hours and also by treatment with alcoholic sodium ethoxide under various conditions. When heated with water, it yielded the oxidation product here described, but no *iso*strychnidine. Strychnidine (10 g.) was heated with water (300 c.c.) (and some air) at 170—185° for 5½ hours in a phosphor-bronze autoclave; 5 g. of the base were recovered unchanged, and the aqueous solution was concentrated to one-fourth of its original volume, filtered, and kept in the ice-chest. An abundant crystallisation occurred and the *dioxyhydroxydihydrostrychnidine* was recrystallised several times from water; flat, pointed, colourless needles, m. p. 260° (decomp., darkening from 250°) (Found: loss at 105°, 15·3; N, 6·4. Found in anhydrous material: C, 68·6; H, 7·0. $C_{21}H_{26}O_4N_2,4H_2O$ requires H_2O, 16·3; N, 6·3. $C_{21}H_{26}O_4N_2$ requires C, 68·1; H, 7·0%). The anhydrous substance is hygroscopic and recovers almost the whole of its water of crystallisation on exposure to the air for a week. The base is much more readily soluble in water than any other strychnine derivative (except the salts) described in this memoir; it is also readily soluble in the simple alcohols and in boiling benzene or chloroform, but very sparingly soluble in hot ethyl acetate or light petroleum. The ferric chloride reaction is exhibited well in the presence of a large excess of hydrochloric acid.

Dioxyhydroxyhexahydrostrychnine.—When tetrahydrostrychnine was heated with methyl-alcoholic ammonia at 130—140° for 48 hours, it was recovered entirely unchanged. Tetrahydrostrychnine (11 g.) was heated with water (300 c.c.) in a phosphor-bronze autoclave at 170—185° for 6½ hours. The brownish-yellow liquid was filtered from a little black material, concentrated somewhat, again filtered from a tar, and kept in the ice-chest. Bunches of coarse needles (3 g., m. p. 197—203°) separated, and several recrystallisations from water yielded bunches of large, fibrous, colourless needles, m. p. 201—203° (with effervescence a few degrees higher) (Found: loss at 105°, 9·3. Found in anhydrous material: C, 64·9; H, 6·9;

N, 7·1. $C_{21}H_{28}O_5N_2,2H_2O$ requires H_2O, 8·5. $C_{21}H_{28}O_5N_2$ requires C, 65·0; H, 7·3; N, 7·3%). Neither in the case of this base nor in that of the corresponding compound from strychnidine (see the preceding section) is the formula with two hydrogen atoms less excluded by the analyses. The substance is readily soluble in methyl alcohol, sparingly soluble in cold ethyl alcohol, and very sparingly soluble in boiling benzene, chloroform, ethyl acetate, or acetone. It is moderately readily soluble in cold water, but less soluble than the similar strychnidine derivative. With ferric chloride in presence of much dilute hydrochloric acid, it gives only a faint brown coloration; in presence of a trace of hydrochloric acid, an intense brownish-red colour develops rapidly.

p-*Aminostrychnidine.*—The various derivatives of strychnidine all couple with diazobenzenesulphonic acid in acid solution, giving in the course of time equally intensely-coloured solutions, but the speed of the reaction varies greatly from case to case. In acid solution strychnidine couples much more rapidly than dihydrostrychnidine (A), but in neutral solution the velocities are not very different. We interpret this as due to the increased basic strength of the dihydrostrychnidine (A), and it therefore seems probable that the double bond of strychnidine is not far distant in the molecule from the nitrogen atom that is bound to the aromatic nucleus. *Sulphobenzeneazostrychnidine* is a crimson powder, insoluble in organic solvents. The finely powdered substance (2·6 g.) was added to a solution of hydrated stannous chloride (6·5 g.) in concentrated hydrochloric acid (16 c.c.), and the mixture boiled for a few minutes. It was then cooled, rendered strongly alkaline with sodium hydroxide, and extracted with chloroform. The extracts were dried and evaporated until crystallisation began; much light petroleum was then added. The nearly colourless precipitate crystallised from benzene in microscopic prisms which decompose above 330° (Found: N, 12·4. $C_{21}H_{25}ON_3$ requires N, 12·5%). *Aminostrychnidine* is moderately readily soluble in chloroform, sparingly soluble in hot benzene, and practically insoluble in boiling ethyl acetate or light petroleum. This amine gives, with ferric chloride in hydrochloric acid solution, an eosin-red coloration, quickly fading to yellow; addition of sodium nitrite to an acid solution produces the same colour change, but if the solution is used at once it can be shown to contain a diazonium salt. The product of coupling with β-naphthol and H-acid is violet, and with J-acid red. Diazotised sulphanilic acid and aminostrychnidine give a purple coloration, probably not due to a normal azo-compound since it is discharged by the addition of sodium hydroxide. The most interesting colour reactions of aminostrychnidine are, how-

ever, the following, which show that strychnidine has free *m*- and *p*-positions with respect to the nitrogen atom. When ferric chloride is added to a solution of the base in dilute hydrochloric acid containing hydrogen sulphide, a brownish-reddish-purple colour is produced and the solution exhibits an intense brown fluorescence. Addition of ferric chloride to an acid solution containing dimethylaniline gives a royal-blue colour, doubtless owing to the formation of an indamine of the type of Bindschedler's green. If *m*-tolylenediamine is employed in place of the dimethylaniline, a deep blue coloration is developed, and on warming, the solution becomes intense bluish-eosin-red, and on dilution exhibits a striking greenish-yellow fluorescence.

Sulphobenzeneazomethylstrychnine.—Methylstrychnine (0·75 g.) was dissolved in very dilute acetic acid (200 c.c.) and diazobenzenesulphonic acid (0·85 g., 2·2 mols.) added with stirring. A red oil quickly formed and solidified; this was collected and crystallised from much hot alcohol as a dull brick-red powder (Found: N, 9·7%, showing that only one sulphobenzeneazo-group has been introduced). The *substance* is insoluble in organic solvents with the exception of the simple alcohols; it is moderately soluble in cold water, but a change occurs on boiling, the colour deepens and the solid that separates on cooling is readily soluble in cold acetone.

Strychnic Benzoic Anhydride.—Benzoyl chloride (5 c.c.) was gradually added to a well-agitated solution of strychnic acid (4 g.) in 3% aqueous sodium hydroxide (100 c.c.). The light brown precipitate was collected and crystallised from xylene–light petroleum (b. p. 80—100°) in golden-yellow clusters of minute rods, m. p. 215—218° (Found: C, 73·6, 73·7; H, 6·2, 6·4; N, 6·2, 6·3. $C_{28}H_{28}O_4N_2$ requires C, 73·7; H, 6·2; N, 6·1%). A product requiring less purification, and otherwise identical, is obtained from strychnic acid (6 g.), sodium bicarbonate (14 g.), water (200 c.c.), and benzoyl chloride (8 c.c.). This substance is insoluble in dilute aqueous sodium hydroxide and is *slowly* hydrolysed on boiling the solution; it is also hydrolysed on boiling with water. It is, however, *immediately* hydrolysed by dissolution in cold dilute aqueous acids, even acetic acid, and addition of sodium hydroxide then precipitates strychnine. The behaviour of this compound seems inconsistent with any theory of its nature other than that which we have advanced—the formation of mixed anhydrides in the Schotten–Baumann process has frequently been observed in other cases.

Addendum made on October 3rd, 1927. After the present paper had been set up in proof, the discovery was made that dihydro-

strychnidine (A), m. p. 212—214°, is identical with the substance described in Part IV (this vol., p. 1622) as methyl-ψ-dihydrostrychnidine, $C_{22}H_{28}ON_2$, m. p. 212°. The latter was obtained in very poor yield by the action of heat on the dimethochloride (A) of methoxymethyltetrahydrostrychnidine and it was thought that its formation was due to the following change: $C_{23}H_{32}O_2N_2,2MeCl = C_{22}H_{28}ON_2 + 2MeCl + MeOH$.

It is now clear that a more drastic decomposition must take place and that a $>CH_2$ group also is lost at the high temperature necessary for the change. The identity of the substance thus produced with dihydrostrychnidine (A) was proved by a close comparison of the properties, and also by the m. p. (212—214°) of a mixture, of the two preparations. Moreover the analysis given in Part IV, p. 1622 (Found: C, 78·1; H, 8·0; N, 8·5) agrees rather better with the formula $C_{21}H_{26}ON_2$ (Calc.: C, 78·2; H, 8·1; N, 8·7%) than with the formula $C_{22}H_{28}ON_2$ (Calc.: C, 78·6; H, 8·3; N, 8·3%) suggested at the time, and the same applies to the analyses of the derivatives.

It is also clear that the substance described as methyl*neo*dihydrostrychnidinium iodide (*loc. cit.*, p. 1623), obtained from methoxymethyltetrahydrostrychnidine hydriodide by the action of heat, is in reality dihydrostrychnidine (A) methiodide, and a similar correction must be applied to the corresponding chloride. It is therefore necessary in Part IV, pp. 1596, 1597, 1621, 1622 and 1623, to replace the names methyl-ψ-dihydrostrychnidine by dihydrostrychnidine (A) and methyl*neo*dihydrostrychnidinium iodide (chloride) by dihydrostrychnidine (A) methiodide (methochloride). It is also probable that the substance, m. p. 220—221°, described as methyl-ψ-dihydrobrucidine in Part V of this investigation (this vol., p. 1661) is in reality dihydrobrucidine (A), but the proof of this cannot be supplied until this substance has been obtained by a process similar to that employed in the preparation of dihydrostrychnidine (A). Experiments with this object in view are in progress.

The authors wish to thank the Advisory Council of the Department of Scientific and Industrial Research for a grant which has enabled one of them (A. E. O.) to take part in the investigation.

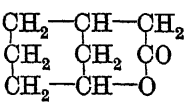
[*Received, July 30th*, 1927.]

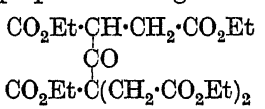
CCCXXI.—3-*Hydroxy*cyclo*hexylacetolactone*.

By ROBERT ROBINSON and AHMAD ZAKI.

ACCORDING to Gulland and Robinson (J., 1923, **123**, 980; *Mem. Manchester Phil. Soc.*, 1925, **69**, No. 10), whose suggestions have been amply justified by the important and outstanding experiments of Schöpf (*Annalen*, 1927, **452**, 211), the bases of the morphine group contain the heterocyclic system (I) associated with other rings.



(I.) 



(II.) $\zeta = O$
(III.) $\varepsilon = N$
(IV.) $\beta = \theta = N$
(V.) $\delta = \zeta = N$
(VI.) $\alpha = \gamma = \eta = \kappa = N$

An examination of the literature shows that substances of this type have not been obtained although the similar systems indicated by II, III, IV, V, and VI (where each letter represents a carbon atom except when otherwise specified) are found among synthesised compounds. It is proposed to attempt the synthesis of simple bases of the type (I) in order to examine the degree of stability of the ring structure. Progress in this direction has been made and is reported at this stage because one of us is unable to continue the work.

There is little doubt that the desired base could be obtained from the *lactone* (VII), named in the title, and we have obtained this substance by the reduction of *m*-hydroxyphenylacetic acid with hydrogen in the presence of platinum-black. The yield, however, is poor, the main product being hexahydrophenylacetic acid. It seemed that a better method of preparation might be through

(VII.) 

(VIII.)

3-keto*cyclo*hexylacetic acid, which might be derived by applying the Dieckmann reaction to the ester of methanediacetic-γ-butyric acid, $CH(CH_2\cdot CO_2H)_2\cdot CH_2\cdot CH_2\cdot CH_2\cdot CO_2H$. The latter we hoped to obtain from the tribasic keto-acid which should be the normal product of hydrolysis of the ester (VIII). This has been prepared, but the scheme broke down owing to the wasteful nature of the operations necessary for the introduction of acetic residues into ethyl acetonedicarboxylate.

EXPERIMENTAL.

m-*Hydroxyphenylacetic Acid*.—Anhydro-α-benzamido-*m*-methoxycinnamic acid (35 g.) was hydrolysed as described by Pschorr (*Annalen*, 1912, **391**, 44), but the resulting alkaline solution was

then acidified by the passage of sulphur dioxide, which precipitated the benzoic acid (compare Buck and Perkin, J., 1924, **125**, 1680). After filtration, concentrated hydrochloric acid was added and the solution boiled to expel sulphur dioxide; on cooling, *m*-methoxyphenylpyruvic acid (14 g.) separated (m. p. 154—155° after crystallisation from alcohol). This acid (8·4 g.) was dissolved in 10% sodium hydroxide (70 c.c.), and 3% hydrogen peroxide (50 c.c.) added. After being kept over-night in the cold, the solution was acidified, and *m*-methoxyphenylacetic acid (6 g., m. p. 66—67° after one crystallisation from water) was isolated by means of ether. *m*-Hydroxyphenylacetic acid has been previously obtained by Salkowski (*Ber.*, 1884, **17**, 507) from *m*-nitrophenylacetonitrile by a series of reactions; we have prepared it by demethylation of its methyl ether: *m*-methoxyphenylacetic acid was boiled with 8 times its weight of freshly distilled hydriodic acid (*d* 1·7) for 2 hours. The solution was cooled and diluted with water, free iodine removed by sulphur dioxide, and the acid isolated by ether as a brown oil which gradually crystallised. The product was purified by one crystallisation from benzene, dissolution in aqueous sodium carbonate, successive extraction of the alkaline solution with carbon disulphide and ether, recovery by means of ether, and a final crystallisation from benzene. The acid had the m. p. (129°) and other properties attributed to it by Salkowski (*loc. cit.*).

Catalytic Reduction of m-*Hydroxyphenylacetic Acid.*—A solution of *m*-hydroxyphenylacetic acid (4·5 g.) in acetic acid (20 c.c.) was vigorously stirred with hydrogen in presence of platinum-black (0·7 g.), prepared by Willstätter's method (*Ber.*, 1912, **45**, 1472). After a little time the flask was evacuated and the mixture stirred with air for 10 minutes; on re-evacuation and admission of hydrogen the rate of absorption was found to have been almost quadrupled. In about 12 hours 2330 c.c. of hydrogen had been absorbed. The filtered solution was steam-distilled until about 2000 c.c. of distillate had been collected; the liquid remaining in the flask was then thoroughly extracted with ether, and after removal of the solvent the residue was twice distilled under diminished pressure. The product appeared to be homogeneous, but owing to the small amount available we do not record the b. p. under diminished pressure; under the ordinary pressure, it has b. p. 240—243°, determined by Siwoloboff's method (*Ber.*, 1886, **19**, 795) (Found: C, 69·0; H, 8·5. $C_8H_{12}O_2$ requires C, 68·6; H, 8·6%). This colourless oil is clearly 3-*hydroxy*cyclo*hexylacetolactone*, for it exhibits the behaviour of a lactone: it is immiscible with water, and on the addition of a drop of sodium hydroxide and a trace of phenolphthalein a red coloration is obtained, which soon disappears,

further quantities of sodium hydroxide being similarly slowly neutralised until the whole of the substance has been decomposed. On acidifying and heating the solution, the lactone was regenerated. The distillate from the steam-distillation contained an acid which was isolated by means of ether and distilled. The fraction, b. p. 243—246°, crystallised in the course of 2 days in large, feather-like aggregates, m. p. 30—31° (Found: C, 67·6; H, 10·0. Calc. for $C_8H_{14}O_2$: C, 67·6; H, 9·8%). From the origin, m. p., analysis, and other properties, there can be no doubt that this substance is identical with hexahydrophenylacetic acid (Wallach, *Annalen*, 1907, **353**, 296). It constituted the main product of the reduction.

Ethyl βδ-*Dicarbethoxy*-γ-*ketopimelate*,

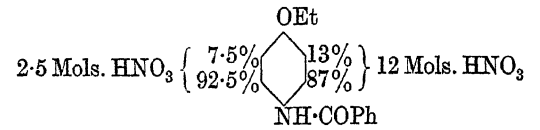
$$CO_2Et{\cdot}CH_2{\cdot}CH(CO_2Et){\cdot}CO{\cdot}CH(CO_2Et){\cdot}CH_2{\cdot}CO_2Et.$$

—An alcoholic solution of sodium ethoxide (from 6·9 g. of sodium) was added during 1½ hours to a mixture of ethyl acetonedicarboxylate (30·3 g.) and ethyl bromoacetate (50 g.), heated on the steam-bath. The mixture was then heated under reflux till neutral, the alcohol distilled, and the product isolated from the residue by means of ether. Thorough drying was found to be essential. The oil was fractionated under 1 mm. pressure, but this process entailed large losses through decomposition. Finally, a homogeneous fraction, b. p. 168—170°/1 mm., was collected (10 g.) (Found: C, 54·8; H, 7·0. $C_{17}H_{26}O_9$ requires C, 54·6; H, 6·9%). Analysis does not determine whether the acetonedicarboxylic ester has been converted into a mono-, di-, tri-, or tetra-substituted derivative, so the ester was hydrolysed by boiling dilute sulphuric acid: acetonediacetic acid, m. p. 142—143° (Volhard, *Annalen*, 1889, **253**, 212) was readily isolated (Found: C, 48·1; H, 6·0. Calc. for $C_7H_{10}O_5$: C, 48·3; H, 5·7%).

Ethyl αββ′-*Tricarbethoxyisobutyrylsuccinate* (VIII).—This substance was obtained from molecular proportions of the foregoing ester (24·7 g.), ethyl bromoacetate, and sodium ethoxide in alcoholic solution. The yield of pure product, b. p. 189—191°/1 mm., was 17 g. (Found: C, 54·8; H, 7·0. $C_{21}H_{32}O_{11}$ requires C, 54·8; H, 6·9%). This would correspond to a 56% yield of the monosubstituted derivative, or a 47% yield of the disubstituted derivative. In view of the amount of recovered material of lower and higher b. p. (10 g. containing at least 2 g. of ethyl bromoacetate) and of the fact that the maximum theoretical yield of disubstituted derivative was 50%, a 47% yield of disubstituted derivative is impossible. The polybasic acid obtained by hydrolysing this ester could not be crystallised.

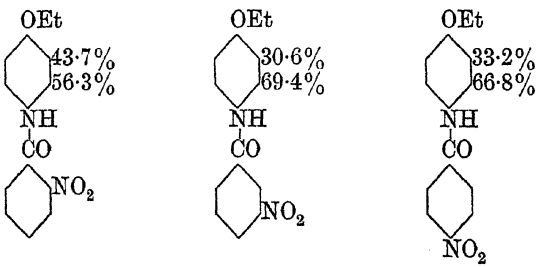
THE UNIVERSITY, MANCHESTER. [*Received, July 18th*, 1927.]

CCCXXII.—*The Relative Directive Powers of Groups of the Forms* RO *and* RR'N *in Aromatic Substitution. Part VII. The Nitration of Benzphenetidide and of* o-, m-, *and* p-*Nitrobenzphenetidides.*



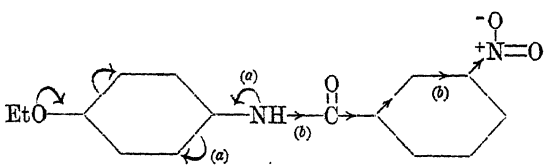
By REGINALD C. FAWCETT and ROBERT ROBINSON.

IN considering the factors governing the relative ease of occurrence of electronic changes, such as those involved in conjugated polarisation, originated or permitted by different atoms, Kermack and Robinson (J., 1922, **121**, 427) suggested two guiding principles: (*a*) that the free electrons in the outer shells are the less active the greater their number; and (*b*) that the activity of free electrons diminishes with increasing atomic weight of the element. Obviously such rules may apply only approximately, and there are alternative ways of stating them, but they serve to correlate experimental results in several fields and give such sequences as NMe_2>SMe>OMe>I>Cl>F for the proton avidity (strength of bases) in the compounds HX and for the effectiveness of the groups in crotenoid systems, and hence for their directive powers in aromatic substitutions of certain types (compare *Chem. and Ind.*, 1925, **44**, 684). The effects of charges, as in the phenoxide and phenylammonium ions, may reverse the order in the series, and this is also true of the effects of substituents which may induce displacements of electrons equivalent to charges. Thus, although the order N>O in aromatic substitution (kationoid reagent, crotenoid system) is theoretically inevitable and justified by everyday laboratory experience so long as we compare neutral, tervalent nitrogen with neutral, bivalent oxygen, yet the application of theory becomes ambiguous when we pass to the comparison of such groups as ·NR·COR and ·OR. Experiment shows that the directive powers of the nitrogenous group can be regulated over a wide range; thus Reverdin (*Ber.*, 1896, **29**, 2595) and Hinsberg (*Annalen*, 1896, **292**, 249) found that the nitration of acet-*p*-anisidide gave acet-3-nitro-*p*-anisidide, establishing beyond question that the directive power of ·NHAc is much greater than that of OMe. Reverdin and Düring (*Ber.*, 1899, **32**, 164) further showed that acet-*o*-phenetidide is changed by nitric acid (41° Beaumé) into its 5-nitro-derivative, although 4-nitro-*o*-phenetidine is obtained by the nitration of *o*-phenetidine in sulphuric acid solution. Similarly the nitration of acet-*o*-anisidide was found to give chiefly the 5-nitro-derivative (Mühlhäuser, *Annalen*, 1881, **207**, 242; Meldola, Woolcott, and Wray, J., 1896, **69**, 1330;



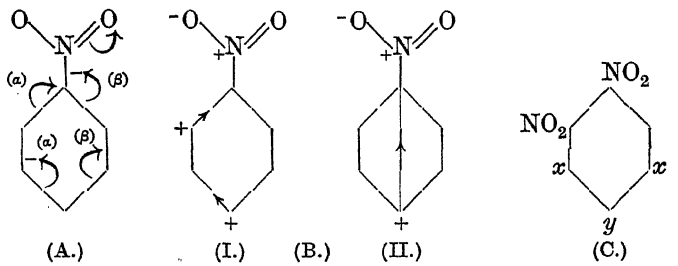
Vermeulen, *Rec. trav. chim.*, 1905, **25**, 12). This has been recently confirmed by Ingold and Ingold (J., 1926, 1310), whose work suggests that owing to the formation of small, undetermined amounts of by-products, the nitration of acet-*o*-anisidide is not a reaction that is suitable for exact quantitative study. On the other hand, Brady, Quick, and Welling (J., 1925, **127**, 2264) found that the nitration of succin-*p*-tolil gave as much as 84% of *N*-2-nitro-*p*-tolylsuccinimide, showing that the group $\cdot N(CO)_2(CH_2)_2$, although itself almost exclusively *p*-directive, is far weaker than methyl in directive power. An explanation, on an electronic basis, of the diminished directive power of nitrogen in such *neutralised* systems (N·CO, etc.) has been already advanced (Robinson, *Chem. and Ind.*, 1925, **44**, 18, 456; Rây and Robinson, J., 1925, **127**, 1618; Part IV, J., 1926, 404; Part V, *ibid.*, p. 411) and may be summarised in the statement that the carbonyl group competes with the aromatic nucleus for the free electrons of the nitrogen octet.

The present investigation is the first of a series in which it is hoped to study the effect of the substituents (R, R') on the directive power of the group R·CO·NR'. In the cases discussed below, R' is H and R is Ph or *o*-, *m*-, or *p*-$NO_2 \cdot C_6H_4$. The circumstance that R' is H involves the possibility of incipient ionisation increasing the directive power or of actual removal of a proton in one of the later phases of the reaction, with the same apparent result. These occurrences should, however, be the more facile the stronger the acid $R \cdot CO_2H$, so they would not influence the directive powers in the sense actually observed, and if taken into account the effects would appear enhanced. The method adopted was to put the groups in turn in competition with ethoxyl, and the reaction examined has been the nitration of the benz-*p*-phenetidides in acetic acid solution at about 0°. Reverdin (*Ber.*, 1911, **44**, 2362) has already studied the nitration of benz-*p*-anisidide and of the isomeric nitrobenz-*p*-anisidides: in each case, the nitrobenzamido-groups were found to be much more powerfully directive than methoxyl, but nothing more than approximately quantitative results were sought. In the present series of experiments, the products were obtained in almost theoretical yield, and thermal analysis showed them to behave as binary mixtures that could contain only traces of other substances. In the case of benz-*p*-phenetidide, the nitration was carried out under two sets of conditions; in the first, nitric acid (2·5 mols.) was gradually added to the phenetidide in acetic acid, and in the second the phenetidide was added to nitric acid (12 mols.) and acetic acid. Thus not only was more acid used in the latter case, but also it was present from the beginning of the operation. The results are



exhibited in the annexed scheme, in which the figures show the proportions in which the nitro-derivatives were formed.

The stronger acid medium has the effect of depressing the directive power of the benzamido-group, and this is clearly due to salt formation and is in harmony with previous experience (compare, *e.g.*, Noelting and Collin, *Ber.*, 1884, **17**, 261; Hollemann, Hartogs, and van der Linden, *Ber.*, 1911, **44**, 704). The nitrobenz-*p*-phenetidides were nitrated under the second set of conditions (12 mols. HNO_3), and as all analogies indicate that these amides should be weaker bases than benz-*p*-phenetidide, the effect of the medium may be expected to be relatively small. The results are expressed graphically thus:



In all three cases, nitration could not be accomplished under the conditions (2·5 mols. HNO_3) that sufficed for the quantitative transformation of benz-*p*-phenetidide, and therefore the general electrical effect of the nitroxyl group makes itself felt over the whole molecule. The figures show, however, that the directive power of the benzamido-group has been diminished to the greater relative extent; the appropriate theory on an electronic basis is represented in the case of the *m*-nitrobenzamido-group by the scheme

in which (*a*) is the directive process and (*b*) is the counteracting general electronic displacement. The effect (*b*) should be more powerful in the *o*- than in the *m*-nitrobenzoyl derivative, and it

should be weakest in the *p*-isomeride. The former deduction is in agreement and the latter in disagreement with the results, which, therefore, suggest that a mechanism exists that enables the more distant group to be the more effective. Such a mechanism may be conjugative (A) or inductive (B) in Kekulé, Dewar, or Claus structures (the last two being regarded as highly improbable and included merely for the sake of completeness), and will also contribute to the enhancement of the effect of an *o*-situated nitroxyl group. In either case, *m*- and *p*-situated nitroxyls induce positive

(A.) (I.) (B.) (II.) (C.)

charges at *x* and *y*, respectively (C). In (A) (β), the conjugation is crotonoid and in (A) (α) it is butadienoid and initiated by the general effect of the nitroxyl; this process is almost indistinguishable from that shown in (B) (I). Oxford and Robinson (Part II, J., 1926, 383) found that the directive powers of the *m*- and *p*-nitrobenzyloxy-groups were identical, and the contrast with the results obtained in the present investigation is probably due to the fact that in the benzamido-compounds there is an unbroken sequence of unsaturated atoms, and the point (C of CO), where the effect can theoretically operate so as to influence the directive power of the group, is nearer to the nitrophenyl group than is the corresponding point (O of $Ar{\cdot}O{\cdot}CH_2$) in the nitrobenzyloxy-compounds. We have examined mathematically the question as to whether a *direct* general effect of the dipole, NO, could give the sequence $o>p>m$, on the theory that in its average position in space a line can be drawn through the centre of the hexagon (benzene ring) and the nitrogen and oxygen atoms. On this stereochemical basis, the disparity between the anticipated effects from the *m*- and *p*-positions is reduced by reason of the oblique orientation of the dipole couple in the *m*-position, but on every probable assumption in regard to the relative distances (nuclear C to N, N to O, nuclear C to a point X, where the effect is operative across the intervening space to the couple N—O) we find $o>m>p$ for the resultant field (at X in the direction of the centre of the nucleus) of the dipole. Taking dynamic conditions into consideration, *e.g.*, free revolution of the nitroxyl group and other

ambiguities, it cannot yet be concluded, however, that an explanation of the order $o>p>m$ is impossible on purely stereochemical lines. It is proposed to extend the investigation with the help of an experimental model.

Finally, a point raised by Orton and Bradfield (this vol., p. 986) in connexion with the directive power of the benzamido-group may be mentioned. These authors have found that the velocity of chlorination of benzanilide exceeds that of acetanilide, which indicates that the directive power of benzamido- is greater than that of acetamido-. (In passing, it may be remarked that Brady, Quick, and Welling, *loc. cit.*, found that phthalimido- had a somewhat greater directive power than succinimido-, providing further evidence in the same direction.) The inconsistency of this result on our electronic basis with the fact that benzoic acid is stronger than acetic acid was commented on. Kermack and Robinson (*loc. cit.*) suggested, however, that the aromatic nucleus is a resonator, being either key-negative or key-positive, according to circumstances. It should be regarded as subservient, in a measure, to the needs of other groups, and ready in some phases to supply electrons, in others to accept them. A further generally applicable conception is that when phases leading to activation and phases leading to inhibition of some particular process or reaction alternate, then the activation phases assume by far the greater importance in producing the observed results. In benzoyl derivatives, there will be phases in which the electron density in the neighbourhood of the carbonyl group is increased (retardation of ionisation of benzoic acid, but acceleration of substitution in benzanilide), and other phases in which it is relatively decreased (acceleration of ionisation of benzoic acid, but retardation of substitution in benzanilide).

EXPERIMENTAL.

2-Nitro-4-aminophenetole sulphate was obtained in 50% yield by Reverdin's method (*Helv. Chim. Acta*, 1927, **10**, 3). 3-Nitro-4-aminophenetole was prepared from phenacetin (40 g.) by the method described in D.R.-PP. 99338 and 38322; the yield of product, m. p. 112·7—113·2°, was 37·5 g.

2-*Nitro*-4-*benzamidophenetole*, (A).—2-Nitro-4-aminophenetole sulphate (10 g.) was added to pyridine (200 c.c.), and benzoyl chloride (10 g.) gradually introduced with vigorous shaking. After 1 hour water was slowly added and the precipitated solid was collected; it crystallised from methyl alcohol (charcoal) in flat, yellow needles, m. p. 149—150° (Found: C, 62·8; H, 5·0. $C_{15}H_{14}O_4N_2$ requires C, 62·9; H, 4·9%).

3-*Nitro*-4-*benzamidophenetole*, (B).—3-Nitro-4-aminophenetole (10

g.) was similarly benzoylated by means of benzoyl chloride (15 g.) in pyridine (150 c.c.); the product crystallised from alcohol (charcoal) in tufts of slender, orange needles, m. p. 121·5—122° (Found: C, 63·0; H, 5·1%).

Mixtures of the Isomerides (A) *and* (B).—The freezing points were determined with the usual precautions, first approximately and then more accurately, the outer bath being kept at such a temperature as to maintain the tube containing the material at 1—2° below the freezing point. The mixture was then heated to 15—20° above the m. p. and allowed to cool after the tube was replaced in the air-jacket. Vigorous stirring was practised at 1—2° above the f. p., and slower but steady stirring in the neighbourhood of the f. p. Several concordant results were obtained for each mixture, and all values were rejected when the degree of supercooling exceeded 0·5—1°. All the graphs constructed were smooth, two-branched curves.

The following f. p.'s were determined:

By adding (A) *to* (B).

% (B)	100·0	95·1	89·8	84·3	78·1	72·4	64·8
F. p.	120·2°	118·2°	116·2°	114·2°	111·95°	109·6°	106·2°

By adding (B) *to* (A).

% (B)	41·7	35·4	33·6	26·5	20·5	13·5	6·4	0·0
F. p.	124·5°	128·1°	129·1°	134·2°	137·4°	141·1°	144·8°	147·75°

*Nitration of Benz-*p*-phenetidide.*—Benz-*p*-phenetidide, prepared by the Schotten–Baumann method, crystallised from alcohol in glistening, white laminæ, m. p. 174·5—175°.

(1) *Nitration with* 2·5 *mols. of nitric acid.* A mixture of boiled nitric acid (*d* 1·41; 5 c.c.) and pure acetic acid (12·5 c.c.) was added in the course of ½ hour to benz-*p*-phenetidide (5 g.) suspended in acetic acid (125 c.c.), the vessel being surrounded by melting ice. The highest temperature recorded was 3°. After 1·5 hours, the product was precipitated by water, collected, washed, and dried (5·85 g. or 98·7%) (Found: C, 62·6; H, 4·9. Calc.: C, 62·9; H, 4·9%). This material had f. p. 117·3°, corresponding, from the graph, with a mixture (*a*) containing 92·5% of the isomeride (B), or to a second composition excluded by the confirmatory tests. A mixture of the nitration product (0·8222 g.) and (A) (0·1315 g.) should therefore contain 79·75% of (B): actually, it had f. p. 112·5°, corresponding with 79·8% of (B). The further addition of (A) (1·1502 g.) to this mixture gave a product of f. p. 128·0°, corresponding to 36·5% of (B) [Calc. from (*a*): 36·1% of (B)].

(2) *Nitration with* 12 *mols. of nitric acid.* Benz-*p*-phenetidide (2 g.) was added to a mixture of boiled nitric acid (10 c.c., *d* 1·41) and

acetic acid (40 c.c.) cooled in melting ice; after 10 minutes' stirring, water (400 c.c.) was added, stirring continued for 15 minutes, and the product isolated (2·35 g., or 99·0%) (Found: C, 63·0; H, 5·0%). The following results were obtained on thermal analysis.

Mixture taken, g.	Isomeride added, g.	F. p.	Composition, % (B): From graph.	Calc. from (*b*).
1·1836	—	115·2°	87 (*b*)	—
1·1836	1·2481 (B)	117·7	93·2	93·3
0·3823	0·8056 (A)	132·6	28·5	28·0

2-*Nitro*-4-o-*nitrobenzamidophenetole*, (C), prepared by the pyridine method, crystallised from methyl alcohol (charcoal) in pale yellowish-green, nacreous plates, m. p. 165—166° (Found: C, 54·5; H, 4·1; N, 12·9. $C_{15}H_{13}O_6N_3$ requires C, 54·4; H, 3·9; N, 12·7%). On exposure to light the crystals become pink. 3-*Nitro*-4-o-*nitrobenzamidophenetole*, (D), obtained similarly in 70% yield, crystallised from methyl alcohol (charcoal) in colourless, prismatic needles, m. p. 131—131·5° (Found: C, 54·2; H, 4·0%).

Mixtures of the Isomerides (C) *and* (D).—

By adding (C) *to* (D).

% (D)	100·0	94·5	87·05	82·5	76·1	69·5	63·8
F. p.	129·7°	126·7°	122·6°	119·9°	116·1°	112·6°	112·6°

By adding (D) *to* (C).

% (D)	40·4	32·9	28·1	22·3	17·1	5·4	0·0
F. p.	138·2°	144·0°	146·9°	150·3°	153·8°	161·0°	164·3°

Nitration of o-*Nitrobenz*-p-*phenetidide*.—The phenetidide (11·8 g.) was derived from *p*-phenetidine (9 g.) and *o*-nitrobenzoyl chloride (12 g.) in pyridine (100 c.c.) solution; it crystallised from methyl alcohol (charcoal) in long, silky, white needles, m. p. 170—171° (Found: C, 62·9; H, 5·1. $C_{15}H_{14}O_4N_2$ requires C, 62·9; H, 4·9%).

o-Nitrobenz-*p*-phenetidide (2·25 g.) was added to a mixture of boiled nitric acid (10 c.c.; *d* 1·41) and acetic acid (40 c.c.), cooled in melting ice, and stirred for 1 hour; the temperature did not rise above 3°. The product was isolated (2·55 g., or 97·9%) (Found: C, 54·2; H, 4·0%). The f. p. of this material was in a neighbourhood in which the determinations of f. p. were somewhat unsatisfactory. The nitration product (0·8397 g.) mixed with (D) (0·8366 g.) had f. p. 117·2°, corresponding with 78% of (D), and hence the original product contained 56·1% of (D). The nitration product (0·3856 g.) mixed with (C) (0·3977 g.) had f. p. 147·2°, corresponding with 27·8% of (D), and hence had initially contained 56·5% of (D).

2-*Nitro*-4-m-*nitrobenzamidophenetole*, (E), obtained in the usual

manner, crystallised from ethyl acetate in matted, hair-like, lemon-yellow needles, m. p. 202—203° (Found: C, 54·4; H, 4·3. $C_{15}H_{13}O_6N_3$ requires C, 54·4; H, 3·9%). The isomeric 3-*nitro*-4-m-*nitrobenzamidophenetole*, (F), crystallised from alcohol in long, silky, golden needles, m. p. 157·5—158° (Found: C, 54·3; H, 4·0%).

Mixtures of the Isomerides (E) *and* (F).—

By adding (E) *to* (F).

% (F)	100·0	93·0	89·2	82·2	80·8	73·0
F. p.	157·4°	153·7°	151·6°	147·9°	147·1°	143·0°

By adding (F) *to* (E).

% (F)	67·0	60·6	52·2	47·4	41·25	34·5	26·3	9·3	0·0
F. p.	152·5°	161·6°	168·9°	172·4°	177·2°	182·4°	187·0°	197·2°	201·6°

Nitration of m-*Nitrobenz*-p-*phenetidide*.—The *m*-nitrobenzoylation of *p*-phenetidine (5 g.) in pyridine solution gave the phenetidide, which crystallised from alcohol in pale yellow needles (7·2 g.), m. p. 163·5—164° (Found: C, 63·1; H, 4·7. $C_{15}H_{14}O_4N_2$ requires C, 62·9; H, 4·9%). The nitration (of 2 g.) was carried out like that of the *o*-nitrobenz-*p*-phenetidide and the yield was 2·30 g. (99·4%) (Found: C, 54·4; H, 4·0; N, 12·9. Calc.: C, 54·4; H, 3·9; N, 12·7%). This crude product was stirred at 18° for 3 hours with methyl alcohol (40 c.c.), then collected, washed with methyl alcohol (10 c.c.), and dried (loss in weight in the process, 0·05 g.). In order to determine whether this washing produced a change in composition, a mixture of (E) (1·0 g.) and (F) (1·0 g.) was treated in exactly the same manner; the recovered material (1·94 g.) had f. p. 170·5°, corresponding to 50% of (F), so the alcohol had dissolved 0·03 g. of each isomeride. The washed nitration product had f. p. 146·0°, corresponding with 78·7% or 70·5% of (F). The nitration product (0·9583 g.) mixed with (F) (1·2589 g.) had f. p. 150·4°, corresponding to 87·0% of (F), and hence the initial content of (F) was 70%. A mixture of the nitration product (0·6811 g.) and (E) (0·6904 g.) froze at 182·4°, corresponding to 34·5% of (F), and hence the original product contained 69·5% of (F). Taking the mean, 70·0% of (F), and correcting for the solubility in methyl alcohol, we find that the crude nitration product contained 69·4% of (F).

2-*Nitro*-4-p-*nitrobenzamidophenetole*, (G), crystallised from alcohol in yellow needles, m. p. 208·5—209·5° (Found: C, 54·4; H, 3·9. $C_{15}H_{13}O_6N_3$ requires C, 54·4; H, 3·9%). 3-*Nitro*-4-p-*nitrobenzamidophenetole*, (H), crystallised from alcohol in flat, glistening, orange needles, m. p. 183·5—184·5° (Found: C, 54·5; H, 4·1%).

Mixtures of the Isomerides (G) *and* (H).—

By adding (G) *to* (H).

% (H)	100·0	95·5	89·9	82·3	74·3	69·3	62·7	58·1

By adding (H) *to* (G).

% (H)	35·8	28·9	23·1	18·9	11·9	9·4	5·5	0·0
F. p.	185·9°	190·4°	194·0°	196·0°	200·2°	201·6°	203·9°	207·2°

Nitration of p-*Nitrobenz*-p-*phenetidide*.—The phenetidide crystallised from methyl alcohol in flat, pale yellow needles, m. p. 189—190° (Found: C, 63·0; H, 4·9. $C_{15}H_{14}O_4N_2$ requires C, 62·9; H, 4·9%). *p*-Nitrobenz-*p*-phenetidide (4 g.) was nitrated at 0° during 1 hour by means of a mixture of boiled nitric acid (20 c.c.; *d* 1·41) and acetic acid (80 c.c.). The product (yield, 99·6%) (Found: C, 54·4; H, 3·9; N, 13·0. Calc.: C, 54·4; H, 3·9; N, 12·7%) was washed with methyl alcohol, exactly as described above for the *m*-nitrobenznitrophenetidides, and 2·31 g. gave 2·20 g. of the dried, washed material. A mixture of (G) (1·0 g.) and (H) (1·0 g.) was washed in the standard manner and gave 1·90 g. of material, f. p. 174·5°, corresponding to 49·0% of (H); hence the methyl alcohol dissolved 0·03 g. of (G) and 0·07 g. of (H). The following results were obtained on analysis of the washed nitration product.

Mixture taken, g.	Isomeride added, g.	F. p.	Composition, % (H): From graph.	Calc. from (*c*).
1·0005	—	168·3°	68·5 (*c*)	—
1·0005	0·1249 (H)	170·2	72·1	72·0
0·9310	0·8504 (G)	185·3	36·7	35·8

After correction for the methyl alcohol washing, the crude nitration product is found to have contained 66·8% of (H).

Attempts were made to carry out a series of nitrations of the nitrobenzphenetidides in 60% aqueous nitric acid, but, owing to the fact that the nitro-derivatives covered the surface of the crystals, quantitative mono-nitration could not be secured.

We are indebted to the Department of Scientific and Industrial Research for grants which enabled one of us to take part in the investigation.

THE UNIVERSITY, MANCHESTER. [*Received, August 23rd*, 1927.]

CCCXXIII.—*Some Sulphur Derivatives of Substituted Benzaldehydes.*

By HERBERT HENRY HODGSON and HERBERT GREENSMITH BEARD.

PREVIOUS work on the mercaptobenzaldehydes appears to be limited to that of Friedländer and Lenk (*Ber.*, 1912, **45**, 2083), who prepared the *o*- and *p*-mercaptans and *o*- and *p*-thioethers of benzaldehyde itself. The present paper records the preparation of several substituted benzaldehydes containing sulphur, some of which exhibit remarkable properties.

The *dioxime* of 3 : 3′-*dinitrodibenzaldehyde* 4 : 4′-*disulphide* is a very stable yellow product which, unlike the corresponding 6 : 6′-*disulphide dioxime*, is converted by cold aqueous sodium hydroxide into what appears to be an isomeride of deeper shade, melting 30° lower, and decomposing with violence when heated rapidly, thereby resembling the second dioxime above. The conversion is accompanied by a gradual and remarkable series of colour changes.

Amino-derivatives of the benzaldehyde thioethers proved to be unstable, thus resembling the simple aminobenzaldehydes, although their solutions in acids may be diazotised normally.

The p-*nitrophenylhydrazones* of 3-*chloro*-4- and -6-*methylthiolbenzaldehyde* were scarlet and orange, respectively, and gave bluish-purple and reddish-purple colorations with alkaline hydroxides, thus showing the much more pronounced bathochromic effect of the methylthiol group when para than when ortho to the hydrazine group (compare the azo-group, Hodgson and Handley, J., 1926, 542).

Bromine displaces the methylthiol group from 3-*amino*-6-*methylthiolbenzaldoxime*, forming 2 : 4 : 5 : 6-*tetrabromo*-3-*aminobenzaldoxime*, but it decomposes the 4-methylthiol isomeride.

EXPERIMENTAL.

3 : 3′-*Dinitrodibenzaldehyde* 6 : 6′-*Disulphide*.—This was prepared by gradually adding aqueous sodium disulphide (crystallised sodium sulphide, 48 g.; sulphur, 6 g.; water, 120 c.c.) to a solution in alcohol (300 c.c.) of 6-chloro-3-nitrobenzaldehyde (64 g.), and boiling for 2 hours; the *disulphide* separated quantitatively as a microcrystalline orange-brown powder, m. p. 230—234° (Found: N, 7·5; S, 20·5. $C_{14}H_8O_6N_2S_2$ requires N, 7·7; S, 17·6%); yield, 60 g. By extracting the crude product (10 g.) with boiling glacial acetic acid (two portions of 100 c.c.) its m. p. could be raised to 257° (8 g.) (Found: N, 7·5; S, 17·6%), and the first extract deposited on cooling a mixture of two kinds of crystals (0·7 g.) which were mechanically separated and proved to be sulphur and a

substance of m. p. 220°; this appears to be a mixture containing mainly the monosulphide (Found: N, 8·5; S, 12·2. Calc.: N, 8·4; S, 9·6%). The second extract also deposited this product, m. p. 220°. The first extract on dilution with water gave a pale straw-coloured substance (0·7 g.), m. p. 207—210° (Found: N, 8·0; S, 14·6%), probably impure monosulphide.

Dioxime. The disulphide (3·5 g.), suspended in alcohol (60 c.c.), was boiled under reflux for 1 hour during the gradual addition of a solution of hydroxylamine hydrochloride (1·6 g.) and sodium acetate (2·6 g.) in water (5 c.c.)—longer boiling produced an inferior product. The hot mixture was filtered, the residue extracted with hot alcohol, and the extract added to the filtrate. The *dioxime* separates from alcohol as a straw-coloured microcrystalline powder which does not melt but decomposes violently between 140° and 160° (yield, 50%) (Found: N, 14·0; S, 16·5. $C_{14}H_{10}O_6N_4S_2$ requires N, 14·2; S, 16·2%); it is insoluble in ether, but moderately soluble in acetic acid.

Di-p-nitrophenylhydrazone. The disulphide (0·36 g.), dissolved in hot glacial acetic acid (100 c.c.), was treated at 50—60° with a solution of *p*-nitrophenylhydrazine (0·36 g.) in glacial acetic acid (5 c.c.); the hydrazone was deposited very gradually, although quantitatively, as red micro-needles, m. p. 283—284° (decomp.) (Found: S, 9·8. $C_{26}H_{18}O_8N_8S_2$ requires S, 10·1%). Alkalis give an immediate reddish-purple colour.

3 : 3′-*Dinitrodibenzaldehyde* 4 : 4′-*Disulphide.*—This is prepared almost quantitatively as above from 4-chloro-3-nitrobenzaldehyde. The crude product is practically pure (m. p. 228—232°), and crystallises from glacial acetic acid in bright yellow needles, m. p. 237—238° (Found: N, 7·8; S, 17·7. $C_{14}H_8O_6N_2S_2$ requires N, 7·7; S, 17·6%).

Dioxime. Oximation as described above was complete in 15 minutes, as shown by the entire solubility of the product in aqueous sodium hydroxide. It is very sparingly soluble in all the usual solvents and crystallises from glacial acetic acid in fine, yellow needles, m. p. 260—261° (Found: N, 14·1; S, 16·3. $C_{14}H_{10}O_6N_4S_2$ requires N, 14·2; S, 16·2%).

Behaviour towards Aqueous Sodium Hydroxide.—The yellow solution of this dioxime in cold aqueous sodium hydroxide undergoes the following sequence of colour changes during 15—30 minutes: yellow, yellowish-green, olive-green, deep green, reddish-green, red. When the alkali is added to a hot aqueous suspension of the dioxime, the initial deep green colour rapidly turns to red. On acidification of the red solution with acetic or hydrochloric acid, a substance is precipitated (? isomeric dioxime) which possesses a

deeper yellow colour than the original and is more soluble in acetic acid, acetone, or methyl or ethyl alcohol. This product separates from alcohol in crystalline clusters, m. p. 230—232° (decomp.; shrinking at 160—170°) (Found: N, 14·0; S, 15·9. $C_{14}H_{10}O_6N_4S_2$ requires N, 14·2; S, 16·2%). The change at 160—170° increases in violence with the rate of heating, and becomes explosive if the m.-p. tube is plunged in a bath at 170°. Probably this more labile substance is in a similar physical state to the dioxime of 3 : 3′-dinitrodibenzaldehyde 6 : 6′-disulphide above.

Di-p-*nitrophenylhydrazone.* This may be prepared as above, except that the disulphide is dissolved in only 30 c.c. of glacial acetic acid. The product separates immediately as a fine, orange-red, microcrystalline powder, m. p. 305—310° (decomp.) (Found: S, 10·0. $C_{26}H_{18}O_8N_8S_2$ requires S, 10·1%); it gives a claret colour with alkalis.

Preparation of Thioethers from the Disulphides.

3-*Nitro*-6-*methylthiolbenzaldehyde.*—The corresponding disulphide (10 g., m. p. 257°), suspended in alcohol (50 c.c.), was treated gradually with a solution of sodium hydroxide (12 g.) and crystallised sodium sulphide (5 g.) in water (60 c.c.). Dissolution rapidly ensued with rise of temperature, and after the dark red mixture had been kept at 50—60° for 15 minutes, it was cooled, diluted with water (100 c.c.), and vigorously stirred with methyl sulphate (10 c.c.). The granular product (8·8 g.) was extracted with hot 60% acetic acid and left a very sparingly soluble product (this contained an aldehyde group, but has not been identified). The 3-*nitro*-6-*methylthiolbenzaldehyde* was precipitated by dilution of the acetic acid extract, and on recrystallisation from this acid it separated in pale straw-coloured needles, m. p. 159—160° (Found: N, 7·2; S, 16·3. $C_8H_7O_3NS$ requires N, 7·1; S, 16·2%). The by-product was always obtained in spite of many attempts to prevent its formation under different conditions; its production was minimised by the vigorous agitation.

The *oxime* crystallises from alcohol in colourless needles, m. p. 187° (Found: N, 13·4; S, 15·2. $C_8H_8O_3N_2S$ requires N, 13·2; S, 15·1%), and forms a pale yellow, sparingly soluble *sodium* salt. The p-*nitrophenylhydrazone* crystallises from glacial acetic acid in reddish-orange needles, m. p. 250—252° (Found: S, 9·8. $C_{14}H_{12}O_4N_4S$ requires S, 9·6%), and gives a claret colour with alkalis.

3-*Nitro*-4-*methylthiolbenzaldehyde.*—When 3 : 3′-dinitrodibenzaldehyde 4 : 4′-disulphide is reduced by the above procedure, it is essential that the time and temperature of reduction be rigidly

adhered to; methylation then gives a bright yellow, flocculent precipitate, which is very difficult to filter off and dry; dilution of the reaction mixture with three times its volume of water, however, facilitates the filtration (yield, 92%). Extraction with 60% acetic acid leaves almost pure *3-nitro-4-methylthiolbenzaldehyde*, which crystallises from dilute acetic acid in yellow plates, m. p. 141—142° (Found: N, 7·3; S, 16·0. $C_8H_7O_3NS$ requires N, 7·1; S, 16·2%).

The acetic acid extract contained in addition to the above product a non-aldehydic substance which was separated by oximation as follows: The crude product (10 g.), suspended in alcohol (60 c.c.), was boiled for 2 hours under reflux with a solution of hydroxylamine hydrochloride (3·5 g.) and sodium acetate (6 g.) in water (5 c.c.); the mixture was diluted with water (100 c.c.), made alkaline with sodium hydroxide, and heated to 50°, whereby about 70% dissolved. On acidification of the filtered solution, *3-nitro-4-methylthiolbenzaldoxime* was precipitated; it crystallised from alcohol in yellow needles, m. p. 210° (Found: N, 13·5; S, 15·2. $C_8H_8O_3N_2S$ requires N, 13·3; S, 15·1%). This product was totally insoluble in water, only sparingly soluble in the usual solvents, and formed an orange *sodium* salt which gave a red solution in water. *3-Nitro-4-methylthiolbenzaldehyde*-p-*nitrophenylhydrazone* crystallises from glacial acetic acid as an orange, microcrystalline powder, m. p. 294—296° (decomp.) (Found: S, 9·7. $C_{14}H_{12}O_4N_4S$ requires S, 9·6%), and gives a claret colour with alkalis.

3-Nitroso-4-methylthiolbenzyl Alcohol (?).—The residue (3 g.) from the foregoing oximation separation crystallises from hot water in orange-yellow needles, m. p. 127°, and is moderately soluble in the usual solvents. The colours given with concentrated sulphuric acid and alcoholic potassium hydroxide are light cherry-red and deep reddish-orange, respectively, in contrast to the deep red and pale yellow given by 3-nitro-4-methylthiolbenzaldehyde. The product forms neither an oxime nor a *p*-nitrophenylhydrazone; it does not respond to Liebermann's nitrosoamine reaction, but when heated with hydriodic acid (*d* 1·7) it gives methyl iodide and a mercaptan. Further, it only gradually gives a silver mirror when warmed with ammoniacal silver nitrate, and is, in general, a less active reducing agent than the above thioether (Found: C, 52·2, 52·3, 52·3; H, 5·31, 5·26, 5·25; N, 7·72, 7·76, 7·7; S, 17·3, 17·3, 17·4; *M*, cryoscopic in naphthalene, 182, 182. $C_8H_9O_2NS$ requires C, 52·4; H, 4·9; N, 7·65; S, 17·4%; *M*, 183). On reduction with titanous sulphate, only 3 atoms of hydrogen were used, but 3-nitro-4-methylthiolbenzaldehyde consumed only 5 atoms instead of the anticipated 6. The data agree with those required for 3-nitroso-

4-methylthiolbenzyl alcohol, but this constitution is only tentatively adopted.

Reduction of the Nitrobenzaldehyde Thioethers and Preparation of the Chlorobenzaldehyde Thioethers.—The thioether (5 g.), suspended in water (80 c.c.), was reduced by adding sodium hyposulphite (18 g.) all at once (about 1 g. of an insoluble complex by-product was invariably formed). The resulting aminobenzaldehyde thioether could be precipitated by alkalis, but was almost unfilterable and resinified rapidly on keeping (compare *m*-aminobenzaldehyde); the reaction mixture was therefore acidified at 0—10° with hydrochloric acid, diazotised by solid nitrite (12 g.), and decomposed in the usual way with cuprous chloride, the chloro-compound being removed by distillation with steam.

3-*Chloro*-6-*methylthiolbenzaldehyde* is readily soluble in the usual solvents and crystallises from alcohol in colourless cubes, m. p. 65° (Found: Cl, 19·1. C_8H_7OClS requires Cl, 19·0%); yield, 1·6 g. Its *oxime* crystallises from alcohol in colourless needles, m. p. 114° (Found: Cl, 17·5. C_8H_8ONClS requires Cl, 17·6%), and its p-*nitrophenylhydrazone* from glacial acetic acid in orange needles, m. p. 246°, giving a reddish-purple colour with alkalis.

3-*Chloro*-4-*methylthiolbenzaldehyde* was obtained in much smaller yield than its isomeride, and was not so readily volatile in steam. It is soluble in the usual solvents and crystallises from alcohol in colourless needles, m. p. 58—59° (Found: Cl, 18·9%). Its *oxime* crystallises from alcohol in colourless needles, m. p. 134° (Found: Cl, 17·6%), and the p-*nitrophenylhydrazone* from glacial acetic acid in scarlet micro-needles, m. p. 222—223°, which give a bluish-purple colour with alkalis.

Reduction of the Oximes of 3-*Nitro*-4- *and* -6-*methylthiolbenzaldehyde.*—The oxime (2 g.), dissolved in 20% aqueous sodium hydroxide (4 c.c.), was added to a boiling solution of ferrous sulphate (18 g.; crystallised) in water (100 c.c.); ammonia was added periodically and the boiling continued for 1 hour. The hot mixture was filtered, and the aminomethylthiolbenzaldoxime separated in colourless needles on cooling; yield, 80%.

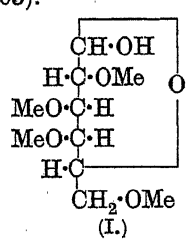
3-*Amino*-6-*methylthiolbenzaldoxime*, m. p. 140° (Found: N, 15·5. $C_8H_{10}ON_2S$ requires N, 15·4%), was treated with bromine water in hydrochloric acid solution at 0°, whereupon 2 : 4 : 5 : 6-*tetrabromo*-3-*aminobenzaldoxime* was formed; it crystallised in colourless needles, m. p. 202—203° (Found: Br, 70·0. $C_7H_4ON_2Br_4$ requires Br, 70·8%), from glacial acetic acid. This product contains no sulphur, is soluble in alkalis, and diazotises in concentrated sulphuric acid solution; the diluted diazo-solution couples with alkaline β-naphthol.

3-*Amino*-4-*methylthiolbenzaldoxime*, m. p. 100° (Found: N, 15·3%), is decomposed by bromine into a tarry complex substance insoluble in alkalis.

Analytical Note.—Estimations of sulphur by the Carius method in products containing the methylthiol group were without exception too low, but the oxidation method with sodium peroxide proved satisfactory.

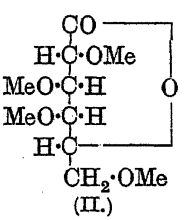
The authors desire to thank the Department of Scientific and Industrial Research for a grant to one of them (H. G. B.), and Messrs. J. W. Leitch and Co. and the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD. [*Received, April 14th*, 1927. *Revised, August 9th*, 1927.]



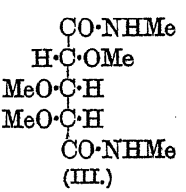
CCCXXIV.—*The Ring Structure in Normal Galactose. Oxidation of Tetramethyl δ-Galactonolactone.*

By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and DAVID IDRIS JONES.



THE form of galactose present in α- and β-methylgalactosides, lactose, raffinose, and melibiose is recognisable as the form which appears in crystalline tetramethyl galactose (Haworth and Long, this vol., p. 544; Charlton, Haworth, and Hickinbottom, *ibid.*, p. 1527; compare Schlubach and Moog, *Ber.*, 1923, **56**, 1957). This compound is readily characterised by its physical properties and by its crystalline anilide. Its oxidation to tetramethyl δ-galactonolactone has also been described (Haworth, Ruell, and Westgarth, J., 1924, **125**, 2468). In the present series of experiments, this lactone has again been examined and the characteristic crystalline *phenylhydrazide* (m. p. 135—137°) of the corresponding tetramethyl galactonic acid has been prepared. From the latter compound the lactone can readily be regenerated and the purified product obtained in this way has properties which are indistinguishable from those previously recorded. The oxidation of this lactone was conducted with nitric acid (*d* 1·42), and from this treatment a liquid product resulted which was isolated in the form of the methyl ester. That this consisted almost entirely of methyl *l*-arabotrimethoxyglutarate was shown by its conversion into the crystalline amide and methylamide. The degradative oxidation of the original sugar was thus carried out in two stages, involving first the oxidation to the lactone by bromine water, and secondly its conversion into a dibasic acid; and this mode of procedure in stages possesses the distinct advantage

that the final product is essentially homogeneous, whereas this is not the case when the sugar is oxidised direct with nitric acid (compare Hirst, J., 1926, 350). Only a trace of *d*-dimethoxysuccinic acid, which was isolated as the diamide, was found to be present in the oxidation product. The absence of any trace of tetramethoxymucic acid excludes the possibility of a 1 : 6-oxide linking. The *l*-arabotrimethoxyglutaramide was recognised by its rotation $[\alpha]_D$ + 50° in water, and by its decomposition on heating at 230°. Direct comparison with an authentic specimen prepared from arabinose (Hirst and Robertson, J., 1925, **127**, 358) indicated its identity. When the ester was treated with methylamine in methyl-alcoholic solution, the crystalline *l-arabotrimethoxyglutaromethylamide* (III) separated as needles, m. p. 173°; $[\alpha]_D^{18°}$ + 59·9°. Comparison with an authentic specimen prepared by an alternative method, *viz.*, from pure methyl *l*-arabotrimethoxyglutarate obtained from normal trimethyl arabinose, proved its identity (Haworth and Jones, this vol., p. 2349). Since the crystalline methylamide has a definite m. p. (without decomposition) the comparison could in this case be made by means of a mixed m.-p. determination, a procedure which cannot be followed with equal certainty with the crystalline amide.



These results prove the constitution of the tetramethyl δ-galactonolactone, and lead by inference to the conclusion that crystalline tetramethyl galactose possesses an amylene-oxide structure, as was previously suggested on other grounds (Pryde, J., 1923, **123**, 1808; Haworth, Ruell, and Westgarth, *loc. cit.*). This sugar should now be definitely indexed as 2 : 3 : 4 : 6-tetramethyl galactose (I), and the derived lactone as 2 : 3 : 4 : 6-tetramethyl galactonolactone (II). By inference, it is concluded that free galactose possesses the amylene-oxide structure, since there appear to be no reasonable grounds for postulating a difference in ring structure between galactose and α- and β-methylgalactosides (compare Drew and Haworth, J., 1926, 2303).

(II.)

(III.)

EXPERIMENTAL.

Preparation of Tetramethyl Galactose.—Octamethyl lactose (Haworth and Leitch, J., 1918, **113**, 198) was hydrolysed in the

usual manner with aqueous hydrochloric acid, the neutralised solution being thereafter extracted with chloroform to remove the tetramethyl galactose. The crude tetramethyl galactose so obtained was purified by conversion into the crystalline anilide (m. p. 192°), which is easily obtainable in a very pure state (Irvine and McNicoll, J., 1910, 97, 1454). Hydrolysis of the anilide with 5% aqueous hydrochloric acid (Haworth, Ruell, and Westgarth, J., 1924, 125, 2473), followed by distillation of the product, now gave a pure specimen of tetramethyl galactose in the form of a syrup containing both the α- and β-modifications of the sugar; $n_D^{13°}$ 1·4682; $[\alpha]_D^{15°}$ + 118° in water ($c = 1·9$; equilibrium value). A small quantity of this syrup dissolved in ether yielded crystals when rubbed with a glass rod during the evaporation of the solvent. When nucleated with this crystalline material, the main bulk crystallised readily to give in good yield solid tetramethyl galactose, m. p. 71—72° after recrystallisation from light petroleum (compare Schlubach and Moog, *loc. cit.*).

Preparation of Tetramethyl δ-Galactonolactone.—For comparative purposes three methods were employed for the preparation of this lactone. In the first, the directions given by Haworth, Ruell, and Westgarth were followed, the liquid tetramethyl galactose mentioned above being used; the resulting lactone was a liquid whose physical constants were in exact agreement with those previously recorded. The second method involved the preparation of the lactone from crystalline tetramethyl galactose, the experimental conditions being otherwise unchanged. The product (b. p. with bath temperature 163—166°/0·18 mm.; $n_D^{14°}$ 1·4606) was a liquid which could not be induced to crystallise (0·1603 G. required 6·9 c.c. of N/10-sodium hydroxide for neutralisation. Calc.: 6·85 c.c.).

A polarimetric study of its behaviour in aqueous solution showed $[\alpha]_D$ + 157° approx. (initial value by extrapolation); $[\alpha]_D$ + 26·2° (equilibrium value after 14 hours). The values of $[\alpha]_D$ plotted against time gave a curve indistinguishable from that already recorded by Haworth, Ruell, and Westgarth (*loc. cit.*) and by Drew, Goodyear, and Haworth (this vol., p. 1237). The third method for preparing the lactone in a highly pure condition lay in the regeneration of the compound from the crystalline phenylhydrazide of the corresponding 2:3:4:6-tetramethyl galactonic acid. The lactone (1·9 g.) prepared from the liquid tetramethyl galactose (α+β forms) was mixed with the theoretical amount of freshly distilled phenylhydrazine and sufficient ether to form a homogeneous solution. The mixture was heated on the water-bath for 30 minutes and a solid mass remained. This was broken up, rubbed with ether, and filtered, giving a white, crystalline solid (2·55 g.; m. p. 135—137°), which was the pure *phenylhydrazide*

of tetramethyl galactonic acid. Recrystallisation from ether or benzene failed to raise the m. p. (Found : C, 56·25; H, 7·5; N, 8·5; OMe, 32·4. $C_{16}H_{26}O_6N_2$ requires C, 56·1; H, 7·6; N, 8·2; OMe, 36·3%). The phenylhydrazide (1·9 g.) was treated with a slight excess of $N/10$-aqueous hydrochloric acid (60 c.c.) and heated at 100° for 3 hours. This gave a pale yellow solution, which was evaporated to dryness under diminished pressure, the residue being finally dried for 2 hours at 100°/12 mm. The lactone was then extracted by dry chloroform containing a little ether, and after removal of the solvent and thorough drying, it was finally purified by distillation to give a colourless liquid (1·09 g.), $n_D^{13°}$ 1·4609; $[\alpha]_D$ + 156° (initial value). Equilibrium value after 14 hours +26·1°. 0·3139 G. required for neutralisation 13·6 c.c. of $N/10$-sodium hydroxide (Calc. : 13·4 c.c.).

Oxidation of Tetramethyl δ-Galactonolactone with Nitric Acid.—The lactone used was a specially purified specimen ($n_D^{13°}$ 1·4606) which conformed exactly in its polarimetric behaviour to the standards accepted for the pure lactone. A solution containing 5 g. of lactone in 40 c.c. of nitric acid (d 1·42) was gently warmed for ½ hour at 50—60°, whereupon oxidation commenced. The reaction continued slowly and smoothly as the temperature was gradually raised to 90°, and appeared to be complete after 6 hours at this temperature. Throughout the subsequent dilution, removal of the nitric acid and water by distillation under diminished pressure, and esterification of the oxidation products with methyl alcohol, the usual methods were employed, details of which have already been published. The esterified product was obtained as a clear, mobile liquid weighing 4·33 g. This was neutral to litmus and without action on Fehling's solution. Distillation gave (I) 3·6 g., b. p. 95°/0·08 mm., $n_D^{15°}$ 1·4359, $[\alpha]_D^{20°}$ + 44·7° in water ($c = 1·2$); (II) 0·56 g., b. p. 110°/0·18 mm., $n_D^{15°}$ 1·4369, $[\alpha]_D^{20°}$ + 33·8° in water ($c = 2$). The first fraction agreed in physical properties with methyl *l*-arabotrimethoxyglutarate (Hirst and Robertson, *loc. cit.*) and analysis showed it to be very nearly pure (Found : C, 47·6; H, 7·3; OMe, 58·8. Calc. for $C_{10}H_{18}O_7$: C, 48·0; H, 7·2; OMe, 62·0%).

Confirmation was obtained by the formation of the corresponding amide. The ester (0·97 g.) dissolved in methyl-alcoholic ammonia (10 c.c.) gave after 15 hours a first crop of crystals in the form of needles, m. p. 270—278° (decomp.), which appeared to be a mixture of *d*-dimethoxyglutaramide and *l*-arabotrimethoxyglutaramide (Found : C, 41·6; H, 7·15; N, 14·0; OMe, 33·4%). The main crop, which crystallised in the course of a few days, weighed 0·55 g. (yield 63% of theory). Recrystallised from methyl alcohol, this material decomposed at 230° with evidence of melting beginning at 228°, and it was shown to be *l*-arabotrimethoxyglutaramide by com-

parison with an authentic specimen; $[\alpha]_D$ + 50·2° in water (c = 1·14) (Found: C, 43·2; H, 7·2; N, 12·4; OMe, 40·1. Calc.: C, 43·6; H, 7·3; N, 12·7; OMe, 42·2%).

The corresponding methylamide was prepared by dissolving the ester (0·46 g.) in methyl alcohol (6·0 c.c.) saturated with methylamine, and allowing the solution to remain at room temperature for 4 days. After removal of the solvent in a vacuum desiccator, the resulting solid mass was recrystallised from ethyl acetate, giving needles; m. p. 172°, alone or mixed with an authentic specimen of the methylamide (Haworth and Jones, *loc. cit.*) prepared from pure methyl *l*-arabotrimethoxyglutarate; yield 0·4 g.; $[\alpha]_D^{15°}$ + 59·9° (Found: C, 48·3; H, 8·2; N, 10·9; OMe, 35·55. Calc.: C, 48·35; H, 8·1; N, 11·2; OMe, 36·4%).

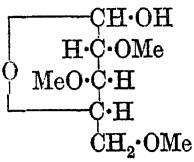
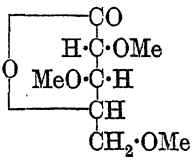
CCCXXV.—1:3:4:6-*Tetramethyl* (γ-)*Fructose and* 2:3:5-*Trimethyl* (γ-)*Arabinose. Oxidation of* d- *and* l-*Trimethyl* γ-*Arabonolactone.*



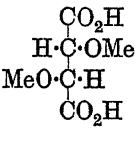
By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and ABRAHAM LEARNER.

THE representative of the so-called γ-sugars in the arabinose series was first prepared as *l*-trimethyl γ-arabinose by Baker and Haworth (J., 1925, **127**, 365), who assigned a butylene-oxide structure to this sugar for the reason that it gave on oxidation with bromine water a crystalline trimethyl arabonolactone which was characterised as a γ-lactone. The latter conclusion was confirmed by Haworth and Nicholson (J., 1926, 1899), who showed that unsubstituted γ-arabonolactone prepared by oxidation of *l*-arabinose gave, on methylation, the same crystalline trimethyl derivative as Baker and Haworth had isolated by oxidation of trimethyl γ-arabinose (I).

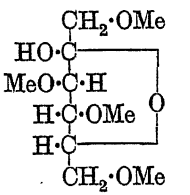


The allocation of a butylene-oxide structure to both the lactone and the sugar was supported by the comparison of the rate of hydrolysis of the former with that of other γ-lactones (Charlton, Haworth, and Peat, J., 1926, 89; Drew, Goodyear, and Haworth, this vol., p. 1242). These conclusions have now been tested by degradation of *l*-trimethyl γ-arabonolactone by oxidative methods which are herein described.

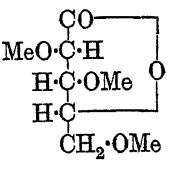
In the meantime, the corresponding optical enantiomorph, *viz.*, *d*-trimethyl γ-arabonolactone, has also been isolated (Avery, Haworth, and Hirst, this vol., p. 2308) from the products of oxi-



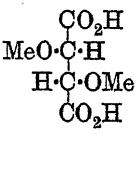
dation of tetramethyl γ-fructose. The crystalline form, melting point, and magnitude of specific rotation of the two specimens were identical, but the sign of rotation was opposite. It became evident that the final proof of the constitution of this lactone was an issue of considerable importance in the structural chemistry of the sugars, since the solution of the problem of the structure of sucrose rested upon this proof. Accordingly, the two enantiomorphous specimens of trimethyl γ-arabonolactone were submitted independently to oxidation with nitric acid (*d* 1·42). The product isolated from the *l*-trimethyl γ-arabonolactone (II) was recognised as *d*-dimethoxysuccinic acid (III), inasmuch as it gave a crystalline amide and a crystalline methylamide which were identical with authentic specimens specially prepared from *d*-tartaric acid.



(I.)



(II.)



(III.)

(IV.)

(V.)

(VI.)

Similarly, the *d*-variety of trimethyl γ-arabonolactone (V), which had been isolated from tetramethyl γ-fructose (IV), gave on oxidation *l*-dimethoxysuccinic acid (VI); this was characterised as the crystalline amide and methylamide, which were identified as before by direct comparison with authentic specimens prepared for this purpose from *l*-tartaric acid (Haworth and Jones, this vol., p. 2349).

These experimental results must be considered in relation to the structurally isomeric trimethyl δ-arabonolactone, which has been shown to be amylene-oxidic and to give rise on oxidation (Haworth and Jones, *loc. cit.*) to *l*-arabotrimethoxyglutaric acid, which was similarly characterised through the crystalline methylamide (compare Hirst and Robertson, J., 1925, **127**, 358). It was therefore demonstrated that whilst normal trimethyl arabinose contains an amylene-oxide ring, the trimethyl γ-arabinose, on the other hand, has a butylene-oxide structure; that *l*-trimethyl γ-arabonolactone derived from the latter sugar must be indexed as 2 : 3 : 5-trimethyl arabonolactone, and that to the *d*-isomeride isolated in the manner

indicated above as a degradation product of the fructose residue in methylated sucrose is similarly to be assigned the constitution of *d*-2:3:5-trimethyl arabonolactone. These conclusions confirm in their entirety the inferences already drawn from the results of the earlier studies of the lactones and of the reference compounds herein described.

An additional point of interest which emerges from the further study of these lactones is that the two γ-lactones displayed great stability towards nitric acid, contrasting remarkably with the labile character of the corresponding δ-lactone of this series and also with other δ-lactones which have hitherto been submitted to oxidative degradation. This behaviour is in harmony with the distinctive properties of γ- and δ-lactones which have already been elucidated in the course of earlier work (Drew, Goodyear, and Haworth, *loc. cit.*).

EXPERIMENTAL.

Oxidation of l-*Trimethyl* γ-*Arabonolactone.*—Arabonic acid, obtained in the usual way from arabinose by the action of bromine water, was purified by conversion into the cadmium salt, which could be readily recrystallised from water in place of alcohol as mentioned in the literature. After removal of the cadmium as sulphide, the lactone was obtained on concentrating the aqueous solution (Bauer, *J. pr. Chem.*, 1884, **30**, 367; 1886, **34**, 46). *l*-Trimethyl γ-arabonolactone was then obtained by methylating arabonolactone (Haworth and Nicholson, *loc. cit.*). It had m. p. 30—32° alone or mixed with specimens prepared from arabonolactone and from trimethyl γ-arabinose (Baker and Haworth, *loc. cit.*); $[\alpha]_D$ −44° in water (initial value) decreasing to −25° after 20 days. A solution containing 1·7 g. of this material in 17 c.c. of nitric acid (*d* 1·32) was heated on the water-bath until reaction commenced at 95°. At this temperature, evolution of nitrous fumes took place slowly, and the oxidation was allowed to proceed for 7 hours at 95—100°. Even then no definite end-point had been reached, but the rate of reaction had become extremely slow. 35 C.c. of distilled water were then added, and the nitric acid was removed by distillation under diminished pressure with frequent additions of water. The product was thus obtained as a colourless syrup, which was esterified by digestion for 8 hours with 40 c.c. of methyl alcohol containing 1·6 g. of hydrogen chloride. The mineral acid was neutralised in the usual way with silver carbonate, the solvent evaporated, and the esterified oxidation product purified by distillation, which proceeded smoothly only after a preliminary heating for 3 hours at 120°. This effected the transformation of some methyl trimethylarabonate into the lactone of the corresponding acid. During the preliminary heating,

a small quantity of methyl oxalate was collected. The main fraction (A) distilled from a bath at 159—170°/16 mm., giving a colourless syrup (0·8 g.), n_D^{16} 1·4391; $[\alpha]_D^{16°}$ +41·5° in water (c = 1·1; initial value) (0·1041 G. required, as lactone, 2·0 c.c. of N/10-sodium hydroxide for neutralisation; for hydrolysis and neutralisation, 8·7 c.c.). These properties correspond with those required by a mixture containing approximately 65% of methyl *d*-dimethoxysuccinate and 35% of *l*-trimethyl arabonolactone. The presence of methyl *d*-dimethoxysuccinate was proved by the formation of the corresponding amide and methylamide. The distillate (A) (0·23 g.), dissolved in 2·3 c.c. of methyl-alcoholic ammonia, gave, after 40 hours, 0·07 g. of *d*-dimethoxysuccinamide, the identity of which was confirmed by comparison with an authentic specimen, melting to a dark liquid at 269°, decomposing rapidly at 283°; $[\alpha]_D$ +97° in water (c = 0·433) (Found: C, 40·7; H, 6·8; OMe, 33·7. Calc. for $C_6H_{12}O_4N_2$: C, 40·9; H, 6·8; OMe, 35·2%). Again, 0·13 g. of the distillate (A), dissolved in 1·3 c.c. of methyl alcohol saturated with methylamine, gave crystals on evaporation of the solvent after 3 days. These recrystallised from ethyl acetate as long needles (yield, 0·06 g.), m. p. 205—206°, alone or mixed with an authentic specimen of the methylamide of dimethoxysuccinic acid prepared from *d*-tartaric acid (Haworth and Jones, *loc. cit.*). No trace of the amide or methylamide of trimethoxyglutaric acid could be detected in the course of these experiments.

Oxidation of d-*Trimethyl γ-Arabonolactone.*—The *d*-trimethyl γ-arabonolactone was prepared from tetramethyl γ-fructose by the method described by Avery, Haworth, and Hirst (this vol., p. 2317); it had m. p. 33°; $[\alpha]_D$ +44·5° (initial value) in water ⟶ +25·5° (after 20 days). This material (2·5 g.) was dissolved in 28 c.c. of nitric acid (*d* 1·42), the procedure thereafter being similar to that described above. A small quantity of oxalic acid (identified as methyl oxalate) was formed during the oxidation. The esterified product was distilled from a bath at 155—160°/13 mm., and gave 1·42 g. of colourless syrup (B), $n_D^{15°}$ 1·4400; $[\alpha]_D$ − 50° in methyl alcohol (c = 1·50) (0·0581 G. required 1·0 c.c. of N/10-sodium hydroxide for neutralisation, as lactone, and 4·9 c.c. of N/10-sodium hydroxide for complete hydrolysis and neutralisation). These figures correspond to a mixture containing 32% of methyl *l*-dimethoxysuccinate and 68% of *d*-trimethyl γ-arabonolactone. The amide [yield 0·202 g. from 0·50 g. of the product (B)], prepared in the usual way, was obtained as long needles, which melted after preliminary darkening at 245—250° to a dark liquid at 270° (rapid decomp. at 283°); $[\alpha]_D^{18°}$ − 94° in water (c = 0·9) (Found: C, 40·9; H, 6·8; N, 15·7; OMe, 33·2. Calc. for $C_6H_{12}O_4N_2$: C, 40·9; H,

6·8; N, 15·9; OMe, 35·2%). The corresponding methylamide was also prepared as long needles (from ethyl acetate), m. p. 204—205° alone or mixed with a specimen of the methylamide of *l*-dimethoxysuccinic acid prepared from *l*-tartaric acid (Haworth and Jones, *loc. cit.*).

No trace of the amide or methylamide of trimethoxyglutaric acid was found in the mother-liquors arising from these experiments.

The authors wish to express their thanks to the Department of Scientific and Industrial Research for a maintenance grant to one of them.

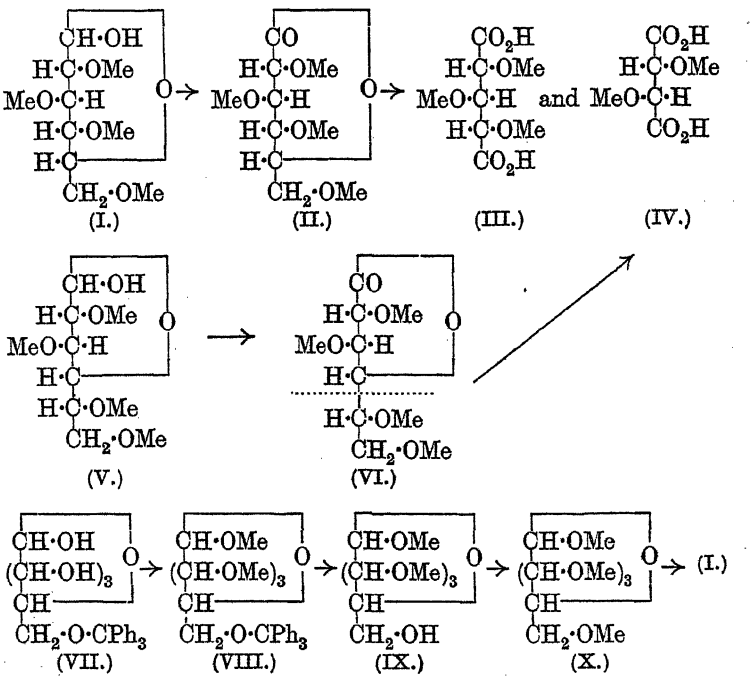
[*Received, August 16th,* 1927.]

CCCXXVI.—*The Structure of the Normal and γ-Forms of Tetramethyl Glucose. Oxidation of Tetramethyl δ- and γ-Gluconolactones.*



By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and ERNEST JOHN MILLER.

IN a paper on the revision of the structural formula of glucose (Charlton, Haworth, and Peat, J., 1926, 89), the constitution assigned to the usual form of tetramethyl glucose represented this sugar as an amylene oxide, whilst the butylene-oxide formula was assigned to its labile or γ-form. The experimental basis for these conclusions was the recognition that the lactones derived from these two sugars were, respectively, δ- and γ-lactones. These conclusions have been tested in the course of subsequent work (Drew, Goodyear, and Haworth, this vol., p. 1237), and further experimental data are now furnished which confirm the recognition of the two forms of the methylated sugar as 2 : 3 : 4 : 6-tetramethyl glucose (*i.e.*, the normal crystalline variety) and 2 : 3 : 5 : 6-tetramethyl glucose (the labile or γ-variety, which is a liquid). This inference with respect to the normal form of the sugar was supported by the direct oxidation of the normal crystalline sugar with nitric acid (Hirst, J., 1926, 350).

Tetramethyl δ-gluconolactone has been prepared in a condition of greater purity by preliminary conversion into the crystalline phenylhydrazide (m. p. 115°; $[\alpha]_D + 42{\cdot}1°$ in ethyl alcohol) of the corresponding acid, followed by regeneration of the lactone from this derivative. The physical constants of the regenerated lactone differ but slightly from those already recorded, and the substance is still recognised as a liquid. On the other hand, the lactone derived

by oxidation of the liquid tetramethyl γ-glucose is crystalline, and the physical constants are also on record (Drew, Goodyear, and Haworth, *loc. cit.*).

The study of these two lactones has now been continued by the application of the method of direct oxidation with nitric acid. Tetramethyl δ-gluconolactone, when treated with this reagent, gave a mixture of methoxyglutaric and methoxysuccinic acids, which were separated and identified through their crystalline amides and methylamides. Whilst the comparison of the amides with authentic specimens could be made with a considerable measure of certainty, yet, for reasons already explained (Haworth and Jones, this vol., p. 2349), it appeared to be advantageous to strengthen the validity of such comparisons by the adoption of the methylamides as reference compounds; but it should be added that the preparation of the amides enables a more satisfactory estimate to be made of the yields of the products of oxidation. The experiments have shown that the δ-lactone is

degraded to give a considerable yield (47%) of *i*-xylotrimethoxyglutaric acid (III) and a smaller yield (20%) of *d*-dimethoxysuccinic acid (IV), since the methylamides of these products were shown to be identical with authentic specimens prepared from other

sources. The isolation of the xylotrimethoxyglutaric acid affords definite proof that the oxygen of the oxide ring cannot be attached to carbon atom 2, 3, or 4, since the stereochemical arrangement of the groups associated with these carbon atoms is preserved in the *i*-xylotrimethoxyglutaric acid. On the other hand, the possibility of the attachment of the oxygen of the ring to carbon atom 6 in normal glucose derivatives is excluded by a large number of observations, amongst which may be mentioned (1) the oxidation of methylglucoside to the methylglucoside of glycuronic acid (Smolenski, *Rocz. Chem.*, 1923, **3**, 153); (2) the preparation herein described of 2 : 3 : 4-trimethyl β-methylglucoside (IX) [which is readily converted into normal tetramethyl methylglucoside (X)] from 6-triphenylmethyl glucose (VII), the constitution of which has been proved by Helferich, Klein, and Schäfer (*Annalen*, 1926, **447**, 19). The only remaining point for the attachment of the oxygen of the ring is the 5-position. The conclusion is therefore drawn that the structural formula (II) represents the constitution of tetramethyl δ-gluconolactone, and thus the formula (I), which represents crystalline tetramethyl glucose as an amylene oxide, is confirmed.

Similar experiments were conducted on the degradative oxidation of tetramethyl γ-gluconolactone, and these revealed the greater stability of this lactone towards nitric acid as compared with the δ-lactone. A further distinction is that a portion of the lactone appeared to undergo very profound degradation during the oxidation, a circumstance which has a definite bearing on the constitution of the substance. The only dibasic acids definitely recognised in the products from this treatment were oxalic acid and *d*-dimethoxysuccinic acid (IV), which was isolated as the amide and methylamide, both of which are crystalline, the latter compound being compared with an authentic specimen of the methylamide obtained ultimately from *d*-tartaric acid (compare Haworth and Jones, *loc. cit.*). An exhaustive but unsuccessful search was made for the presence of a glutaric acid derivative, the experimental conditions being such that the presence of a derivative of this acid could easily have been detected had it been formed. The isolation of *d*-dimethoxysuccinic acid from tetramethyl γ-gluconolactone proves definitely that the oxygen of the oxide ring cannot be attached to carbon atom 2 or 3, and thus the propylene-oxide formula for γ-glucose derivatives, advocated by Irvine and Patterson (J., 1922, **121**, 2152), is definitely disproved. Again, the oxygen of the ring cannot be attached at position 6, since tetramethyl γ-gluconolactone is derivable (in two stages) from 2 : 3 : 6-trimethyl glucose (Charlton, Haworth, and Peat, *loc. cit.*) but not from the 2 : 3 : 4-isomeride. The failure to isolate trimethoxyglutaric acid, when considered in relation to the

fact that the amylene-oxide structure has already been assigned to the δ-lactone, suffices to exclude the possibility of attachment of the oxide ring at carbon atom 5, and it follows, therefore, that the oxygen of the ring must be linked to carbon atom 4. Tetramethyl γ-glucose and its related lactone are thus seen to have a butylene- or γ-oxide structure (V and VI).

In the above reaction, scission of the lactone had occurred at the point indicated by the dotted line drawn between the fourth carbon atom, which is attached to one junction of the oxide ring, and the fifth carbon atom of the chain. Consideration of alternative methods by which a compound of formula (VI) could undergo scission appears to supply a reason for the failure to obtain *d*-dimethoxysuccinic acid in a yield greater than 20%. A comparison with the course which the oxidation of the δ-lactone takes, giving both a glutaric and a succinic acid derivative, suggests that if an analogous breakdown of the γ-lactone occurred, this might lead to the formation, not only of *d*-dimethoxysuccinic acid, but also of methoxymalonic acid. The isolation of the latter, which we failed to recognise, would be rendered difficult by reason of its instability. Indications were given of the presence of a dimethyl saccharolactone, which had presumably been formed by the oxidation of the terminal $-CH_2OMe$ group at position 6 to a carboxyl group. A similar oxidation of this terminal group is recorded in the case of 2 : 3 : 6-trimethyl glucose (Irvine and Hirst, J., 1922, **121**, 1213) and also with 2 : 3 : 5-trimethyl arabinose (Baker and Haworth, J., 1925, **127**, 365).

Incidentally, it may be remarked that the butylene-oxide ring structure of the γ-glucose residue in glucose-diacetone receives confirmation. Support is thus given to the inferences drawn by Karrer and Hurwitz (*Helv. Chim. Acta*, 1921, **4**, 728), although their conclusions and experimental methods were severely attacked by Irvine and Patterson (J., 1922, **121**, 2155), whose criticisms are seen to have been based on a misapprehension as to the structure of the monomethyl derivative of glucose-diacetone.

EXPERIMENTAL.

Preparation of Tetramethyl δ-Gluconolactone (II).—Specially purified tetramethyl glucose (I) (m. p. 86°) was converted into tetramethyl gluconic acid by digestion with bromine water at 60° until the solution no longer gave a positive Fehling's test. The lactone was then isolated by the usual method as a colourless liquid, b. p. 106—107°/0·04 mm.; $n_D^{14°}$ 1·4566; $[\alpha]_D^{22°}$ + 99° in water ($c = 2·27$; initial value), decreasing rapidly to the constant value $[\alpha]_D^{22°}$ + 30·8° after 8 hours. Attempts to induce the lactone to crystallise were unsuccessful, and further purification was effected

by regenerating the compound from the crystalline phenylhydrazide of the corresponding tetramethyl gluconic acid. The phenylhydrazide was prepared by the method described by Charlton, Haworth, and Peat (*loc. cit.*); recrystallised from benzene, it had m. p. 115°, $[\alpha]_D$ + 42·1° in ethyl alcohol (c = 1·0). Treatment with 5% aqueous hydrochloric acid for 3 hours on the water-bath served to regenerate the acid, and the lactone was isolated by evaporating the solution to dryness under diminished pressure and extracting the residue with dry chloroform admixed with a little ether. The phenylhydrazine hydrochloride was filtered off, the solvent evaporated under diminished pressure, and the residual syrup purified by repeated distillation in a high vacuum. The final distillate had b. p. 101°/0·06 mm.; $n_D^{14°}$ 1·4565; $[\alpha]_D^{18°}$ + 101° in water (c = 2·06; initial value), decreasing in the course of 8 hours to a constant value $[\alpha]_D^{18°}$ 29·6°. The regenerated lactone was therefore almost identical in physical properties with the original specimen, and further repeated attempts to induce crystallisation were unsuccessful.

Oxidation of Tetramethyl δ-Gluconolactone.—A specimen of the lactone (4·0 g.), which had been purified as above, was dissolved in nitric acid (32 c.c.; d 1·42). A vigorous reaction took place at 70°. This was moderated by cooling the reaction vessel, and after 1 hour the temperature was raised to 90° and the reaction allowed to proceed to completion (6 hours). The solution was diluted with water and the reaction product isolated as the methyl ester as described below for the tetramethyl γ-gluconolactone. The esterified product was distilled, giving a colourless liquid (A) (yield, 2·7 g.), b. p. 98—100°/0·05 mm.; $n_D^{15°}$ 1·4400; $[\alpha]_D^{16°}$ + 21·7° in water (c = 2·2). This material appeared to be a mixture containing approximately 30% of methyl *d*-dimethoxysuccinate and 70% of methyl *i*-xylotrimethoxyglutarate (Found: C, 46·8; H, 7·2; OMe, 61·3. Calc.: C, 47·6; H, 7·1; OMe, 61·5%). The presence of both these substances was proved by the isolation of the corresponding crystalline amides and methylamides.

Amides.—The distillate (A) (1·0 g.) was dissolved in 6 c.c. of methyl alcohol saturated with ammonia and kept for 70 hours, during which 0·19 g. of *d*-dimethoxysuccinamide separated as clusters of long needles. These darkened when heated above 200°, melted at 270° to a dark liquid, and decomposed rapidly at 283°; $[\alpha]_D$ + 94° in water (c = 0·51). Direct comparison with an authentic specimen established the identity of this material. The disturbance of the solution consequent upon the removal of the dimethoxysuccinamide induced rapid crystallisation of a second substance of markedly different habit and appearance; this was filtered off after 4 days, and washed with methyl alcohol and ether; yield, 0·25 g.;

m. p. 197°. It was optically inactive. Comparison with an authentic specimen prepared from xylose proved its identity with *i*-xylotrimethoxyglutaramide.

Methylamides.—The distillate (A) (1·4 g.) was dissolved in methyl alcohol (8 c.c.) saturated with methylamine; after 3 days, the solvent and the excess of methylamine were removed by evaporation in a vacuum desiccator. The residual solid mass was dissolved in 30 c.c. of boiling ethyl acetate, the solution cooled, and the resulting crystals were washed with a little ethyl acetate and then with ether; m. p. 158—163° (yield, 0·34 g.). Recrystallisation from ethyl acetate now gave the methylamide of *i*-xylotrimethoxyglutaric acid in long needles which, alone or when mixed with an authentic specimen prepared from xylose, melted at 165—167°. The substance was optically inactive (Found: C, 48·3; H, 8·3; N, 11·5; OMe, 34·3. Calc. for $C_{10}H_{20}O_5N_2$: C, 48·4; H, 8·1; N, 11·3; OMe, 37·5%). The mother-liquor from the first crop of crystals, on evaporation to dryness under diminished pressure, gave a residue which was recrystallised three times from ether–ethyl acetate (equal vols.); yield, 0·05 g.; long needles, m. p. 206°, alone or when mixed with a specimen of the methylamide of *d*-dimethoxysuccinic acid prepared from *d*-tartaric acid.

Oxidation of Tetramethyl γ-Gluconolactone (VI).—The lactone used was a crystalline specimen, m. p. 26—27°, conforming exactly with the polarimetric standards for the material prepared by Drew, Goodyear, and Haworth from tetramethyl γ-glucose (this vol., p. 1242). This lactone (3·4 g.) was dissolved in nitric acid (26 c.c.; *d* 1·42) and heated on the water-bath at 80° for ½ hour, but showed no appreciable change; the temperature was accordingly raised to 90°, but the reaction was sluggish and had not reached completion after 5 hours at this temperature; nevertheless it was decided to examine the products at this stage. The solution was diluted with water and the nitric acid removed by distillation under diminished pressure with frequent additions of water. The residue was esterified with methyl alcohol (50 c.c.) containing hydrogen chloride (2·4 g.), the mineral acid neutralised with silver carbonate, and the filtered solution evaporated to a syrup which contained a small quantity of mineral matter. The latter was removed by dissolving the syrup in benzene, and the subsequent evaporation of the solvent served to remove all traces of water. Distillation of the esterified product was difficult owing to the presence in small amount of a substance which underwent transformation when heated at 120° in a vacuum. This gave a minute quantity of a volatile liquid, probably methyl alcohol, of which the sudden evolution in the form of vapour caused violent bumping. The reaction product was there-

fore heated at 135—140°/11 mm. until this transformation was complete. Distillation now proceeded smoothly and gave (*a*) 0·3 g. of a colourless liquid which solidified in the receiver and was mainly methyl oxalate—some of this material had been collected during the preliminary heating; (*b*) 0·7 g., b. p. 135—140°/12 mm., $n_D^{15°}$ 1·4365; (*c*) 0·85 g., b. p. 140—160°/12 mm., $n_D^{15°}$ 1·4442, $[\alpha]_D$ + 57° in water ($c = 1·1$; initial value), decreasing to + 50° after several days; (*d*) residue, 0·2 g. Fractions (*b*) and (*c*) were colourless liquids which developed an acid reaction in aqueous solution; neutralisation of these solutions indicated the presence of a lactone. This observation, together with previous experience gained in distilling the esters of γ-hydroxy-acids, suggested that the transformations which preceded distillation were due to the elimination of methyl alcohol from the ester of a γ-hydroxy-acid, with the formation of a lactone. The presence of a lactone was further demonstrated by the change in rotation of the aqueous solution when kept for several days.

Amides and Methylamides.—Both fractions (*b*) and (*c*) yielded crystalline *d*-dimethoxysuccinamide when dissolved in methyl-alcoholic ammonia. In one experiment, 0·120 g. of (*b*) gave after 4 days 0·064 g. of long needles, which were filtered off and washed with methyl alcohol and ether; these darkened at 245°, began to melt with decomposition at 270°, and decomposed entirely at 283°. Control experiments made in the same apparatus and under identical conditions, in which specimens of the *d*-dimethoxysuccinamide prepared from *d*-tartaric acid were employed, gave identical results; $[\alpha]_D^{20°}$ + 95° ($c = 1·1$) (Found: C, 40·8; H, 7·1; N, 15·7; OMe, 34·7. Calc. for $C_6H_{12}O_4N_2$: C, 40·9; H, 6·8; N, 15·9; OMe, 35·2%). Further proof of identity was furnished by preparing the corresponding methylamide. From 0·15 g. of fraction (*b*) in 1·1 c.c. of methyl alcohol saturated with methylamine, a mixture of syrup and crystals was obtained by removal of the solvent under diminished pressure. The crude crystalline material weighed 0·06 g., and on recrystallisation from ethyl acetate gave needles which, alone or mixed with an authentic specimen of the methylamide of *d*-dimethoxysuccinic acid prepared from *d*-tartaric acid, melted at 204° (Found: C, 46·7; H, 7·9; N, 13·8. Calc. for $C_8H_{16}O_4N_2$: C, 47·05; H, 7·8; N, 13·7%).

Fraction (*c*) (0·500 g.) gave analytically pure *d*-dimethoxysuccinamide (0·068 g.), m. p. 270° (decomp. 282°) (Found: C, 40·9; H, 7·1; N, 15·5%). An exhaustive examination was made of the syrup remaining after evaporation of the mother-liquors from the amide formations. A further very minute quantity of *d*-dimethoxysuccinamide was obtained, but no other crystalline material. In particular, no trimethoxyglutaramide could be isolated. For this

examination the whole of the remaining portions of (*b*) and (*c*) were treated with methyl alcohol and ammonia. *Titration of fraction* (*c*): 0·1040 G. required 3·9 c.c. of *N*/10-sodium hydroxide for neutralisation of the lactone portion, and 8·3 c.c. (total) of *N*/10-sodium hydroxide for hydrolysis and neutralisation. These figures, in conjunction with the yield of crystalline amide (which gives an approximate estimate of the amount of dimethoxysuccinic ester present), indicated that the major portion of (*c*) consisted of a dibasic lactone-ester, possibly the methyl ester of dimethyl saccharolactone. The amount of unchanged tetramethyl γ-gluconolactone was apparently very small, and this was confirmed by the failure to isolate the characteristic and easily recognisable crystalline phenylhydrazide of the corresponding tetramethyl gluconic acid.

[With ABRAHAM LEARNER.]

Methylation of Triphenylmethyl Glucose (VII).—Crystalline triphenylmethyl glucose (3·0 g.) (as prepared by Helferich, Klein, and Schäfer, *loc. cit.*) was dissolved in methyl iodide and treated in the usual manner with silver oxide. The operation was repeated three times, and the crude product so obtained gave OMe, 21·7 (Calc. for $C_{29}H_{34}O_6$: OMe, 25·9%), the low value being attributable to the presence of a small quantity of triphenylcarbinol. The methylated product was hydrolysed by 100 c.c. of methyl alcohol containing 0·5% of hydrogen chloride. After being kept for 5 minutes at 65° and for 2½ hours at room temperature, the solution was neutralised with silver carbonate. The residual syrup obtained after evaporation of the solvent was extracted with warm water. The aqueous extract, evaporated at 50° under diminished pressure, yielded a syrup which crystallised partially when nucleated with a specimen of 2 : 3 : 4-trimethyl β-methylglucoside. Purification of this material by distillation from a bath at 135°/0·1 mm. yielded a colourless liquid which crystallised on cooling. The crystals were drained on porous earthenware, and recrystallised from light petroleum, giving matted needles; these, alone or when mixed with a specimen of 2 : 3 : 4-trimethyl β-methylglucoside (IX) prepared from gentiobiose, melted at 92—93° (Found: C, 50·7; H, 8·6. Calc. for $C_{10}H_{20}O_6$: C, 50·8; H, 8·5%).

CCCXXVII.—*Acid and Salt Effects in Catalysed Reactions. Part XI. The Hydrolysis of Ethyl Acetate and the Catalytic Catenary.*

By HARRY MEDFORTH DAWSON and WILLIAM LOWSON.

THE detailed study of the velocity of the acetone–iodine reaction in the presence of weak acids and the corresponding salts (see previous papers) has shown that catalytic effects of considerable magnitude are to be attributed to the undissociated acid and also to the acid anion. For various other reactions, evidence in favour of the catalytic activity of the undissociated acid has already been furnished by observations on the changes in reaction velocity which occur when the concentration of the acid is altered or when the corresponding salt is added, and an attempt has been made to explain the facts in terms of the so-called dual theory. According to later developments, the dual theory would seem to represent a very incomplete statement of the actual relations, and in the expectation that other reactions would show catalytic effects parallel with those observed in the action of iodine on acetone, measurements have been made of the rate of hydrolysis of ethyl acetate in presence of mixtures of acetic acid and sodium acetate. The mixtures used are represented by the general formula cHA + xMA, in which c is constant and x is variable.

Preliminary observations with 0·1N-acid solutions showed that, with a continually increasing salt content, the velocity falls at first to a minimum, and increases later in such a way that it can be represented as a linear function of x. Since for such a series of acid–salt mixtures the concentration of the hydroxyl ion is proportional to x, it was thought possible that the effects could be accounted for by the joint action of the hydrogen and hydroxyl ions. The reaction velocities calculated on this hypothesis are, however, much smaller than those observed, as may be illustrated by reference to the data for the most concentrated salt solution ($x = 2{\cdot}5$), for which the observed velocity is about 8 times as great as the calculated value. Furthermore, when the observed velocity was plotted against the p_{H} value of the solutions, it was found that the minimum velocity corresponds approximately with $p_{\text{H}} = 5{\cdot}1$. This represents a hydrogen-ion concentration which is much larger than would be expected on the assumption that the hydrogen and hydroxyl ions are the only active catalytic agents. The isocatalytic point on the $\overset{+}{\text{H}}$–$\overset{-}{\text{OH}}$ catenary is actually given by $[\overset{+}{\text{H}}]_i = \sqrt{k_{\text{OH}}K_w/k_h}$ and by substituting $k_{\text{OH}}/k_h = 1000$ and $K_w = 10^{-14}$, this equation yields a hydrogen-ion concentration which corresponds with $p_{\text{H}} = 5{\cdot}5$.

It thus appears that the observed minimum-velocity (*M.V.*) point differs in respect of both velocity and hydrogen-ion concentration from the isocatalytic point characteristic of the $\overset{+}{H}$–$\overset{-}{O}H$ catenary, and this divergence led us to infer that the observed catalytic effects are connected with the catalytic activity of the undissociated acetic acid molecule and of the acetate anion. At the same time, the difference of 0·4 between the p_H values of the observed *M.V.* point and of the isocatalytic point on the $\overset{+}{H}$–$\overset{-}{O}H$ catenary is small enough to suggest that the anionic catalytic effect will not be confined to the acetate ion, but will be shared by the acetate and hydroxyl ions. The relations involved in such circumstances have been already considered in connexion with the catalytic effects exhibited by acetate buffers (compare this vol., p. 1146).

In accordance with the above views, it follows that the initial value of the specific reaction velocity (velocity referred to unit concentration of ester) in the presence of catalysts of the series $0{\cdot}1CH_3{\cdot}CO_2H + xCH_3{\cdot}CO_2Na$ should be represented by the formula

$$\begin{aligned} v &= v_h + v_a + v_{OH} + v_m \\ &= k_h[\overset{+}{H}] + k_a[\overset{-}{A}] + k_{OH}[\overset{-}{O}H] + k_m[HA] \quad . \quad . \quad (1) \end{aligned}$$

This equation may be reduced to the form $v = f[\overset{+}{H}]$, but for the present purpose it will be applied directly to the experimental observations.

Attention may, in the first instance, be directed to the results for those solutions which contain relatively large proportions of salt. In such solutions, the catalytic effect of the hydrogen ion can be almost neglected, whilst the concentration, and therefore the catalytic effect, of the undissociated acetic acid is constant. The observed changes in reaction velocity are therefore attributable to variations in the magnitude of the catalytic effects which are represented by the second and third terms in equation (1). If the straight line which expresses the connexion between v and x is extrapolated to $x = 0$, it is obvious that the intercept on the ordinate affords a measure of $v_m = k_m[HA] = 0{\cdot}1k_m$. The value thus obtained for k_m is $14{\cdot}5 \times 10^{-7}$.

Having thus determined k_m, the value of k_a may be derived from the observed velocity for any acid–salt mixture which falls on the linear portion of the v–x curve, in that k_a is the only remaining unknown quantity in equation (1). Rewriting this, we have

$$v_a = k_a x = v - k_h[\overset{+}{H}] - k_{OH}[\overset{-}{O}H] - k_m c_2$$

and from the data for the mixture $0{\cdot}1CH_3{\cdot}CO_2H + 2{\cdot}0CH_3{\cdot}CO_2Na$, the value obtained for k_a is $2{\cdot}0 \times 10^{-7}$.

The four coefficients being known, it is now possible to apply equation (1) to the interpretation of the experimental results.

EXPERIMENTAL.

The observations, which were made at 25° with an ester concentration of 0·4 mol. per litre,* are concerned solely with the initial velocity of hydrolysis. The molar concentration of acetic acid (y) produced during a measured time interval (t) was determined by titration of 25 c.c. samples of the solution with 0·1N-sodium hydroxide. The value of y is based on an increase of 1—2 c.c. in the volume of standard alkali required to neutralise the test sample, and it is estimated that the error involved is not greater than $\pm$ 0·03 c.c. The ester hydrolysed during the period of observation thus corresponds with 1—2% of the total ester present, and in the region of the minimal velocities the time required for this is about 2 months. The specific velocity is given by $v = y/at$, where a is the initial ester concentration, and this velocity, it may be noted, is identical with the initial value of k in the equation $k = 1/t \,.\, \log_e a/(a - y)$ for a unimolecular reaction, in that this equation reduces to the form $k = y/at$ when y is small compared with a.

The results of the experiments are summarised in Table I. Col. 1 shows the molar concentration (x) of acetate, col. 2 the hydrogen-ion concentration calculated from $[\overset{+}{H}] = K(c - [\overset{+}{H}])/(x + [\overset{+}{H}])$, and from this the values of $[\bar{A}]$, $[\bar{OH}]$, and [HA] are derived. Cols. 3—6 give the values of v_h, v_a, v_{OH}, and v_m, respectively, col. 7 the total calculated velocity $v = v_h + v_a + v_{OH} + v_m$, and col. 8 the corresponding observed specific velocity. The values employed for the various velocity coefficients are: $k_h = 6{\cdot}1 + 10^{-3}$,† $k_a = 2{\cdot}0 \times 10^{-7}$, $k_{OH} = 6{\cdot}5$, and $k_m = 14{\cdot}5 \times 10^{-7}$; for the ionisation constant of acetic acid $K = 1{\cdot}85 \times 10^{-5}$, and for the ionic product of water $K_w = 10^{-14}$.

With reference to Table I it may be noted that the catalytic effects produced by the acetate and hydroxyl ions are in a constant ratio, the value of which is given by $v_a/v_{OH} = k_aKc/k_{OH}K_w = 5{\cdot}7$. The general agreement between the numbers in the last two columns affords substantial evidence that the observed catalytic effects are

* On account of "salting-out," this was reduced to 0·2 mol./litre in the case of the three most concentrated salt solutions.

† This value is based on the results obtained in the detailed investigation of the hydrolysis of ethyl acetate under the catalytic influence of acetic acid (compare Dawson and Lowson, this vol., p. 2107).

2·5	0·074	0·04	5·00	0·88	1·45	7·4	7·6

due to the combined action of the hydrogen, acetate, and hydroxyl ions and of the undissociated acetic acid molecule.

In accordance with relations derived previously (Dawson and Dean, J., 1926, 2872; Dawson, this vol., p. 1146), the plot of the reaction velocity against p_H yields a symmetrical curve of catenary type. This curve is characterised by a minimum (isocatalytic) point, the hydrogen-ion concentration of which is given by

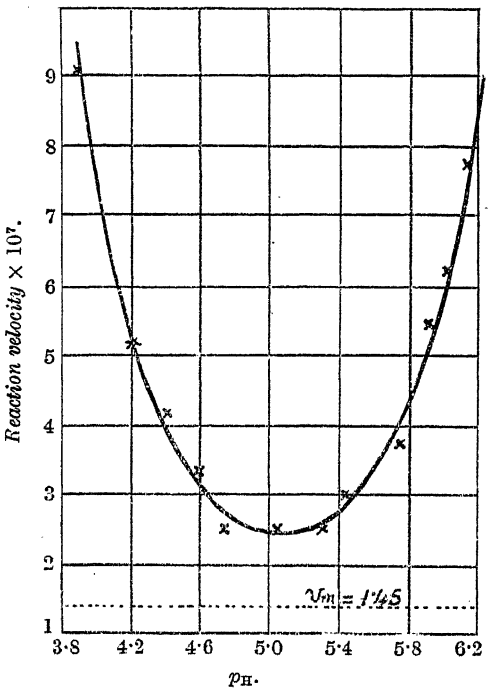
$$[\overset{+}{H}]_i = \sqrt{(k_a K c + k_{OH} K_w)/k_h}$$

and the corresponding minimum reaction velocity by

$$v_i = 2\sqrt{k_h(k_a K c + k_{OH} K_w)} + k_m c,$$

if k_m be neglected in comparison with k_h.

By substitution of the values for the various constants, these equations give $[\overset{+}{H}]_i = 8{\cdot}4 \times 10^{-6}$, or $(p_H)_i = 5{\cdot}07$, and $v_i = 2{\cdot}48 \times 10^{-7}$.



The diagram shows a catenary curve which has been drawn to show the connexion between the observed reaction velocities and the p_H values of the solutions. These p_H values are those derived on the assumption that the mass law is applicable to the ionisation of acetic acid and that the acetate is completely ionised. The co-ordinates of the apex of this catenary are obviously in close agreement with the above values of v_i and $(p_H)_i$.

The dotted horizontal line represents the velocity v_m due to the undissociated acetic acid. This may be regarded as the base line for the u—p_H curve, where u is the ionic reaction velocity.

According to the procedure adopted on p. 2445 for the evaluation of the coefficients k_m and k_a, the former was derived by extrapolation

of the linear portion of the v–x curve, whilst the latter was obtained from the slope of this line. Since the slope is determined by the joint action of the acetate and hydroxyl ions, a knowledge of k_{OH} is implied, and when the value of this coefficient is not known, other methods must be used for the derivation of k_a. These need not be described in the present paper, but reference may appropriately be made to an alternative method for the determination of k_m.

FIG. 1.

Catalytic activity of 0·1*N*-$CH_3 \cdot CO_2H$ + x*N*-$CH_3 \cdot CO_2Na$ *in the hydrolysis of ethyl acetate. Reaction velocity* ($v \times 10^7$) *plotted against* p_H.

If the hydrogen-ion concentrations of solutions of the constant-acid series are expressed in terms of the hydrogen-ion concentration of the isocatalytic mixture, such that $n = [\overset{+}{H}]/[\overset{+}{H}]_i$, the equation for the reaction velocity may be written

$$v = k_h[\overset{+}{H}]_i(n + 1/n) + k_m c$$

and for larger values of n this becomes

$$v = nk_h[\overset{+}{H}]_i + k_m c \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The corresponding equation for the minimum velocity is

$$v_i = 2k_h[\overset{+}{\mathrm{H}}]_i + k_m c \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Multiplying (2) by 2 and (3) by n, we obtain by subtraction

$$k_m = (nv_i - 2v)/(n-2)c \quad . \quad . \quad . \quad . \quad (4)$$

The use of equation (4) for the determination of k_m presumes a knowledge of the isocatalytic data, but does not entail measurements of reaction velocity for solutions which contain a much larger proportion of salt than that which is present in the isocatalytic mixture. In this respect, the method is very different from the extrapolation method, and since for various reasons the experimental realisation of the linear portion of the v–x curve is not always possible, the method represented by equation (4) may frequently be found to be useful for the determination of k_m.

Its application in the present case is illustrated by Table II, in which the relevant numbers for the solutions containing relatively small quantities of salt are recorded.

TABLE II.

$c = 0{\cdot}1$. $[\overset{+}{\mathrm{H}}]_i = 8{\cdot}4 \times 10^{-6}$, $v_i = 2{\cdot}5 \times 10^{-7}$.

x.	$[\overset{+}{\mathrm{H}}] \cdot 10^5$.	n.	$v \cdot 10^7$.	$k_m \cdot 10^7$.
0	135	159	81·6	15·0
0·005	34·5	40·5	23·1	14·3
0·015	12·2	14·4	9·1	14·4
0·03	6·15	7·3	5·2	14·8

In spite of the wide variation in the value of the "reduced" hydrogen-ion concentration (n), the numbers under k_m are remarkably concordant, and this may be regarded as further evidence in support of the validity of the general theoretical considerations on which the method of interpreting the results is based. According to this, the catalytic effects associated with acetic acid and its salts in the hydrolysis of ethyl acetate are very similar to those previously met with in the case of the acetone–iodine reaction. The main difference is attributable to the fact that the ratios k_m/k_h and k_a/k_h are much larger for the latter reaction than for the ester hydrolysis. This is also true for the ratio k_{OH}/k_h. The actual values of the ratios are shown in Table III.

TABLE III.

Reaction.	$10^5 \times k_m/k_h$.	$10^5 \times k_a/k_h$.	$10^{-3} \times k_{\mathrm{OH}}/k_h$.	$10^{-6} \times k_{\mathrm{OH}}/k_a$.
(A) Acetone–iodine ...	320	970	43	4·4
(B) Hydrolysis of ethyl acetate ...	24	3·3	1·05	32

According to the above figures k_a/k_h is about 300 times as great for reaction A as for reaction B. This is mainly responsible for the fact that the amount of acetate which must be added to 0·1*N*-acetic acid to reduce the reaction velocity to a minimum is nearly 20 times as great in B as it is in A. On the other hand, k_{OH}/k_a is about 7 times as great in B as it is in A. This explains why the anionic catalytic effect in B is shared by the acetate and hydroxyl ions, although the corresponding effect in A is almost entirely due to the acetate ion. That the nature of the catalysed reaction affects the relative activities of the undissociated acid and the corresponding anion is evident from the value of the ratio k_m/k_a; this is 0·33 in reaction A and 7·2 in reaction B.

Catalytic Effects for Different Reactions and the General Catenary.—Since the catalytic effects associated with the two reactions which have been compared are in agreement with the requirements of the general catalytic catenary (compare this vol., p. 213), according to which the reduced ionic velocity $r = u/u_i$ is connected with the reduced hydrogen-ion concentration, $n = [\overset{+}{H}]/[\overset{+}{H}]_i$, and the reduced p_H value, $\Delta p_H = \log_{10} n$, by the equations

$$r = \tfrac{1}{2}(n + 1/n) = \tfrac{1}{2}(10^{\Delta p_H} + 10^{-\Delta p_H})$$

these reduced quantities should afford a basis for the comparison of the ionic catalytic effects which are peculiar to a given acid in a series of different reactions. It has, in fact, been shown (this vol., p. 756) that the reduced hydrogen-ion concentration (n_0) of a solution of the pure acid and the corresponding reduced ionic velocity (r_0) are determined solely by the relative magnitudes of the catalytic coefficients and are independent of the concentration and therefore of the degree of ionisation of the acid. The value of n_0 (or r_0) determines the position which must be assigned to a given pure acid on the general catalytic catenary, and this position obviously varies with the nature of the catalysed reaction. For acetic acid, the value of n_0 is 10 when the acid catalyses the acetone–iodine reaction, and about 175 when it catalyses the hydrolysis of ethyl acetate. Such wide variations in n_0 do not, of course, affect the validity of the relations which find expression in the equation of the general catalytic catenary, but they serve to show that the catalytic activity of a given pure acid expressed in terms of that of the corresponding *M.V.* mixture varies very considerably with the nature of the catalysed reaction.

Summary.

Measurements have been made of the catalysing power of acetic acid–sodium acetate mixtures in the hydrolysis of ethyl acetate.

For a fixed concentration of acid, the addition of salt first reduces the velocity, which passes through a minimum, and then increases it according to a linear formula.

The observed reaction velocities can be explained in terms of the joint catalytic effects produced individually by the hydrogen, acetate, and hydroxyl ions and by the undissociated acetic acid.

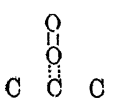
The connexion between the reaction velocity and the p_H value of the solution is represented very closely by a catenary curve.

The ratios k_a/k_h and k_m/k_h are much smaller for the hydrolysis of ethyl acetate than for the acetone–iodine reaction, and the catalytic catenary is of the compound type.

THE UNIVERSITY, LEEDS. [*Received, July 16th*, 1927.]

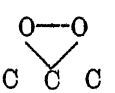
CCCXXVIII.—*The Heat of Adsorption of Oxygen on Charcoal. Part II.*

By WILLIAM E. GARNER and DOUGLAS MCKIE.



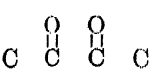
DEBYE and SCHERRER (*Physikal. Z.*, 1917, **18**, 291) concluded from an *X*-ray examination by the powder method that amorphous carbon was merely graphite in a powder form. This conclusion was criticised by Ruff, Schmidt, and Olbrich (*Z. anorg. Chem.*, 1925, **148**, 313), who are of the opinion that amorphous carbon is a true modification which begins to pass into a para-crystalline variety at 1100°, and that the different forms of amorphous carbon are to be attributed to the admixture of varying proportions of graphite and a para-crystalline form. From their investigation, it would appear that the adsorptive powers of charcoal are due to the amorphous form alone.

The energy content of amorphous carbon is 3 Cals./mol. higher than that of graphite. This difference in energy must be associated with structural differences probably extending throughout the body of the carbon. The most probable structure of amorphous carbon, in view of its mode of formation from cellulose or sugars, is that of an interlocking network of carbon chains, which are the degradation products of the original cellulose molecules. With such a structure, adjacent carbon chains will touch at points irregularly along their length. Where contact occurs between carbon atoms of adjacent chains, presumably something analogous to chemical combination has occurred, but there must exist atoms in the body of the carbon the valency forces of which are not fully saturated by neighbouring atoms. The excess of potential energy of amorphous carbon would be expected to lie in such atoms and in those exposed in the capillary surfaces of the charcoal.



Each of the surface atoms forms part of a chain extending into and rigidly fixed in the body of the carbon. The surface atoms may possess the haphazard distribution of their fellows in the body of the charcoal. Those projecting some distance from the surface are conceivably unsaturated chemically. Birge (*Physical Rev.*, 1926, **28**, 259), from a consideration of results on the heat of vaporisation of carbon and an examination of the molecular spectra of oxygen and the oxides of carbon, concluded that 1 g.-mol. of gaseous carbon contains 141 Cals. more potential energy than carbon in bulk. This value sets the limit for the potential energy of the most active carbon atoms on the surface of charcoal. The potential energy of these atoms will very probably range between 141 Cals. and zero, the former value corresponding with carbon atoms practically in the gaseous state and the latter with atoms almost completely surrounded by neighbouring atoms. The nature of the law of the distribution of energy among the surface atoms is unknown.

The potential energy of the carbon surface should be liberated during chemical changes occurring thereon, *e.g.*, during the adsorption of oxygen. Under the most favourable conditions, the heat of adsorption of this gas should approach a value of the order of 300,000 cals. per g.-mol. of oxygen adsorbed.



There is some justification for assuming that combination between oxygen molecules and carbon atoms on the surface can take place according to definite stoicheiometrical relationships. This would be the case if electron sharing occurs between the surface and adsorbed atoms. Also, there is the possibility of physical adsorption, the oxygen being held by subsidiary valency forces on the surface. The following simple structural forms may be present on a carbon surface which has adsorbed oxygen (C C C . . . represents the surface):

(I.)

(II.)

(III.)

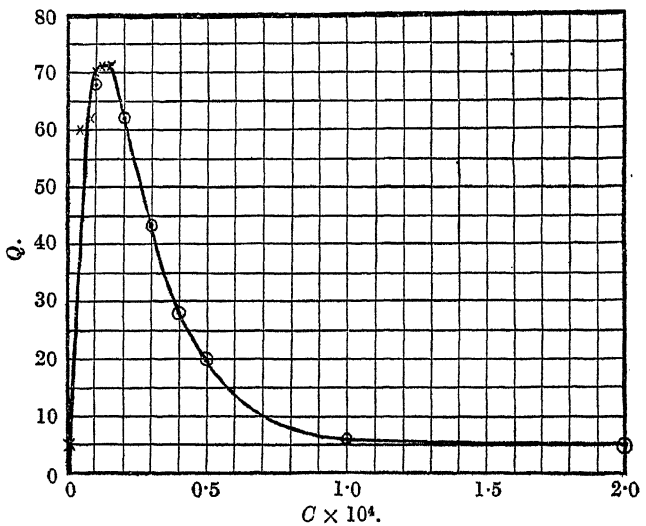
(I) represents the process of physical adsorption of oxygen in which there is no electron transference or sharing between the atoms. The adsorption is, in this case, a reversible process, and the adsorbed oxygen molecules can be recovered unchanged. (II) and (III) are examples of modes of chemical combination. Desorption of oxygen should occur as carbon dioxide in (II) and as carbon monoxide in (III). Other types of complex may exist, but our object is to present as simple a picture as possible.

Our knowledge of these adsorption complexes is based on (*a*)

the nature of the products obtained on desorption, and (*b*) measurements of heats of adsorption. The products would appear to depend, not only on the temperature of desorption, but also on factors concerning the adsorption process. The amount of oxygen adsorbed by a given mass of charcoal and the temperature at which adsorption occurs are the main factors involved. At low temperatures and high initial gas pressures, the adsorbed gas can be recovered as oxygen on decreasing the pressure or on raising the temperature (Dewar, *Proc. Roy. Soc.*, 1904, *A*, **74**, 122). This form of adsorbed oxygen is represented by (I). The heat of adsorption is very low, about 3 Cals. per mol. of gas adsorbed. If the gas is admitted at low pressures, *e.g.*, 0·01 mm., and at the ordinary or slightly higher temperature, the adsorbed oxygen can be recovered as oxides of carbon (II and III) on raising the temperature. The heat of adsorption under these conditions is much higher. At room temperature, the maximum heat of adsorption is 70 Cals./g.-mol. (Keyes and Marshall, *J. Amer. Chem. Soc.*, 1927, **49**, 156) and rises rapidly with increase in temperature (Blench and Garner, J., 1924, **125**, 1288). At high pressures and at room temperature, the heat of adsorption is only 4 Cals./mol., and the adsorption complexes may be of all three types, (I), (II), and (III). Rhead and Wheeler (J., 1913, **103**, 471) have shown that the complexes formed at 300° break down into carbon dioxide and monoxide at higher temperatures. Type (II), giving dioxide, would appear to be less stable than (III). The maximum evolution of carbon dioxide occurs at approximately 300—400°, and of carbon monoxide at 600—700° (Rhead and Wheeler, *loc. cit.*). Since both carbon dioxide and monoxide are liberated over a wide range of temperatures,* the forces holding the molecules of the gas on the surface cannot be uniform from molecule to molecule. This is what would be anticipated were the surface adsorbing oxygen truly amorphous.

An investigation continuing the work of Blench and one of us and using a more refined technique has thrown additional light on the nature of the adsorption complexes. The detailed experimental method will be described in a later paper. It will be sufficient to state here that the adsorption was carried out in a vacuum calorimeter of known water equivalent and the rise in temperature measured by means of a thermocouple. The heat of adsorption varies with the initial gas pressure, *i.e.*, with the amount of oxygen adsorbed, in a curious manner. This will be seen by combining the results of McKie and those of Keyes and Marshall (Table I). Although the latter authors measured the heats of adsorption by a

* Only a fraction of the complexes breaks down when the carbon is heated over a range of 50°.



different experimental method (by the ice calorimeter), their results agree very well with those of McKie. Charcoals with practically the same activity must have been used in both series of experiments.

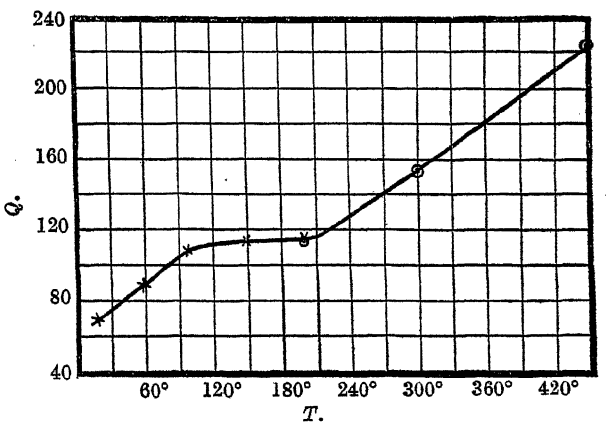
		2·0	5·1
		4·0	4·4

FIG. 1.

C represents the number of g.-mols. of oxygen adsorbed per g. of charcoal, and Q is the molar heat of adsorption.* Different charcoals show the same maximum value of Q, although this does not necessarily occur at the same value of C. The results are plotted in Fig. 1. There is a sharp rise in the heat of adsorption up to a maximum value of 70 Cals. and then a slower fall down to 4 Cals. as the density of adsorbed oxygen increases. A similar curve has been obtained by Kistiakowski (*Proc. Nat. Acad. Sci.*, 1927, **13**, 1) for the heat of adsorption of hydrogen on nickel.

* The oxygen admitted is almost completely adsorbed at a surface density of $C = 0$ to $C = 0{\cdot}1 \times 10^{-4}$.

The internal area of the charcoal used in the above experiments has been determined by measuring the adsorption isotherms of straight-chain alcohols on the charcoal (area = 66 m.^{2} per g.) (Garner, McKie, and Knight, *J. Physical Chem.*, 1927, **31**, 641). At the maximum of Fig. 1, only 1/140 of the carbon atoms are covered with oxygen, so that the range of figures given in Table I refers only to the formation of an incomplete unimolecular film of oxygen molecules on the surface.



The heat of adsorption varies with the temperature. Values are shown in Table II for $C = 0{\cdot}1 \times 10^{-4}$. The agreement between

TABLE II.

Relation between heat of adsorption and temperature.

Temperature	18°	57°	100°	150°	200°	300°	450°
Q (McKie)	70	91	108	114	116	—	—
Q (Blench and Garner)	—	—	—	—	115	154	224

FIG. 2.

the values of McKie and those of Blench and Garner at 200° is probably a coincidence, since the latter were not so accurately determined as the former.

Fig. 2 brings out the nature of the rise in Q. This approaches a constant value between 100° and 200° and then rises rapidly. In the interpretation of these results, it is necessary to bear in mind that the accuracy of the values decreases with increase in temperature. Up to 100°, only negligible amounts of carbon dioxide are produced on admitting oxygen to the charcoal, but at higher temperatures this gas is liberated in increasing amounts. At 450°, more than 30% of the oxygen combining with the surface is liberated as dioxide. This makes the deduction of the heat of

adsorption uncertain. Nevertheless, we believe the general trend of the curve to be correct.

The temperature coefficient of the heat of adsorption is too great to be accounted for by changes in the specific heats of the resultants and reactants. It must be due to a change in the type of complex with the temperature. The heat of adsorption approaches a constant value at 100—200°. This suggests that the type of complex which is formed does not undergo much change over this range of temperatures. Below 100°, at least two types must be present, one of which gives place to the other on increase in temperature. This change is nearly complete at 100°. It is highly probable that at this temperature only one structural form is present. This cannot be (I), but is very probably (II). The experiments of Rhead and Wheeler on the decomposition of the complex indicate that this is the case; carbon dioxide is the main product of desorption at 300—400°. If this is so, then the rise in Q above 200° must be ascribed to the formation of (III). If Q were very large for type (III), then a high temperature would be necessary before desorption could be brought about. This is supported by the fact that the maximum evolution of carbon monoxide does not occur until 600—700° is reached.

Although the heat of adsorption obtained between 100° and 200° is believed to be that of type (II), it is not suggested that this heat is other than an average value. Owing to the varying potential energy of the carbon atoms on which the complex is formed, a range of heats of adsorption for type (II) would be expected. This would account for the wide range of temperatures over which the complex is broken down to give carbon dioxide.

Returning to Fig. 1, we are met with greater difficulties in interpretation. The decrease in Q as the amount of gas adsorbed increases is undoubtedly due to the increasing predominance of molecularly adsorbed oxygen (I). The low heat, and the fact that from such charcoals oxygen may be recovered, requires that this be the case. The occurrence of a maximum value and the fall at very low surface concentrations afford an interesting problem for the complete solution of which there are not sufficient data. If it be assumed that the fall is due to the occurrence of physical adsorption at very low pressures, it must also be assumed that the oxygen is very tightly bound to the surface, which occurs very rarely for physical adsorption. At $C = 0{\cdot}01 \times 10^{-4}$ g. mol./g., only 1 in every 1400 of the surface carbon atoms is covered, and these will be the most unsaturated of the surface atoms. If a physical complex is formed, it may thus be comparatively stable.

An alternative and preferable explanation would be that, at

very low pressures and surface densities, an active form of type (II) is formed which only slowly liberates its internal energy as heat or radiation. The liberation of energy may occur so slowly that we cannot measure it by our methods. In support of this, it may be mentioned that the rate of liberation of heat is slower when $C = 0{\cdot}04 \times 10^{-4}$ than when $C = 0{\cdot}1 \times 10^{-4}$. It is probable that an activated form of type (II) would give up its energy if struck by an oxygen molecule, and this may be the explanation of the increased heat of adsorption as the density of the gas above the carbon increases.

Support for this view was found on studying the adsorption of mixtures of oxygen and nitrogen. Nitrogen is adsorbed when admitted together with oxygen in greater amounts than if admitted either to a bare carbon surface or to a surface on which oxygen has been adsorbed. The gas is not, however, held so firmly as either oxygen or nitrogen which has been adsorbed on a bare surface; it evaporates when the pressure is lowered. An unstable carbon, oxygen, and nitrogen complex is formed. The complexes formed when nitrogen is admitted after oxygen are much more stable (compare *Trans. Faraday Soc.*, 1926, **22**, 459).

These results indicate that the adsorbed oxygen molecules are in a chemically active state immediately after formation, and that this activity is lost on standing. They support the view expressed above that the initial portion of the curve in Fig. 1 is due to the formation of a complex of type (II), which has retained a large portion of its heat of formation. A similar explanation can also be given for Kistiakowski's curve (*loc. cit.*).

Summary.

The heat of adsorption of oxygen on charcoal varies with the amount of oxygen adsorbed per g. of charcoal. A maximum value (70 Cals.) was obtained when the number of g.-mols. of oxygen adsorbed per g. of charcoal was $1{\cdot}5 \times 10^{-5}$. The maximum heat of adsorption increases rapidly with increase in temperature, approaching 115 Cals. between 100° and 200°. It rises again from 200° to 450°.

The results have been discussed with regard to the light they throw on the chemical constitution of the C_xO_y complex.

One of us (D. McK.) wishes to express his indebtedness to the Department of Scientific and Industrial Research for a maintenance grant.

THE RAMSAY LABORATORIES OF INORGANIC AND PHYSICAL CHEMISTRY, UNIVERSITY COLLEGE, LONDON. [*Received, August 5th*, 1927.]

CCCXXIX.—*The Interaction of Bromine with Acetic Anhydride. Part II.*

By KENNEDY JOSEPH PREVITÉ ORTON, HERBERT BEN WATSON, and HUBERT IVOR HUGHES.

IT has been stated by Orton and Jones (J., 1912, **101**, 1722), and subsequently by W. H. Gray (Thesis, Univ. of Wales, 1913) and by Orton, Watson, and Bayliss (Part I, J., 1923, **123**, 3081), that pure acetic anhydride is unattacked by halogens at the ordinary temperature when light is completely excluded. The anhydride used by these investigators was obtained by fractional distillation of Kahlbaum's acetic anhydride "free from homologues," and their observation does not appear to find confirmation in the results of earlier workers (Gal, *Ann. Chim. Phys.*, 1862, **66**, 187; Urech, *Ber.*, 1880, **13**, 1687; Lapworth, J., 1904, **85**, 40). The stability to bromine of specimens of acetic anhydride of varied origin and purified by different methods has now been examined; in every case reaction occurs, and it appears probable that the material employed by the previous workers contained a trace of some inhibitor which was not removed by fractionation. A search for possible inhibitors has revealed the fact that introduction of quinoline in minute quantity prevents the reaction from proceeding to any perceptible extent during a long interval of time (with bromine = 0·25*M* and quinoline = 0·006*M*, no measurable amount of bromine reacted in 93 hrs.); moreover, acetic anhydride containing a trace of quinoline is still stable to bromine after fractionation. After this "latent period," reaction proceeds at a measurable rate, but the disappearance of bromine is much slower than when pure anhydride is employed; the retardation at this stage is probably to be attributed to the presence of a hydrobromide of quinoline, for a similar retardation is produced by introduction of a trace of sodium or potassium bromide or of certain other salts. Sodium acetate exerts an influence which is similar to but not as powerful as that of quinoline (with $Br_2 = 0{\cdot}26M$ and $NaC_2H_3O_2 = 0{\cdot}005M$, no fall of titre after 17 hrs.), whilst pyridine, dimethylaniline, triethylamine, diethylamine, *iso*quinoline, ammonium acetate, methylamine, and ethylamine are less effective. Addition of a trace of nitric acid or of acetyl nitrate is accompanied by an extremely powerful inhibition (compare Gray, *loc. cit.*); the effect of the former is probably due to acetyl nitrate formed by reaction of the nitric acid with the anhydride, for the bromination of propionic anhydride (which is similar to that of acetic anhydride, but considerably

slower) is inhibited by acetic anhydride and nitric acid in conjunction, but not by nitric acid alone.

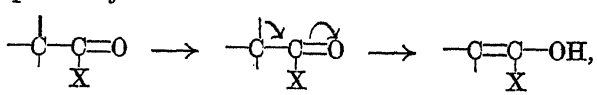
The speed of interaction of bromine with acetic anhydride is now found to be greatly influenced by the concentration of the halogen. The course of the reaction indicates autocatalysis, and introduction of acetyl bromide (one of the products, Gal, Urech, *locc. cit.*) causes a considerable acceleration. The effect of acetyl bromide is identical with that of hydrogen bromide at equimolar concentration, indicating that the halogen acid reacts all but completely with the anhydride, $(CH_3\cdot CO)_2O + HBr = CH_3\cdot COBr + CH_3\cdot CO_2H$, as has been shown by an aspiration method. Introduction of propionyl or benzoyl bromide brings about an acceleration identical with that produced by acetyl bromide at the same concentration. These facts recall the bromination of carboxylic acids (Watson, J., 1925, **127**, 2067), and a similar series of changes of the following type is indicated:

$$CH_3\cdot COBr + Br_2 = CH_2Br\cdot COBr + HBr \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$(CH_3\cdot CO)_2O + HBr \rightleftarrows CH_3\cdot COBr + CH_3\cdot CO_2H \quad . \quad . \quad . \quad . \quad (2A)$$

$$(CH_3\cdot CO)_2O + CH_2Br\cdot COBr \rightleftarrows CH_2Br\cdot CO\cdot O\cdot CO\cdot CH_3 + CH_3\cdot COBr \quad . \quad . \quad . \quad (2B)$$

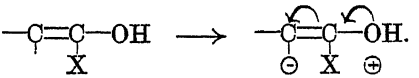
$$CH_3\cdot CO_2H + CH_2Br\cdot CO\cdot O\cdot CO\cdot CH_3 \rightleftarrows (CH_3\cdot CO)_2O + CH_2Br\cdot CO_2H \quad . \quad . \quad . \quad . \quad (3)$$



When the bromide of another acid is added initially, these reactions will be preceded by

$$(CH_3\cdot CO)_2O + R\cdot COBr \rightleftarrows CH_3\cdot CO\cdot O\cdot CO\cdot R + CH_3\cdot COBr, \text{ or}$$
$$(CH_3\cdot CO)_2O + 2R\cdot COBr \rightleftarrows (R\cdot CO)_2O + 2CH_3\cdot COBr \quad . \quad . \quad (4)$$

That acetic anhydride can react with acid bromides in this manner is demonstrated by distilling a quantity of the anhydride with either bromoacetyl or benzoyl bromide, whereby a good yield of acetyl bromide is obtained; it is not suggested that reaction (3), which is analogous to the reactions of acids with anhydrides observed by Kaufmann and Luterbacher (*Ber.*, 1909, **42**, 3483), proceeds to any great extent under the conditions of the authors' experiments, in which the acetic anhydride was always in great excess. In the above series of reactions the rate of disappearance of bromine will be $dx/dt = k(a-x)[\text{AcBr}]$, where a is the initial concentration of bromine. If the acetyl bromide be present in excess, the reaction will be of the first order; values of $k_1 = 1/t \cdot \log_e a/(a-x)$, however, were not constant. If the bromine also reacts with the enolic form of the anhydride (this form being produced slowly and reacting with halogens rapidly; compare Part I), the rate of disappearance of bromine will be $dx/dt = k(a-x)[\text{AcBr}] + k'[\text{Ac}_2\text{O}]$, where x is



the total amount of the halogen which reacts in time t. In the case when both acid bromide and anhydride are in excess, this reduces to $dx/dt = C(a - x) + C' = C(a - x + P)$, where $C' = CP$, which on integration becomes $C = 1/t \cdot \log_e (a + P)/(a + P - x)$. Constant values of C were obtained by use of this expression. The observed facts are thus interpreted by supposing that the reaction proceeds mainly through a series of changes involving the bromination of the acid bromide, but also to a small extent through the enolised anhydride. Addition of a small quantity of sulphuric acid, ferric chloride,* or stannic chloride results in a marked increase in the rate of disappearance of bromine (compare Part I); their effect probably consists in an acceleration of the enolisation of the anhydride. Acetyl chloride (or added hydrogen chloride), trichloroacetic acid, and monobromoacetic acid are without appreciable effect. When pure anhydride is used, pure dry iodine is now found to be a catalyst, but iodine bromide (added as such) and iodine chloride are more effective, the former being a particularly good catalyst.

According to the hypothesis of activation by electronic displacement (Allan, Oxford, Robinson, and Smith, J., 1926, 401; Ingold and Ingold, *ibid.*, p. 1310) there will be but little tendency for a proton to become loosened from the methyl group of acetic acid, for the carboxyl group is "self-contained" (Ray and Robinson, J., 1925, **127**, 1618); adjustment of the covalencies of the carbonyl carbon atom of acetic anhydride, however, will take place to a smaller extent, since the singly-linked oxygen is conjugated on both sides (compare Lea and Robinson, J., 1926, 411), whilst with acetone and acetyl bromide no such adjustment is possible. In the three compounds last mentioned, therefore, loosening of a proton will occur, and will be most marked in acetyl bromide owing to the "polar effect" of the bromine atom (Baker and Ingold, J., 1926, 2466). The loosened proton is attracted towards the negatively charged carbonyl oxygen, and enolisation takes place (in preference to direct substitution by a reagent, as is shown by the dynamics of the bromination of acetone; Lapworth, *loc. cit.*). The sequence $CH_3{\cdot}COBr > (CH_3)_2CO > (CH_3{\cdot}CO)_2O > CH_3{\cdot}CO_2H$ is thus obtained for velocity of enolisation. The series of changes up to this point may be written

* Using pure anhydride, the authors have failed to confirm the violet colour ascribed in Part I (p. 3090) to solutions of anhydrous ferric chloride. Such solutions are brown in colour.

and on activation of the enolide

The activated enolide will react with bromine at the negatively charged carbon atom, the products being the monobrominated ketonic derivative and hydrogen bromide. In acetyl bromide, the activation of the enolide will be opposed by the polar effect of the bromine atom, and hence *rapid* enolisation will be followed by a comparatively slow reaction with bromine (compare Watson, *loc. cit.*, p. 2075), whilst in acetone and acetic anhydride slow enolisation is followed by rapid reaction with the halogen. These considerations lead to the idea suggested originally by Lapworth (*loc. cit.*) that the bromination of carbonyl compounds in general is preceded (provided an α-hydrogen atom is present) by conversion into the enolic form; it is not necessary, however, to assume the formation of an intermediate dibromide which immediately loses hydrogen bromide, nor has such a dibromide been isolated. This scheme correlates the results of Lapworth and others on the bromination of ketones and aldehydes, those of Watson on the bromination of carboxylic acids, and also those described in the present paper.

Experimental.

The velocity measurements were carried out by withdrawal at suitable intervals of 2 (± 0·01) c.c. of the reaction mixture, addition to aqueous potassium iodide, and titration of the iodine liberated with *N*/10-thiosulphate. Unless otherwise stated, titres are expressed as c.c. of *N*/10-thiosulphate, and time in minutes. Temperature throughout = 25°.

Reaction of Bromine with Different Specimens of Acetic Anhydride.—The anhydride was fractionated through an eight-pear stillhead, and the bromine (B.D.H. "A.R." quality) was purified as described by Watson (*loc. cit.*, p. 2076).

Br_2 = 0·25—0·27*M*, initially; mol. ratio Ac_2O/Br_2 = 40.

Effect of Purification of Bromine.—Method 1 as above: results are the mean of those in previous table. Method 2: bromine distilled from potassium bromide and zinc oxide (compare Stas, *Mem. Acad. Belgique*, 1865, **35**, 3; West, J., 1924, **125**, 1279), then dried over quick-lime and distilled in an all-glass apparatus. Method 3: bromine distilled from potassium bromide and zinc oxide, then washed with distilled water and dried under concentrated sulphuric acid, separated, and distilled from a little barium carbonate.

Effect of Purification of Acetic Anhydride by Different Methods.—Specimens of the anhydride were distilled from phosphorus pentoxide (method 1), potassium permanganate (2), or chromic anhydride (3); allowed to stand for 48 hours over pure anhydrous sodium acetate and then distilled (4), refluxed for 12 hours over sodium acetate and then distilled (5), and treated with 0·1% by volume of bromine, allowed to stand until colourless, refluxed for 6 hours over sodium acetate, and distilled (6). In each case, the anhydride was fractionated both before and after the treatment described.

Effect of Nitric Acid and of Acetyl Nitrate.—A solution of pure nitric acid (prepared from pure potassium nitrate and pure sulphuric acid) in acetic acid (m. p. 16·4°) was freed from nitrous acid by aspiration with purified air (Gray, *loc. cit.*) and estimated in a Lunge nitrometer. 0·05 C.c. of this solution and 0·3 c.c. of bromine were made up to 25 c.c. at 25° with acetic anhydride, giving HNO_3 = 0·003M. The titre of 2 c.c. of this solution was as follows :

Time (days)	0	3	5	7	10	17
Titre (c.c.)	10·55	10·40	10·40	10·25	9·95	9·55

0·1 C.c. of acetyl nitrate, prepared as described by Pictet and Khotinsky (*Compt. rend.*, 1907, **144**, 210), b. p. 27°/30 mm., and 0·3 c.c. of bromine were made up to 25 c.c. with acetic anhydride. Titre of 2 c.c. as follows :

Time (days)	0	14
Titre (c.c.)	11·38	11·15

Propionic anhydride, prepared by fractionation of Kahlbaum material (b. p. 166°/771·5 mm.), reacted with bromine as follows :

Time (hrs.)	0	2	3	5	7	10
Titre (c.c.)	9·32	9·12	8·18	7·75	7·10	6·40

With propionic anhydride, to which a little nitric acid (0·03M) had been added, a titre of 10·05 c.c. fell to 2·85 c.c. in 48 hours. When acetic anhydride (0·03M) and nitric acid (0·03M) were both added, a titre of 10·98 c.c. fell only to 10·95 c.c. in 5 days.

Effect of Catalysts and Other Substances.—Solutions of hydrogen bromide and hydrogen chloride in the anhydride, pure acetyl chloride, and pure acetyl, benzoyl, and propionyl bromides were obtained as described by one of us (Watson, *loc. cit.*). The sulphuric acid, ferric chloride, and stannic chloride were purified by distillation

or sublimation, and pure iodine and iodine bromide were prepared as described in Part I, p. 3094.

Examination of a Solution of Hydrogen Bromide in Acetic Anhydride.—The solution was prepared in the same way as those employed in the velocity measurements. A known volume was placed in a bubbler standing in a thermostat at 25°, and a measured volume of pure, dry air was aspirated through this solution and then into standard alkali; the excess of alkali was determined by titration, and the bromide estimated as silver bromide. The amounts of acetic anhydride and acetic acid aspirated over were obtained by blank experiments under identical conditions, the proportion of acetic acid in the mixture being calculated from the equation $HBr + (CH_3{\cdot}CO)_2O = CH_3{\cdot}COBr + CH_3{\cdot}CO_2H$. If the vapour aspirated into the alkali contained acid bromide and no hydrogen bromide, the results would give Mols. acid/Mols. bromide = 2. The mean of two experiments was as follows: Conc. of HBr = 1·41*M*. 500 C.c. of air aspirated through 35 c.c. of this solution in 10 mins. Alkali neutralised = 21·20 c.c. of *N*/20. Alkali equivalent

to Ac_2O and HAc aspirated over = 4·95 c.c. (from blank expt.). Alkali equivalent to HBr or AcBr aspirated over = 16·25 c.c. Wt. of AgBr = 0·0766 g. Hence, mol. acid aspirated over = 0·000812, and mol. bromide = 0·000407. Mol. acid/mol. bromide = 1·99. Applied to other similar solutions, the method gave the following results: Solution of acetyl chloride in acetic anhydride, mol. acid/mol. chloride = 1·98; solution of hydrogen chloride in acetic acid, mol. acid/mol. bromide = 0·98.

Reaction of Acetic Anhydride with Acid Bromides.—Acetic anhydride and bromoacetyl bromide in molar proportion were slowly distilled in an all-glass apparatus; a considerable quantity of liquid distilled at 76—79°/760·9 mm.; this fraction was added to water and the bromine precipitated as silver bromide, giving Br, 63·75 (calc. in AcBr: Br, 65·04%); a smaller fraction distilled at 137—138°, smelt strongly of acetic anhydride, and was probably a mixture of the anhydride with unchanged bromoacetyl bromide (%Br as COBr, 26·05; %Br as COBr in bromoacetyl bromide, 39·6). A fraction of high b. p. remained, probably $(CH_2Br{\cdot}CO)_2O$, which is formed when the mixed anhydride, $CH_2Br{\cdot}CO{\cdot}O{\cdot}CO{\cdot}CH_3$, is distilled (Naumann, *Annalen*, 1864, **129**, 273). Benzoyl bromide (2 mols.) was distilled with acetic anhydride (1 mol.); a large fraction, collected at 77—82°/775 mm., gave %Br as COBr, 65·36; from the liquid remaining some benzoic anhydride (m. p. 40°) and benzoic acid were obtained.

Reaction of Bromine with Acetic Anhydride and Excess of Acetyl Bromide.—In both experiments, $Ac_2O = 9{\cdot}067M$, $AcBr = 1{\cdot}898M$, $P = 0{\cdot}01125$. Titre in c.c. of $N/50$-thiosulphate.

CCCXXX.—*On the Photobromination of* cyclo*Hexane.*

By Basil John Wood and Eric Keightley Rideal.

The photochemical bromination of *cyclo*hexane vapour has been studied by Pusch (*Z. Elektrochem.*, 1918, **24**, 336) and Noddack (*ibid.*, 1921, **27**, 359), who showed that approximately one molecule of bromine was removed for each quantum of light absorbed. The reaction appeared to be the simplest case of photobromination, for there was no evidence of chain formation as in the bromination of toluene, stilbene, cinnamic and tartaric acids, and possibly hydrogen.

The majority of these photobrominations possess marked temperature coefficients, a general interpretation for which has been given by Pratolongo (*Gazzetta*, 1918, **48**, i, 121) and Tolman (*J. Amer. Chem. Soc.*, 1923, **45**, 2285). The existence of a temperature coefficient is believed to be an indication that only those bromine molecules already excited, presumably thermally, to a definite sub-level are capable of becoming excited to a reacting level on absorption of a quantum of the monochromatic radiation employed. The existence of a temperature coefficient for this reaction would clearly be incompatible with the conclusions of Pusch and of Noddack, and the reaction is now shown, in fact, to possess no temperature coefficient for the mercury green line.

In the bromination of hydrogen (Bodenstein and Lütkemeyer, *Z. physikal. Chem.*, 1924, **114**, 208) and of stilbene, cinnamic acid, and potassium oxalate (Berthoud, *Trans. Faraday Soc.*, 1925, **21**, 557; *Helv. Chim. Acta*, 1924, **7**, 318; see also Ghosh and Purkayestha, *J. Indian Chem. Soc.*, 1926, 261), the rate of reaction is claimed to be proportional to the square root of the light intensity and thus to indicate that the reaction involves the formation of bromine atoms according to the reaction

$$Br_2 + h\nu \longrightarrow 2Br \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Berthoud (*loc. cit.*) suggests the following mechanism

$$A + Br \longrightarrow ABr \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$ABr + Br_2 \longrightarrow ABr_2 + Br \quad . \quad . \quad . \quad . \quad . \quad (3)$$

$$2ABr \longrightarrow 2A + Br_2 \text{ or } ABr_2 + A \quad . \quad . \quad . \quad . \quad (4)$$

and deduces the relationships $d[ABr_2]/dt = kI^{\frac{1}{2}}[Br_2]$ or $kI^{\frac{1}{2}}[Br_2]^{\frac{1}{2}}$, respectively, for total or weak absorption of the active radiation, both rates being independent of the concentration of the acceptor. It is difficult to understand how the rate of a photochemical reaction involving bromine atoms with a high primary photochemical efficiency can vary with the square root of the light intensity. If

we equate the rate of formation of bromine atoms by (1) and (3) to their rate of removal by (2) and by the following reactions

$$ABr + Br \longrightarrow ABr_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

$$2Br \longrightarrow Br_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

we obtain

$$2kI_0[Br_2] + k_3[ABr][Br_2] = k_2[A][Br] + k_5[ABr][Br] + k_6[Br]^2.$$

The reaction rate is then

$$d[ABr_2]/dt = k_5[ABr][Br] + k_4[ABr]^2 + k_3[ABr][Br_2].$$

It is clear that this rate is not proportional to the square root of the light intensity unless the rates of the various methods by which ABr_2 is formed can be considered as negligibly small in comparison with the reaction rate $2Br \longrightarrow Br_2$, *i.e.*, with a reaction of low photochemical efficiency.

If the reaction is not a chain mechanism, we can, following Berthoud, represent it on the atomic view as the sequence of reactions (1), (2), (5), and (6). As the concentration of the bromine atoms is small, we can equate their rate of formation at any instant to their rate of removal, thus, $d[Br]/dt = 2kI_0[Br_2] - k_2[A][Br] - k_5[ABr][Br] - k_6[Br]^2 = 0$. Similarly, since [ABr] is small, $k_2[A][Br] = k_5[ABr][Br]$; moreover, $d[ABr_2]/dt = k_5[ABr][Br]$. For weak absorption of active radiation we thus obtain

$$d[ABr_2]/dt = kI_0[Br_2] - k_6[Br]^2/2 = kI_0[Br_2],$$

since [Br] is assumed to be small.

On this view, the reaction velocity will again be proportional to the light intensity unless but a small fraction of the bromine atoms is removed by the acceptor, in which case the photochemical efficiency is small, and the reaction velocity will be dependent on the concentration of the acceptor.

If the reaction takes place between the acceptor and excited bromine molecules rather than atoms, we obtain for the rate of production of these molecules

$$d[Br_2']/dt = kI_0(1 - e^{a[Br_2]d}),$$

where a is the extinction coefficient and d the thickness of the absorption layer. If τ be the life of an excited bromine molecule and T the time between successive collisions of the excited molecule and the acceptor, the rate of production of the reaction product is (compare Turner, *Physical Rev.*, 1924, **23**, 464)

$$\begin{aligned} d[ABr_2]/dt &= kI_0(1 - e^{-a[Br_2]d})\tau/(T + \tau) \\ &= kI_0[Br_2]\tau/(T + \tau) \end{aligned}$$

for weak absorption. It is clear that this will be independent of the concentration of the acceptor if τ be large compared with T. Since τ is of the order of 10^{-8} second (possibly larger according to Eggert, *Physikal. Z.*, 1923, **24**, 504), we should anticipate that the reaction velocity will not be affected by the concentration of the acceptor until this has fallen to a pressure such that T becomes comparable with τ; this pressure can be calculated from the kinetic gas theory to be only some 0·3 mm. Hg in the case of *cyclo*hexane. Thus, if the primary photochemical action be either the formation of an excited bromine molecule or a dissociation into atoms, the reaction rate would be independent of the concentration of the acceptor except at very low pressures. We would also conclude that for weak light absorption the reaction velocity for the bromination of *cyclo*hexane would be strictly proportional to the light intensity, a view confirmed by experiment.

Finally, it is well known that bromination of many substances in solution is greatly affected by oxygen, which acts as an inhibitor. It was decided to investigate this effect in the case of *cyclo*hexane, because such a quantitative study would give information on the mechanism of the bromination process. The most probable hypothesis is that the reaction proceeds through an excited molecule in the following steps:

$$\mathrm{Br_2} + h\nu \longrightarrow \mathrm{Br_2'} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1\text{A})$$

$$\mathrm{C_6H_{12}} + \mathrm{Br_2'} \longrightarrow \mathrm{C_6H_{12}Br_2'} \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

$$\mathrm{C_6H_{12}Br_2'} \longrightarrow \mathrm{C_6H_{11}Br'} + \mathrm{HBr} \quad . \quad . \quad . \quad . \quad . \quad (8)$$

or $$\mathrm{C_6H_{12}Br_2'} + \mathrm{O_2} \longrightarrow \mathrm{C_6H_{12}} + \mathrm{Br_2} + \mathrm{O_2} + \varepsilon \quad . \quad (9)$$

$$\mathrm{C_6H_{11}Br'} + \mathrm{Br_2} \longrightarrow \mathrm{C_6H_{10}Br_2} + \mathrm{HBr} \quad . \quad . \quad (10)$$

The excited complex $\mathrm{C_6H_{12}Br_2'}$ formed in (7) can either decompose spontaneously (8), or be deactivated by collision with oxygen (9).

The rate of formation of excited bromine molecules, for weak absorption, is equal to $kI_0[\mathrm{Br_2}]$; the formation rate of the complex $= kI_0[\mathrm{Br_2}]\tau/(T + \tau)$. Since its concentration is small, its formation rate can be equated to its rate of disappearance by reactions (8) and (9) with respective velocity coefficients k_8 and k_9. The reaction rate is determined by the probability of reaction (8), which is equal to $k_8/(k_8 + k_9[\mathrm{O_2}])$. Hence the rate of bromination is given by

$$d[\mathrm{C_6H_{11}Br}]/dt = kI_0[\mathrm{Br_2}]\tau k_8/(\tau + T)(k_8 + k_9[\mathrm{O_2}])$$

There are two alternative ways in which the inhibiting effect of oxygen might operate: (*a*) In the sequence of reactions $\mathrm{Br_2} + h\nu \longrightarrow 2\mathrm{Br}$; $\mathrm{C_6H_{12}} + \mathrm{Br} \longrightarrow \mathrm{C_6H_{12}Br}$; $\mathrm{C_6H_{12}Br} + \mathrm{Br} \longrightarrow \mathrm{C_6H_{11}Br} + \mathrm{HBr}$,

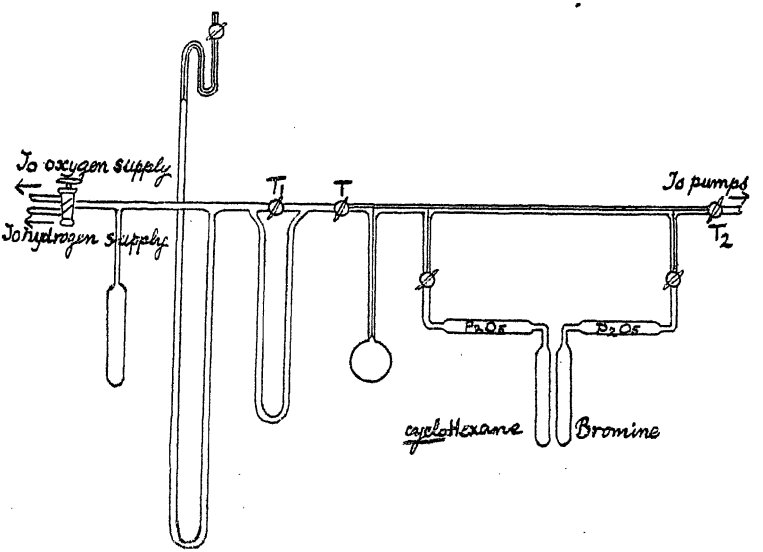
the bromine atoms, in addition to combining with themselves, might be rendered inactive by the reactions $Br + O_2 \longrightarrow BrO_2$; $BrO_2 + Br \longrightarrow Br_2 + O_2$. (*b*) In the series $Br_2 + h\nu \longrightarrow Br_2'$; $C_6H_{12} + Br_2' \longrightarrow C_6H_{11}Br + HBr$, the activated bromine molecules may be deactivated by the reaction $Br_2' + O_2 \longrightarrow Br_2 + O_2$, as well as by $Br_2' \longrightarrow Br_2$. In either case, it can readily be shown that the inhibition must be dependent on the concentration of the acceptor, but since it has actually been found to be independent (see Experimental), it follows that these two hypothetical modes of operation are eliminated, and that the inhibiting mechanism is expressed by equation (9).

EXPERIMENTAL.

Pusch and Noddack in their examination of the reaction under consideration estimated the rate of removal of bromine by spectrophotometric and titration methods, but here the reaction was followed throughout its course by measuring the pressure change. Monochromatic light was employed, the green line $\lambda = 5460$ Å. from a mercury-vapour lamp and light filter being sufficiently intense to give easily measurable velocities.

The apparatus used is shown in Fig. 1. The reaction vessel used at first was a glass cylinder with flattened ends, but in the form subsequently employed the ends were of plane parallel glass fused on. It is connected by capillary tubes through two taps to reservoirs containing bromine and *cyclo*hexane. Two other connexions are made—one to the pumps, and the other to the gauge.

The pressure gauge consists of a sulphuric acid differential manometer of fine-bore tubing, connected to a mercury manometer and a large bulb kept in ice which serves to maintain a constant pressure. A two-way tap is connected to the gauge through which hydrogen and oxygen can be admitted. Exhaustion can be effected through a soda–lime tube and liquid-air trap by mercury diffusion pumps backed by an oil pump. This is necessary, as a high vacuum is required to remove oxygen and the reaction products. Connexion can also be made with a water pump when required.



The reaction vessel is contained in a metal box, with plane parallel glass faces, through which circulates water from a thermostat constant to within $\pm 0{\cdot}1°$.

Light from the mercury lamp reaches the reaction vessel after passing through (1) a vessel with plane parallel glass faces in which cold water removes the infra-red; (2) a filter of saturated potassium dichromate solution, to which neodymium magnesium nitrate has been added until the yellow line disappears, thus isolating the

mercury green line (R. W. Wood, "Physical Optics," p. 15); and (3) an adjustable diaphragm. At first, a small glass mercury lamp was used, which was run in series with a resistance of 220 ohms from a constant 220 volts supply and took 0·65 amp. This was later replaced by a quartz mercury-vapour lamp taking 4 amps. with a *P.D.* of 150 volts, giving much more intense illumination.

Materials.—The purest obtainable bromine was further purified by distilling it twice over potassium bromide and zinc oxide, and finally over phosphorus pentoxide in an all-glass system; it was stored over phosphorus pentoxide. The *cyclo*hexane was purified

FIG. 1.

by repeated shaking with sulphuric acid, and finally by distillation. The hydrogen used in the gauge was passed over hot palladinised copper and through drying tubes. Oxygen was obtained by electrolysis of hot baryta solution and was dried before entering the apparatus.

The tap leading to the bromine reservoir was lubricated with a mixture of nujol and paraffin wax, which sufficed for some weeks without renewal. The most satisfactory lubricant for the tap to the *cyclo*hexane reservoir was a mixture of chlorinated bees' wax and aniline.

Method of Operation.—Connexion was first made between the water pump and the *cyclo*hexane and bromine reservoirs in turn, and a quantity of the vapours was drawn over to remove air present

in the reservoirs. This operation was only repeated after the taps on these reservoirs had been cleaned out.

The whole system was evacuated by the diffusion pumps for some hours. *cyclo*Hexane and bromine vapours were then admitted to the reaction vessel to known pressures, as follows: Pure hydrogen was let into the gauge up to the tap T to a measured pressure; by regulating the temperature of the *cyclo*hexane, it was then let into the system to a slight excess pressure, the tap T_1 was shut, T opened, and the excess drawn out by turning T_2 until the level on the sulphuric acid manometer was the same on both sides. T was now shut, more hydrogen was let into the gauge, and bromine vapour let into the reaction cell until the pressure was just below that in the gauge. T was then opened, T_1 shut, and bromine let in until the pressures on each side were the same.

The progress of the reaction was followed by observing the pressure decrease on the sulphuric acid manometer, T_1 being turned off when measurements were taken.

As the thermal reaction between bromine and *cyclo*hexane is appreciable at the temperatures used, it was necessary to measure this in order to ascertain the amount due to the photochemical reaction alone. This was usually done by screening off the light for a time and measuring pressure decreases due to the dark reaction only. Measurements were also made in which the thermal reaction was allowed to proceed to completion.

Before each run the system was evacuated for at least 2 hours. The reaction vessel was heated with a Bunsen burner while under a high vacuum to remove the reaction products which condensed on the cell and cut down the light entering the system.

The pressures employed (in terms of Hg, to which all measurements are reduced) were about 5 cm. of *cyclo*hexane and 4 cm. of bromine, an excess of the former being invariably present. The pressure changes finally recorded did not, in general, correspond to any definite stage in the bromine substitution, but were somewhat variable. It was therefore necessary to run the reaction to completion in each case, the final value being taken as proportional to the amount of bromine present, and bromine concentrations at any one time being deduced from the pressure changes at that time.

The following are the results of two typical runs at 30° for the dark reaction, which required about 4 hours for completion; $k = 1/t.\log_{10} a/(a-x)$. Cell A (with flattened ends) was used.

	(I.)	(II.)

			Mean 59			Mean 58

The thermal reaction is thus seen to conform to the unimolecular law. As the photochemical reaction also conforms to the same law, it was thought that this reaction might be due to diffuse daylight, but blackening of the lead tubes only reduced the coefficient to 0·0049, which must be due to a true dark reaction.

Temperature Coefficient of the Photochemical Reaction.—In these experiments, the first lamp mentioned on p. 2470 was used with a filter transmitting the green line. The reaction cell was filled as before, and removal of a stop let the light into the system. Readings were taken every minute, the light was shut off, and the thermal reaction velocity measured. As before, the reaction was taken to completion.

Experiments were conducted at 30° and at 40°, one of the latter being recorded as an example :

Br_2 pressure = 4·41 cm. C_6H_{12} pressure = 5·17 cm. ∞ value = 2·090 cm.

Green filter.

t.	$a - x$.	$k \times 10^4$.	t.	$a - x$.	$k \times 10^4$.	t.	$a - x$.	$k \times 10^4$.

k for thermal velocity = 70

	Press. of				
Temp.	C_6H_{12}.	Br_2.	k for green filter.	k (thermal).	k (green alone).
40°	4·41	5·17	0·0103	0·0071	0·0032
	4·03	5·27	0·0106	0·0070	0·0036
30	3·91	5·07	0·0099	0·0066	0·0033
	4·01	5·06	0·0099	0·0065	0·0034

The temperature coefficient of the photochemical reaction is thus unity within the limits of accuracy of the experiment. By the use of the mercury lamp with no filter, unimolecular coefficients were also obtained. Two experiments gave a temperature coefficient of 1·05 :

Temp.	k (total).	k (thermal).	k (photochemical alone).
40°	0·027	0·007	0·020
30	0·025	0·006	0·019

The thermal reaction appears to have only a slight temperature coefficient. In these experiments, the capillary connexions were not blackened.

The measurement of the thermal velocity coefficient at 100° gave a value of $k = 0{\cdot}011$.

The small temperature coefficient of the dark reaction would appear to point to this being a surface action rather than a true bulk reaction (compare Norrish, J., 1923, **123**, 306). Experiments with two different reaction cells at 30° gave identical velocity coefficients, and the ratio of surface area to volume was the same in each case, thus lending support to this view.

Effect of Intensity of Light.—In this series of experiments, the glass mercury lamp was replaced by a quartz lamp giving much more intense light. The reaction-cell used had plane parallel glass windows. The light intensities were compared by means of a thermopile and galvanometer. In making measurements, the thermostat cell was removed and the thermopile brought up to the same position behind the cell in each case. The intensity was varied by altering the distance of the lamp from the system, and is given in terms of the galvanometer deflexion.

Light intensity,	Pressure of		
cm.	Br_2.	C_6H_{12}.	$k \times 10^4$.
9·55	3·73	5·33	645 } Mean 654
	4·01	5·09	663 }
6·00	4·06	5·02	450
	4·02	5·07	440 } Mean 441
	3·91	5·17	435

Separate determination of the thermal velocity coefficient gave $k = 0{\cdot}0060$.

Ratio of reaction velocities = $(654 - 60)/(441 - 60) = 1{\cdot}56$.

Ratio of light intensities = $9{\cdot}55/6{\cdot}00 = 1{\cdot}59$.

The agreement shows proportionality between velocity and light intensity.

Influence of Concentration of cyclo*Hexane.*—In all the foregoing experiments, the original *cyclo*hexane pressure was within 10% of 5 cm. No general falling off of the unimolecular coefficient was observed as the *cyclo*hexane concentration was reduced during the progress of the reaction, and it would thus appear that the rate is independent of the *cyclo*hexane pressure. An attempt was made to test this point by using *cyclo*hexane pressures of from 5 to 2 cm. with 4 cm. of bromine. With 5 and 4 cm. of *cyclo*hexane, the total pressure changes for complete reaction were approximately the same, and the unimolecular coefficients were identical, corresponding to the substitution of 2—3 atoms of bromine; with 3·2 cm. the

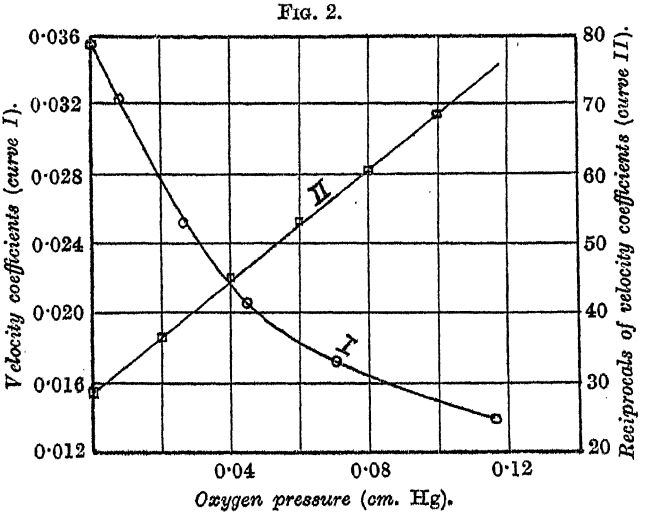
total pressure changes were less, corresponding either to incomplete substitution or to incomplete removal of bromine. The reaction was therefore followed by direct measurement of the bromine concentration, which, together with pressure measurements, should give an indication of the extent of the substitution by bromine. This was effected by measurements of the intensity of the emergent light with a potassium photoelectric cell. The light from the mercury lamp passed through a condensing lens on to a stop placed at the focal distance from a second lens, the approximately parallel beam being passed through the reaction vessel on to the cell. The photoelectric cell was in series with a galvanometer, a high resistance, and a constant voltage of 159 volts. For calibration, galvanometer readings were taken corresponding to bromine pressures measured on the sulphuric acid manometer. The reaction could be followed by plotting galvanometer deflexions against time. Simultaneous galvanometer and pressure readings were made for experiments with various *cyclo*hexane concentrations. It was found that the bromine pressure plotted against pressure changes gave a straight line—the gradient in all cases corresponding to the substitution of two bromine atoms in the molecule—thus confirming the assumption that the bromine concentration could be taken as proportional to the difference in pressure from the infinity value. With low *cyclo*hexane concentrations, the pressure change ceased before complete removal of bromine, although, for the initial stages of the reaction, bromine pressures plotted against pressure changes gave a straight line of the same gradient as with higher *cyclo*hexane concentrations.

The table shows values of the unimolecular coefficient ($k' = 1/t.\log_{10}[Br_2]_0/[Br_2]_t$) for the removal of bromine calculated from bromine concentrations measured with the photoelectric cell for various *cyclo*hexane concentrations.

C_6H_{12} press., cm.	Br_2 press., cm.	$k' \times 10^4$.	C_6H_{12} press., cm.	Br_2 press., cm.	$k' \times 10^4$.
7·13	2·10	198	3·93	1·79	187
6·10	2·01	186	3·12	1·53	178
5·24	2·25	182	2·11	1·96	161

It will be seen that the rate is independent of the *cyclo*hexane concentration within the limits of experimental error.

Influence of Oxygen.—Preliminary experiments showed that the reaction was inhibited by oxygen. The velocity in the presence of pressures of oxygen from 0·01 to 1 cm. Hg was measured. Oxygen was let into the gauge up to the tap T to a known pressure, diluted with hydrogen, and pumped out to a measured pressure (about 2 cm. Hg); the reaction vessel was evacuated, and the oxygen–



hydrogen mixture let in to the system; 5 cm. of *cyclo*hexane and 4 cm. of bromine were let into the reaction vessel as before, and the velocities measured.

In this series of experiments the capillary connexions were blackened; the thermal velocity was measured in the absence of oxygen and gave $k = 0{\cdot}0048$. The light intensity was kept constant throughout.

The table shows the velocity coefficients for various oxygen pressures. It is to be noted that the reaction still obeys the unimolecular law.

FIG. 2.

The thermal velocity coefficient does not diminish for oxygen pressures up to 0·49 cm., but for 1 cm. it appears to fall slightly. These results are plotted in Fig. 2 (Curve I). Curve II shows the values of oxygen pressure plotted against the reciprocals of the corresponding velocity coefficients; it will be seen that a straight line is obtained.

The inhibition by oxygen can thus be represented by the equation (compare p. 2468)

$$k_{O_2} = Kk_3/(k_3 + k_2[O_2]),$$

where K is the velocity coefficient in absence of oxygen, k_{O_2} is that for a pressure of oxygen $[O_2]$, and k_9 is a constant. From the gradient of the curve the value of k_9/k_8 is found to be 14·8, and the values deduced from the velocity coefficients with oxygen equal to 0·49 and 1·05 cm. Hg were 14·4 and 15·0, respectively, *i.e.*, agreement with this equation extends up to the highest oxygen pressures used. Experiments were not attempted at higher pressures because k_{O_2} becomes too small.

From the value of k_9/k_8, it is possible to deduce a value for the mean life of the excited complex $C_6H_{12}Br_2'$; when the oxygen pressure is expressed in mm. Hg (instead of cm.), $k_9/k_8 = 1{\cdot}48$. Now, $k_9/k_8 = (1/T)/(1/\tau)$, where τ is the mean life of the complex, and T, the time between successive collisions of oxygen and the complex (each of which is assumed to be effective in causing deactivation) for unit oxygen pressure, is given by $T = 1/A\sigma^2$, where

$$A = 2667\sqrt{2\pi N(m_1 + m_2)/R\theta m_1 m_2}$$ (Turner, *loc. cit.*).

Taking a value of σ as 10^{-7} cm. for the mean of the diameters of the oxygen molecule and the complex, we obtain $T = 2{\cdot}1 \times 10^{-8}$ sec., whence $\tau = 3 \times 10^{-8}$ sec., a value comparable with those obtained for excited molecules by other methods.

Summary and Interpretation of Results.

In the photobromination of *cyclo*hexane under conditions where the light absorption is proportional to the concentration of bromine, it is found that the photoreaction has no temperature coefficient for light of wave-length $\lambda = 5460$ Å. in the range 30—40°. The reaction rate is directly proportional to the light intensity and independent of the concentration of the *cyclo*hexane.

This form of unimolecular law is shown to be compatible, when, as in this case, no chain formation occurs, with two hypotheses: (1) the reaction may proceed through the formation of bromine atoms, or (2) the primary action may be the formation of an excited bromine molecule, the life of which is long compared with the time between collisions with a molecule of the acceptor.

The reaction velocity is reduced by the presence of oxygen. The inhibition is found to be independent of the pressure of the *cyclo*hexane. The quantitative data lead to the conclusion that not atoms but excited bromine molecules are the primary photoactive constituent; further, that it is not these excited molecules but the excited $C_6H_{12}Br_2'$ molecules which are deactivated on collision with oxygen. The mean life of this complex is *ca.* 3×10^{-8} sec. The mechanism of the photobromination and inhibition by oxygen can accordingly be described by the reactions (1A), (7), (8),

(9), and (10) (see p. 2468). The thermal bromination of *cyclo*hexane proceeds slowly on the surface of glass at 30°.

If the following values be taken for the heats (in Cals.) of linking in the various reactions employed: C–Br = 62; C–H = 87; $Br_2 \longrightarrow 2Br = 46{\cdot}2$; H + Br = HBr + 77·7; energy in the radiation $Nh\nu = 53{\cdot}2$, it is clear that the excited bromine molecule of energy content 53·2 Cals. cannot break a C–H union by impact and subsequent transference of its energy alone, but only by forming an association complex, which then undergoes rearrangement. From the above data we obtain

$$C_6H_{12} + Br_2 \longrightarrow C_6H_{11}Br + HBr + 6{\cdot}5$$
$$C_6H_{12} + Br_2' \longrightarrow C_6H_{11}Br + HBr + 59{\cdot}7$$

The products of reaction thus contain 59·7 Cals. If, as is imagined by some (Marshall, *J. Physical Chem.*, 1925, **29**, 842), the hydrogen bromide carries away this energy, there seems no reason why there should not be reaction chains in this reaction as in the bromination of toluene where similar conditions obtain. If, on the other hand, the energy is retained by the bromo-derivative, the difference in structure between bromo*cyclo*hexane and benzoyl bromide may account for the difference in reaction; in one, the transfer of energy to another bromine–hydrogen complex in the same ring is possible, forming dibromo*cyclo*hexane; in the other, the energy is localised on a side chain and can apparently only be transmitted to another molecule on collision. It is hoped to examine the chain formation in the photobromination of toluene in the near future.

Our thanks are due to Messrs. Brunner Mond for assistance in defraying part of the experimental cost, and to the Department of Scientific and Industrial Research for a grant to one of us (B. J. W.) which has enabled us to undertake this investigation.

LABORATORY OF PHYSICAL CHEMISTRY, CAMBRIDGE.

CCCXXXI.—*The Preparation and Properties of* dl-*Glyceraldehyde.*

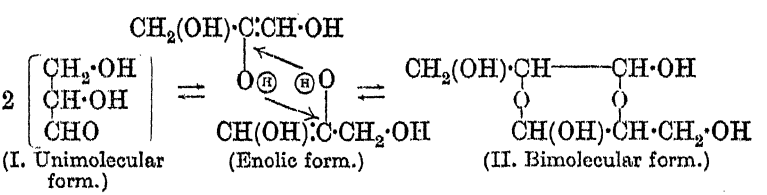
By H. GORDON REEVES.

THE importance of glyceraldehyde is twofold. Not only is it the foundation stone on which the stereochemical configuration of the carbohydrates is constructed, but also it is regarded as an important link in the elusive metabolic chain of chemical reactions by which in the animal body glucose is converted into carbon dioxide and

water. Despite this, it has received comparatively little attention owing probably to the great difficulty experienced in preparing it in a pure condition and to its lability and concomitant sensitiveness towards chemical reagents.

Nearly 70 years ago Van Deen (*Nederl. Tydschr. Geneesk.*, 1860, 4, Aug.) reported that glycerol, when treated with nitric acid or subjected to the passage of an electric current, yielded a fermentable syrup which was optically inactive. Since that time, numerous attempts have been made to prepare glyceraldehyde by the oxidation of glycerol with various agents or by electrolysis of hydroxy-acids, but in every case the yield was most unsatisfactory (for summary see Witzemann, *J. Amer. Chem. Soc.*, 1914, **36**, 1908).

In 1898, Lobry de Bruyn and Adriani (*Rec. trav. chim.*, **17**, 258) made the important discovery that by careful hydrolysis of acraldehyde dibromide, glyceraldehyde could be obtained, and in the same year Wohl (*Ber.*, **31**, 1796, 2394) synthesised the pure aldehyde from acraldehyde through glyceraldehyde diethylacetal. In 1914, Witzemann (*loc. cit.*) proved that glyceraldehyde was formed when glycerol was oxidised with Fenton's reagent (Fenton and Jackson, J., 1899, **75**, 4; *Chem. News*, 1898, **78**, 187); the syrupy product was converted into the diethylacetal by Fischer and Giebe's method (*Ber.*, 1897, **30**, 3055; 1898, **31**, 545), but only 6% of the syrup yielded an acetal, the chief impurity being dihydroxyacetone, which does not form an acetal. Owing to the presence of by-products, the glyceraldehyde, obtained by hydrolysis of the acetal with dilute sulphuric acid, could only be crystallised with great difficulty (compare Meyer and Jacobson, "Lehrbuch der Organische Chemie," I, ii, 157, 171), and the method was too tedious for practical purposes.



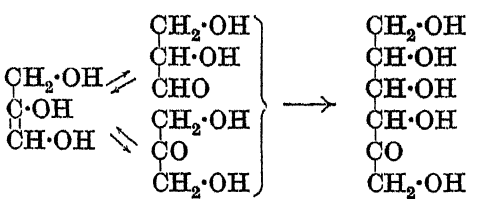
Of the many methods which have been used, that of Wohl is the only one which gives glyceraldehyde in a state of purity, entirely free from dihydroxyacetone and in reasonable yield. For this reason the material used for the present observations was prepared directly from acraldehyde (obtained by Moureu's method, *Ann. Chim.*, 1921, **15**, 158; see also Snellgrove, Thesis, London, 1924) in four stages. (1) Acraldehyde was converted into β-chloropropaldehyde diethylacetal by the action of cold absolute alcohol, saturated with dry hydrogen chloride: the yield was greatly improved by the addition of anhydrous calcium chloride. (2) The elements of hydrogen chloride were removed from the chlorinated acetal by distillation with solid potash, with production of acraldehyde diethylacetal. (3) This was oxidised by aqueous potassium permanganate to glyceraldehyde diethylacetal. (4) The last acetal was hydrolysed by means of dilute sulphuric acid, the acid neutralised, and the pure glyceraldehyde caused to crystallise from the

concentrated liquor by the addition of methyl alcohol and ether. Each of the four stages proceeds smoothly, but, although the yields have been improved in the present research, they are not good.

Glyceraldehyde, as thus obtained, is a white, non-hygroscopic, slightly sweet powder, which crystallises from aqueous methyl alcohol in colourless, pointed needles. Analysis and the m. p. of its *p*-bromophenylosazone (168°) showed it to be pure (Wohl, *loc. cit.*, gives m. p. 168°).

As a basis for the space representation of the sugars, the unimolecular formula (I) for glyceraldehyde is always adopted, but Wohl and Neuberg (*Ber.*, 1899, **32**, 1352; 1900, **33**, 3095) showed by cryoscopic determinations that it was bimolecular (compare glycollaldehyde and dihydroxyacetone) and ascribed to it the formula (II). In aqueous solution, the aldehyde gradually assumes the unimolecular form. In view of the importance of these observations, molecular-weight determinations were repeated with particular care, and the results of Wohl and Neuberg were confirmed.

In preparing the glyceraldehyde for this research, it was noted that the transparent syrup obtained by the hydrolysis of its diethylacetal had most unexpected properties. After standing over-night in a vacuum desiccator, the syrup showed a white opalescence; 24 hours later it had become very viscous and perfectly opaque. These phenomena were noted on only one occasion by Witzemann (*J. Amer. Chem. Soc.*, 1914, **36**, 2223) in his repetition of Wohl's synthesis, and his use of the term " colloidal " in this connexion was unsupported by any evidence. It seemed necessary, therefore, to investigate the molecular complexity of the aldehyde in these various states. The transparent syrup was found to be enolic and, in aqueous solution, unimolecular; the following scheme is therefore suggested as a possible mechanism for the changes described above :



(I. Unimolecular form.) (Enolic form.) (II. Bimolecular form.)

In support of this scheme, the possibility of the formation of a stable six-atom compound from an enol, recently substantiated by Sidgwick (J., 1925, **127**, 907), may be cited. The crystalline bimolecular glyceraldehyde, after repeated crystallisation, was shown by K. H. Meyer's method (*Annalen*, 1911, **380**, 212; Meyer and Kappelmeier, *Ber.*, 1911, **44**, 2718) to contain a trace of the enol.

Fischer and Tafel (*Ber.*, 1887, **20**, 2566) showed that crude

ıymerised under the influence of dilute alkali. Wohl
ş (*loc. cit.*) found that pure glyceraldehyde in presence
ic potash solution readily condensed to β-acrose and
split up into dihydroxyacetone. Nef (*Annalen*, 1907,
910, **376**, 1; 1914, **403**, 204) showed that the first step
of dilute alkali on all carbohydrates was the production
ed enols, which then underwent decomposition by fission
le bond. Thus the γδ-dienol formed by the action of
cose breaks down at the ethylene linkage to give glycer-
The interaction of glyceraldehyde with alkali involves

glucose, had the structure

$$OH{\cdot}CH_2{\cdot}[CH{\cdot}OH]_3{\cdot}C(OH){:}CH{\cdot}ONa,$$

and Wohl and Neuberg (*loc. cit.*) postulated an unsaturated alcohol of the type X·C(OH):CH·OH as an intermediate phase in the conversion of glyceraldehyde into β-acrose under the influence of dilute alkali. The existence of this unsaturated labile form is now definitely proven.

The close resemblance between glyceraldehyde and glucose in chemical properties suggests the possibility of either a 1 : 2- or a 1 : 3-oxide structure rather than the generally accepted straight-chain aldehydic form.

Owing to its extreme lability, glyceraldehyde has hitherto resisted attempts to methylate it completely, but the work is being continued, and it is hoped to publish the results shortly. From the preliminary work, it would appear that glyceraldehyde falls into line with other sugars in its resistance to propylene-oxide formation.

EXPERIMENTAL.

Preparation of Glyceraldehyde.—β-Chloropropaldehyde diethylacetal. To absolute alcohol (2 mols.), cooled in an ice-bath, powdered anhydrous calcium chloride (⅛ mol.; excess should be avoided) was added, and acraldehyde (1 mol.) admitted in small portions at a time with continuous shaking. Dry hydrogen chloride (1 mol.) was now bubbled through the mixture, the temperature of the bath being kept below 5°; the mixture, which became yellow, was kept for 24 hours, during which it separated into two layers. The lower oily layer was drawn off, neutralised with finely powdered sodium bicarbonate, and dried over solid potassium hydroxide without removing the alcohol. Small quantities of the oil were recovered from the supernatant liquor by passing further quantities of hydrogen chloride. The yield was 90% of the theoretical. The pale yellow oil so obtained had a characteristic but not unpleasant odour.

Acraldehyde diethylacetal. (In this preparation exact adherence to the specified conditions is essential.) To 200 g. of the above crude oil in a 1-litre copper flask, 400 g. of pure, dry, finely powdered potassium hydroxide were added slowly in small quantities at a time with vigorous shaking and cooling. The mixture was then distilled very slowly through a three-bulb Young fractionating column; the main bulk passed over between 120° and 130°. This was dried with potassium carbonate and redistilled, the fraction distilling between 120° and 128° being collected (yield, 70%). The acraldehyde acetal was a colourless, mobile liquid with an agreeable ester-like odour, slightly soluble in water, but miscible in all proportions with alcohol and ether. It is readily hydrolysed in the cold by dilute hydrochloric acid.

Glyceraldehyde diethylacetal. The acraldehyde acetal (100 g.) was

emulsified by vigorous shaking with distilled water (1200 c.c.), and the whole cooled to 0°. To the cold emulsion was added, drop by drop with continuous and vigorous shaking, the calculated quantity of a 4% aqueous potassium permanganate solution. The mixture, after being kept for 12 hours at 0°, was heated for ½ hour on the water-bath and filtered from the precipitated manganese dioxide, which was well pressed and then twice washed with 50 c.c. of warm water. The warm filtrate and washings were treated with potassium carbonate solution (500 g. per litre) and immediately cooled; the glyceraldehyde diethylacetal, which separated as a yellow oil on the surface of the liquor, was removed, and the lower aqueous layer extracted four times with ether. The oil and the extracts were combined, and the ether was removed. The residual acetal was redistilled under diminished pressure, b. p. 130°/20 mm. A small amount of unchanged acraldehyde acetal can be recovered. The yield of glyceraldehyde diethylacetal is variable; in no case was it greater than 60%, and in one experiment it fell to 30% for no accountable reason (Wohl and Neuberg reported 40%; Witzemann, 54%). The loss here cannot be explained, since the oxidation itself proceeds quite smoothly.

The acetal is a colourless, viscous liquid with a caustic taste. It is miscible with water, alcohol, and ether, and is readily hydrolysed by dilute mineral acids. Its aqueous solution reduces Fehling's solution in the cold, and in acetic acid it gives a phenylosazone.

dl-*Glyceraldehyde.* 55 G. of the acetal were dissolved in *N*/10-sulphuric acid (550 g.) and kept at room temperature for 48 hours, then at 38° for 24 hours, and allowed to cool. The acid was exactly neutralised with the calculated weight of barium hydroxide, and the whole kept for 2 hours. The precipitated barium sulphate was filtered off and washed with a minimum volume of water. The filtrate was concentrated at 40° in a vacuum over calcium chloride. The further small amount of barium sulphate which had separated when concentration was half completed was filtered off, and concentration continued. Success in crystallisation depends on the *complete* removal of water from the syrup. After one month, a pale yellow, transparent syrup was obtained, which on standing over-night in the vacuum desiccator showed a white opalescence, and after a further 24 hours became creamy and opaque. Trituration with small amounts of pure ice-cold methyl alcohol containing 1% of ether caused immediate separation of the crystalline glyceraldehyde; yield, 60% of the theoretical. (Excess of ether must be avoided, otherwise the product is sticky.)

Properties.—The glyceraldehyde was obtained as a white, non-hygroscopic, slightly sweet powder, m. p. 133°; after being washed

with methyl alcohol, dried on porous tile, recrystallised from 40% aqueous methyl alcohol, and dried over phosphorus pentoxide in a vacuum for one week, it had m. p. 138·5° (Wohl gives 138°, and Witzemann 142°), unaltered by further recrystallisation and desiccation (Found: C, 39·8; H, 6·7. Calc.: C, 40·0; H, 6·7%). It crystallises from aqueous methyl alcohol in short, colourless needles, which are sparingly soluble in water, ethyl alcohol, and ether, and decompose above their m. p. to a sticky, brown, caramel-like mass. Its *p*-bromophenylosazone melted at 168°.

To the properties already described (Abderhalden, "Biochemisches Handlexikon," II, 1911) may be added the following: It is insoluble in benzene, petroleum, and pentane. Its solubility in water at 18° is 3 g. per 100 c.c., and it has $d_{18}^{18°}$ 1·455.

Molecular-weight Determinations.—(a) *The crystalline solid.* A freshly prepared solution containing 0·1480 g. in 25 c.c. of water gave $\Delta = 0·061°$, hence $M = 180·6$. After the solution had stood for one week, Δ was found to be 0·122°, hence $M = 90·3$. Thus dissociation into the unimolecular form occurs in aqueous solution.

(b) *The transparent syrup,* from which the crystals separated, is apparently unimolecular: 0·1204 g. in 25 c.c. of water gave $\Delta = 0·097°$; $M = 92·4$.

The Action of Alkalis and the Existence of an Enolic Modification.—Cold dilute sodium hydroxide (both $N/10$ and N) readily dissolves glyceraldehyde, which passes through all the various changes described by Nef, finally giving β-acrose, polysaccharides, and lactic acid. The alkaline solution resinifies gradually on being warmed. The aldehyde is less soluble in 50% sodium hydroxide and rapidly resinifies in the hot solution. Its behaviour with alkali is thus similar to that of other aliphatic aldehydes.

Colorimetric Measurements with Ferric Chloride Solution.—5 C.c. of 1% aqueous solutions of glucose and glyceraldehyde were each kept at 38° for 10 minutes; 5 c.c. of 0·1% caustic soda solution were then mixed with each, and the mixtures were kept at 38° for a further 10 minutes. On the addition of 1 c.c. of 10% aqueous ferric chloride, the glyceraldehyde solution showed a deeper red coloration than did the glucose solution, and therefore apparently contained a higher percentage of the enolic form. A quantitative estimation was then made with the colorimeter: 1% Aqueous solutions of glucose and glyceraldehyde were used; 2 c.c. of each were kept for 10 minutes at 38° with 7 c.c. of $N/10$-sodium hydroxide. To each was added 1 c.c. of 0·1% aqueous ferric chloride, and the solutions were cooled to room temperature.

The readings on the colorimetric scale were 1·46 and 1·15 for glucose and glyceraldehyde, respectively. Hence, the ratio of enol

in glyceraldehyde to that in glucose = 1·27 : 1. Similar results were obtained with several different preparations.

Refractometric Measurements.—Readings were taken with a Pulfrich refractometer at 20° with sodium light. The following solutions were prepared:

(*a*) *Neutral solution.* 2 C.c. of 1% glucose solution were warmed at 38° for 5 minutes with a mixture of 2 c.c. of *N*/10-hydrochloric acid and 2 c.c. of *N*/10-sodium hydroxide, and cooled to room temperature.

(*b*) *Acid treatment.* As in (*a*), but the alkali was not added until after the cooling.

(*c*) *Alkali treatment.* As in (*a*), but the acid was omitted until after the cooling.

(*d*) A 1% aqueous solution of glucose, as a standard.

Solutions similar to (*a*), (*b*), (*c*), and (*d*) were prepared with glyceraldehyde. The readings obtained show that there is a decrease of 2′ in the angle of refraction of both glucose and glyceraldehyde in alkaline solution, indicating the production of an unsaturated form. These results were confirmed on several occasions with different preparations.

Nature of solution.	Glucose.	Glyceraldehyde.
(*d*) Aqueous (1%)	67° 2′	67° 2′
(*a*) Neutral (⅓%)	67° 9′	67° 8′
(*b*) Acid (⅓%)	67° 9′	67° 8′
(*c*) Alkaline (⅓%)	67° 7′	67° 6′

There is no change in the refractive index of the glyceraldehyde solution after standing for one month.

From (*d*) the refractive index for a 1% solution = 1·33412, whereas that for water is 1·33311 under the same conditions. Hence $[R_L]_D = 19·2$ (calc. for $C_3H_6O_3$: 19·14; for enolic form: 20·08), showing that in aqueous solution no appreciable amount of the enolic form exists, a fact which is substantiated in that ferric chloride gives no coloration.

Bromine Titration for Estimation of the Enol.—A suspension of glyceraldehyde in chloroform slowly decolorises a cold solution of bromine in the same solvent. An alcoholic solution of glyceraldehyde rapidly decolorises alcoholic bromine at −7°.

The bromine titration was carried out as follows: A solution of 0·1 g. of glyceraldehyde in 250 c.c. of absolute alcohol was cooled in ice and salt for ½ hour. Ice-cold *N*/10-alcoholic bromine solution was run in slowly from a burette until the yellow colour of the bromine just persisted (10—12 c.c. usually); 2—3 c.c. of a 10% alcoholic solution of β-naphthol, freshly prepared, were added to

remove the excess of bromine, followed by 15 c.c. of 10% potassium iodide solution, and the mixture was boiled on the water-bath for 10 minutes. The resulting pale yellow solution was cooled and titrated against $N/100$-sodium thiosulphate (usually 1—2 c.c.). The average of four experiments gave enol = 0·54%.

An alcoholic solution of the syrup from which the solid glyceraldehyde was obtained readily decolorised alcoholic bromine solution. Bromine titrations on this syrup (0·1 g. in 50 c.c. of absolute alcohol) gave 5·7% of enol (mean of four experiments).

These results show that, although the crystalline form of glyceraldehyde is contaminated with a little enol, the syrup from which the crystals are obtained contains ten times as much.

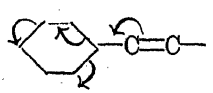
The author expresses his thanks to the Royal Society for a grant which has partly defrayed the cost, also to Dr. R. H. Pickard, F.R.S., in whose laboratory the acraldehyde was prepared, to Professor W. N. Haworth for his interest, and to Dr. J. A. Hewitt for suggesting the work and for advice throughout its progress.

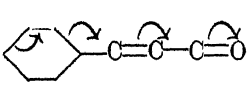
KING'S COLLEGE, W.C. 2. [*Received, August 13th*, 1927.]

CCCXXXII.—*Examples of Feeble Activation of Certain Extended Conjugated Systems by Doubly Bound Oxygen.*

By ROBERT ROBINSON and AHMAD ZAKI.

ALTHOUGH it has recently been shown (Moore and Tucker, *J. Amer. Chem. Soc.*, 1927, **49**, 258) that one of the products of the sulphonation of cinnamic acid is the *m*-derivative, there is a mass of evidence demonstrating the *op*-orienting influence of ethenoid and benzenoid groups. It is therefore surprising to find this contested by Baker and Wilson (this vol., p. 843), especially on the basis of the facts summarised in the scheme below dealing with the results of nitration experiments.

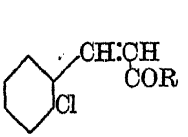




$Ph\cdot CH{:}CH\cdot NO_2$ (meta, 2%)	$Ph\cdot CH_2\cdot CH_2\cdot NO_2$ (meta, 13%)
$Ph\cdot C(NO_2){:}CH\cdot C_6H_4\cdot NO_2$ (meta, 21%)	$Ph\cdot CH_2\cdot NO_2$ (meta, 50%)

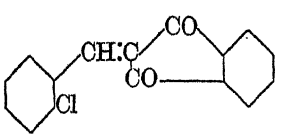
The first three cases are quoted by Baker and Wilson, and instead of phenylnitromethane they mention its dimethyl derivative, $Ph\cdot CMe_2\cdot NO_2$ (meta, 29%). This comparison is not just, because the electron displacement due to the methyl groups must, in accordance with the theory of Allan, Oxford, Robinson, and Smith (J.,

1926, 401) (adopted by Baker and Wilson), have an *op*-orienting effect. Again the nitroxyl group in the *p*-nitrobenzylidenephenylnitromethane should have a weak *m*-directive influence. The disparity, 21—29, in itself indicates the *op*-influence of the unsaturated group, whilst the disparity 21—50 demonstrates it. The argument may be stated as follows. The substitution of nitroxyl for hydrogen in toluene and in the corresponding position in nitrostilbene produces a much smaller change in the direction of *m*-orientation in the latter case. Therefore the *op*-directive power of $\cdot CH{:}CH\cdot C_6H_4\cdot NO_2$ is greater than that of $\cdot CH_3$. Thus the actual evidence put forward by Baker and Wilson leads to a conclusion diametrically opposed to that which they draw.



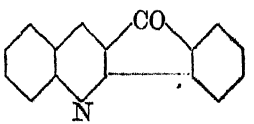
The view advanced by Baker and Wilson is that the effect of the positive change of the nitro-group in ω-nitrostyrene may conceivably be neutralised in the adjustable electric field of the unsaturated centre. Unless the whole unsaturated group has a real net negative charge, this does not appeal as sound electrostatics; and if it has a negative charge, as the result of interaction with the surroundings, then *ipso facto* it would be *op*-directive. The *op*-directive effect of unsaturated groups may be deduced, not only from such widespread phenomena as the *op*-substitution of diphenyl and derivatives, but also indirectly from the increased reactivity of conjugated unsaturated substances in certain directions and especially towards kationoid reagents (compare, for example, K. Meyer and Schoeller, *Ber.*, 1919, **52**, 1468, on the preparation of an azo-derivative of dimethylbutadiene). An interesting example of *op*-direction by an unsaturated group was encountered a few years ago by Miss Margaret D. Scott Murray (University of St. Andrews), who nitrated ethyl benzylidenecyanoacetate in sulphuric acid solution at − 5° to − 10° by means of potassium nitrate (5 mols.). The *o*- and *p*-nitro-derivatives were alone isolated, although not in good yield, and identified by comparison with authentic specimens.

Our view of the cause of the *op*-substitution of cinnamic acid and similar substances is that it is due to the butadienoid-type conjugation of the unsaturated centre with the nucleus as shown in the expression (I).



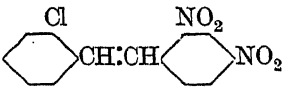
(I.)   (II.)

The crotonoid, conjugated polarisation shown in (II) will doubtless exist in certain phases of the molecule, but should not lead to *m*-substitution, because in these phases the reaction velocity is

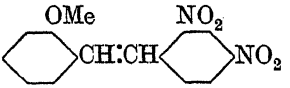


greatly diminished as the result of the positive field over the nucleus, the reagent being kationoid. If the conjugated polarisation were permanent and pronounced, the condition (I) might never be realised, but there is reason to believe that the degree of activation and coherence of all such systems is small. An excellent example is that of *m*-nitrotoluene, in the further nitration of which the methyl group is able to take complete control (Vorländer has shown that the same conditions obtain in quaternary salts derived from *m*-toluidine). Here the methyl group initiates a process favouring reaction, whilst the effect of the nitroxyl is to diminish the reaction velocity, and although the charges associated with the nitroxyl are generally supposed to be much greater than those appearing as the result of the small electron displacement caused by the methyl group, yet it is obvious that phases must occur in which the latter can be effective. The positive field due to the nitroxyl is thus considered to undergo variations; whilst it is considerable over the nucleus, nothing happens, but when, probably as the result of the approach of other charges, the shadow lifts, the molecule becomes, momentarily, equivalent to one of toluene, and substitution in the *o*- and *p*-positions with respect to the methyl group occurs rapidly. An analogous conception applies to systems like those of phenylnitromethane (with two obvious modifications), ω-nitrostyrene and cinnamic acid. The weak coherence of the unsaturated units (C=C, C=O, N=O, C≡N, etc.) in the crotonoid and semi-crotonoid systems is obviously better demonstrated by the occasional failure to exhibit their characteristic properties than by the absence of an anticipated inhibitory effect as in the examples discussed above. We suspect that activation of a mixed system comprising the characteristic group (CO, NO_2, etc.), an aromatic unsaturated group including an even number of carbon atoms, and an ethenoid group is always feeble and have investigated this in three directions. The behaviour of the chlorine atom of *o*- and *p*-nitrochlorobenzene, which is replaceable by anions, is simulated by that of *o*-chlorobenzaldehyde and *o*-chlorobenzoic acid. We have tested the degree of reactivity

(III.)

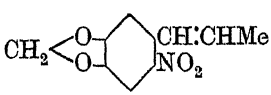


(IV.)

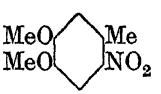


(V.)

of the chlorine atom in the system (III) by attempting a condensation with ammonia which might give a quinoline derivative.



This is a stringent test, in view of the facility with which the quinoline ring may be constructed, but it gave entirely negative results under varied conditions with *o*-chlorobenzylideneacetophenone and ethyl *o*-chlorobenzylidenecyanoacetate. In the case of *o*-chlorobenzylidenediketohydrindene (IV), a greater reactivity would be expected owing to the existence of the two carbonyl groups and it was indeed found possible to convert the substance into the ketoindenoquinoline (V), although in very small yield.



(VI.) 

(VII.)

Similar inactivity has been noted in the stilbene derivatives (VI) and (VII); the former does not react with *p*-toluidine as 2 : 4-dinitrochlorobenzene does, and the latter, unlike 2 : 4-dinitroanisole, is resistant to hydrolytic agents. The inactivity of 1 : 5-dinitronaphthalene, of 2 : 2′-dinitrodiphenyl, and of 2 : 2′-dichloro-6 : 6′-dinitro-4 : 4′-ditolyl towards methyl-alcoholic ammonia at 150° (Burton and Kenner, J., 1922, **121**, 495) also exemplifies the phenomenon of limited conjugation. Finally, 6-nitro*iso*safrole (VIII) has been prepared and we find that the methyl group in it is relatively inert, because an anhydrocotarninenitro*iso*safrole could not be obtained, although 6-nitrohomoveratrole (IX) is readily converted into anhydrocotarninenitrohomoveratrole (Robinson and Robinson, J., 1914, **105**, 1456).

(VIII.) 

(IX.)

In this case, the dissociating semi-crotonoid system, which the molecule formally contains, does not function.

EXPERIMENTAL.

Phenyl 2-chlorostyryl ketone did not yield a quinoline derivative and was recovered unchanged after heating with alcoholic urea and copper powder at 200°, or after boiling with aniline and copper powder. Ethyl 2-chloro-α-cyanocinnamate behaved similarly.

2-*o*-*Chlorobenzylidene*-1 : 3-*diketohydrindene* (IV).—*o*-Chlorobenzaldehyde and diketohydrindene in molecular proportion were heated together at 120°; the product, obtained in excellent yield, crystallised from alcohol in yellow, prismatic needles, m. p. 130—131° (Found: C, 71·3; H, 3·4. $C_{16}H_9O_2Cl$ requires C, 71·5; H, 3·3%). This diketone (2·9 g.), mixed with urea (1 g.), 95% alcohol (5 c.c.), copper powder (0·25 g.), and a trace of cupric chloride, was heated in a sealed tube at 240—250° for 14 hours. On working

up the products from three such experiments, 100 mg. of a weak, yellow base, crystallising from alcohol, were obtained. The substance had m. p. 172—173°, and mixed with ketoindenoquinoline (m. p. 176°; Noelting and Blum, *Ber.*, 1901, **34**, 2470) it melted at 174—175°. The substance could not be obtained at all in experiments made under less drastic conditions and the degree of lability of the halogen in the chlorobenzylideneindandione is evidently negligible.

2′-*Chloro*-2 : 4-*dinitrostilbene* (VI).—A mixture of 2 : 4-dinitrotoluene (52 g.), *o*-chlorobenzaldehyde (40 g.), and piperidine (5 c.c.) was heated on the steam-bath until it set to a solid mass. The product was broken up and boiled with alcohol, the mixture cooled, and the solid isolated. The substance crystallised from alcohol in slender, lemon-yellow needles or from ethyl acetate in bright yellow, prismatic needles, m. p. 174°, that reflect light of many colours (Found: N, 9·4. $C_{14}H_9O_4N_2Cl$ requires N, 9·2%). This stilbene derivative is sparingly soluble in most organic solvents and is most easily crystallised in quantity from acetic acid or by the addition of alcohol to a solution in nitrobenzene. The reactivity of the chlorine atom could not be demonstrated, the substance being recovered unchanged after prolonged boiling with alcoholic *p*-toluidine or after heating with alcoholic ammonia at 100° for several hours. Its hot solution in piperidine is brownish-yellow and becomes green on cooling; if alcohol is added to the hot solution, a copious separation of unchanged material occurs.

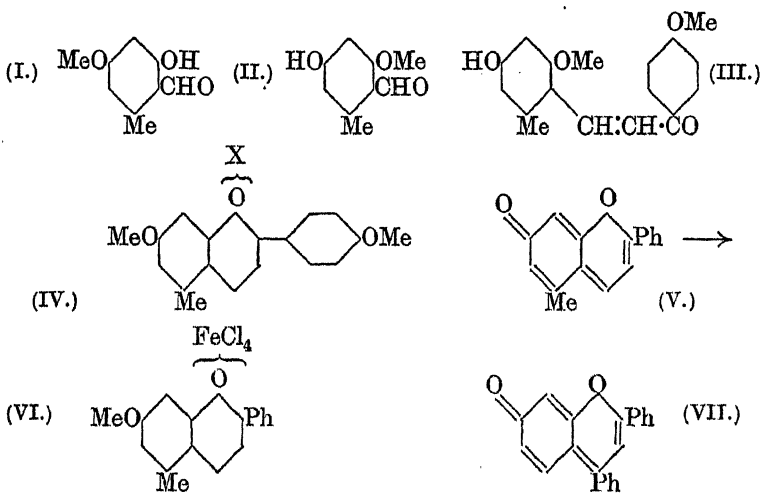
2 : 4-*Dinitro*-2′-*methoxystilbene* (VII).—The preparation was like that just described and the product crystallised from acetone in reddish-orange, stout, prismatic needles, m. p. 176° (Found: N, 9·5. $C_{15}H_{12}O_5N_2$ requires N, 9·3%). This substance is more sparingly soluble in most solvents than the chlorodinitrostilbene; its solutions are yellow and deposit orange needles on cooling. All attempts to replace the methoxy-group by NH_2, NHR, or NR_2, and also to hydrolyse the substance by boiling aqueous and aqueous-alcoholic alkalis, were fruitless.

6-*Nitro*iso*safrole* (VIII).—Bromodihydrosafrole, b. p. 160°/16 mm., is a heavy, almost colourless oil which was obtained by the action of hydrobromic acid (saturated at 0°) on an equal weight of safrole. On heating with aniline, it yields *iso*safrole unmixed with safrole. Since *iso*safrole could not be directly nitrated, the safrole hydrobromide was nitrated and nitro*iso*safrole obtained from the product. Bromodihydrosafrole (20 g.) dissolved in acetic acid (120 c.c.) was nitrated by the gradual addition, with cooling, of a mixture of nitric acid (30 c.c.; *d* 1·42) and acetic acid (30 c.c.). The product was isolated by means of ether after 20 minutes and boiled for

5 minutes with alcohol (100 c.c.) containing potassium hydroxide (10 g.). The solid then precipitated by water crystallised from aqueous methyl alcohol in lemon-yellow needles, m. p. 88° (Found: C, 58·2; H, 4·4; N, 7·0. $C_{10}H_9O_4N$ requires C, 58·0; H, 4·3; N, 6·8%). The substance is readily soluble in most organic solvents, giving yellow solutions, and in sulphuric acid, from the bright red solution in which it is not recovered unchanged. It yields 6-nitropiperonal, recognised by the preparation of its phenylhydrazone, on oxidation with sodium dichromate and hot dilute sulphuric acid. Experiments on the condensation of this substance with ethyl oxalate in presence of alcoholic potassium ethoxide gave ambiguous results; no definite product was isolated. On the other hand, condensation with cotarnine in ethyl-alcoholic solution containing sodium ethoxide did not occur at all.

6-*Amino*iso*safrole*.—Nitro*iso*safrole (6 g.) mixed with tin (15 g.) and concentrated hydrochloric acid (35 c.c.) was heated on the steam-bath until reduction was complete. The amine was extracted by ether and isolated as its very sparingly soluble hydrochloride. The regenerated base crystallised from light petroleum in colourless needles, m. p. 68—69° (Found: C, 67·5; H, 6·2. $C_{10}H_{11}O_2N$ requires C, 67·8; H, 6·2%). It is readily soluble in organic solvents, and may be diazotised and thereafter coupled with β-naphthol to give a crimson azo-derivative. The *hydrochloride* separates from hot water in colourless needles. *Acetamido*iso*safrole* crystallises from alcohol in slender, colourless needles, m. p. 206°, and yields an oily dibromide which is converted into 5 : 6-methylenedioxy-2-methylindole by treatment with alcoholic potassium hydroxide (compare Foulds and Robinson, J., 1914, **105**, 1967).

THE UNIVERSITY, MANCHESTER. [*Received, July 18th*, 1927.]



CCCXXXIII.—*Derivatives of Orcinol. Part I.*

By EDMUND LANGLEY HIRST.

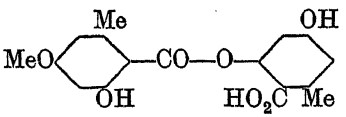
IT has become apparent, during investigations which are now in progress into the structure of certain members of the group of lichen acids, that special importance must be attached to the isomeric orcylaldehyde monomethyl ethers as intermediate substances in synthetic work. It was therefore deemed advisable as a preliminary step to obtain further and more definite chemical evidence concerning the orientation of these two isomerides. This was effected by studying the condensation products of the two methylated aldehydes with acetophenone and with simple sub-

stituted derivatives of acetophenone. Under the appropriate conditions, orcylaldehyde 5-methyl ether (I) would be expected to yield pyrylium salts directly, in the same manner as does resorcylaldehyde (compare Perkin and Robinson, P., 1907, **19**, 149; Decker and von Fellenberg, *Ber.*, 1907, **40**, 3815), whereas the isomeric 3-methyl ether (II) could not do so. When the experiment was made, the orcylaldehyde monomethyl ether (m. p. 188°) described by Gattermann (*Annalen*, 1907, **357**, 346) failed to yield a pyrylium salt either with acetophenone or with acetylanisole, whilst with the latter reagent in the presence of alkali it gave the unsaturated *ketone* (III), which did not give a pyrylium salt until demethylation had been effected by means of hydriodic acid.

The orientation of the original substance as orcylaldehyde 3-methyl ether (4-hydroxy-2-methoxy-6-methylbenzaldehyde), which was previously proposed by Gattermann, is thus confirmed. On the other hand, the isomeric orcylaldehyde monomethyl ether (everninaldehyde; Hoesch, *Ber.*, 1913, **46**, 886) readily formed pyrylium salts when condensed with acetophenone in an acid medium and it must accordingly be orcylaldehyde 5-methyl ether (I).

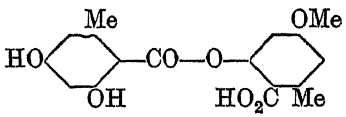
Amongst the compounds investigated, the 4′ : 7-dimethoxy-2-phenyl-5-methylbenzopyrylium salts (IV) obtained from everninaldehyde and acetylanisole were remarkable for their exceedingly intense powers of fluorescence; qualitative comparisons of pyrylium salts from the two orcylaldehyde monomethyl ethers and from orcylaldehyde indicated that the greatly enhanced fluorescent activity of the 4′ : 7-dimethoxy-compounds is connected with the simultaneous presence of the two methoxy-groups in the molecule.

The properties and behaviour of all the compounds examined were strictly normal and comparable with those of pyrylium salts prepared from resorcylaldehyde or similar substances. Details will be found in the experimental section.



Attempts to prepare the bases corresponding to these pyrylium salts led in each case to the isolation of the anhydro-base. Very few of these compounds have hitherto been examined in detail on account of the difficulty experienced in obtaining them in a crystalline condition, and in the present work only one anhydro-base has been made to crystallise : *7-hydroxy-2-phenyl-5-methylbenzopyrylium chloride* gave with sodium acetate a red *base* (V) which could be crystallised (although with difficulty) from its solution in benzene. A study of its properties showed that it was a normal example of a base of the anhydronium type. Thus it formed, when heated with methyl sulphate, a salt of *7-methoxy-2-phenyl-5-methylbenzopyrylium hydroxide*, which was identified by direct comparison of the corresponding *ferrichloride* (VI) with an authentic specimen. A similar transformation of the anhydro-base by reaction with methyl iodide could not be effected, the failure being due in all probability to the insoluble nature of the base. The reaction with methyl sulphate renders the base directly comparable with the compound (VII) which was isolated in a crystalline condition by Armit and Robinson (J., 1925, **127**, 1604), and the discovery of this further example provides additional experimental evidence in support of the views of these authors regarding the structure of anhydronium bases.

Further evidence in support of the constitutional formulæ assigned to the orcylaldehyde monomethyl ethers has been obtained by connecting the present series of experiments with the work of Fischer and Hoesch (*Annalen*, 1912, **391**, 347) on the partly methylated orsellinic acids. This was accomplished by preparing from orcylaldehyde 3-methyl ether the corresponding carbomethoxy-derivative, *5-methylcarbonato-orcylaldehyde 3-methyl ether* (*5-methylcarbonato-3-methoxy-o-tolualdehyde*). This substance was oxidised in neutral solution by potassium permanganate to give 5-methylcarbonato-3-methoxy-o-toluic acid (5-methylcarbonato-orsellinic acid 3-methyl ether), which had been prepared directly from orsellinic acid by Fischer and Hoesch (*loc. cit.*).



5-Methylcarbonato-orcylaldehyde 3-methyl ether is a phototropic substance, turning deep yellow when exposed to light for a few hours and becoming colourless again in the dark.

The action of alkali on 5-methylcarbonato-orsellinic acid 3-methyl ether led to the formation of orsellinic acid 3-methyl ether. The alternative formulæ suggested by Perkin and Everest (" The

Natural Organic Colouring Matters," 1918, pp. 549 and 551) for ramalic acid (one of the commoner lichen acids) require, in the form in which they are printed, that orsellinic acid 3-methyl ether should be one of the products formed on hydrolysis. But it was found by Hesse (*J. pr. Chem.*, 1898, **57**, 253; compare Perkin and Everest, *op. cit.*) that everninic acid and not orsellinic acid 3-methyl ether is obtained when ramalic acid is hydrolysed. In view of Fischer's work on evernic acid (*Ber.*, 1913, **46**, 3253; 1914, **47**, 505), which fixes its structure by relating it to lecanoric acid (Fischer and Fischer, *Ber.*, 1913, **46**, 1138), the alternative formulæ possible for ramalic acid should therefore be (VIII) and (IX). Experiments are now in progress by means of which it is hoped to be able to make a decision between the two.

(VIII.)

(IX.)

EXPERIMENTAL.

Pyrylium Salts from Orcylaldehyde.—(a) Orcylaldehyde (2 g.; prepared from orcinol by Gattermann's method, *loc. cit.*) and acetophenone (2 g.) were condensed in methyl-alcoholic solution (10 c.c.) by saturating the cold mixture with dry hydrogen chloride. The crystalline precipitate that appeared after a few minutes (yield, almost quantitative) was washed with a little methyl alcohol and recrystallised from hot water containing a little hydrochloric acid, *7-hydroxy-2-phenyl-5-methylbenzopyrylium chloride* being obtained in long, yellow needles, m. p. 206° (decomp.) after darkening at 170°. The *perchlorate* (orange, rectangular prisms, m. p. indefinite but below 245°), *iodide* (red, rectangular prisms, m. p. 225° decomp.), *mercurichloride* (golden needles, m. p. 229—230° decomp.), and *ferrichloride* (golden-brown needles, m. p. 147—148° decomp. Found: C, 44·0; H, 3·3. $C_{16}H_{13}O_2Cl_4Fe$ requires C, 44·1; H, 3·0%) were prepared from the chloride by the usual methods. The behaviour of all the salts was normal. The chloride showed no fluorescence in methyl alcohol, but gave an apple-green fluorescence with sulphuric acid.

The corresponding *anhydro-base* (V) was precipitated by sodium acetate from a hot solution of the chloride in water. It was obtained crystalline on very slow evaporation of its solution in benzene, as dark red needles, which sintered and melted with decomp. at 156—165° (Found: C, 81·4; H, 5·5. $C_{16}H_{12}O_2$ requires C, 81·4; H, 5·1%). The base was very slightly soluble in water and showed

a slight fluorescence in methyl alcohol. Boiling hydrochloric acid regenerated the chloride (m. p. 206°). The dry base did not react with methyl iodide in boiling benzene. When, however, the base was heated for 2 hours at 120° with an excess of freshly distilled methyl sulphate, reaction ensued and on addition of a mixture of hot water and hydrochloric acid, saturated with ferric chloride, *7-methoxy-2-phenyl-5-methylbenzopyrylium ferrichloride* was precipitated. This crystallised from acetic acid in golden-yellow, rectangular plates or needles, m. p. 181° (decomp.), and was identified by direct comparison with an authentic specimen (see below) (Found: C, 45·5; H, 3·6. $C_{17}H_{15}O_2Cl_4Fe$ requires C, 45·4; H, 3·3%).

(b) Orcylaldehyde and acetylanisole gave in good yield, under conditions similar to the above, *7-hydroxy-4'-methoxy-2-phenyl-5-methylbenzopyrylium chloride*. This was insoluble in dilute hydrochloric acid and crystallised from methyl alcohol–dilute hydrochloric acid in red needles, m. p. 242—243° (decomp.) after darkening at 225° (Found: C, 61·6; H, 5·7. $C_{17}H_{15}O_3Cl,1\frac{1}{2}H_2O$ requires C, 61·9; H, 5·5%). The *iodide* (microscopic, red prisms, m. p. 235—236° decomp.) was insoluble in all the solvents tried, whereas the *ferrichloride* (yellow needles or elongated plates, m. p. 149—150° decomp.) was much more readily soluble in acetic acid than the corresponding 7-hydroxy-2-phenyl-5-methylbenzopyrylium ferrichloride. The chloride fluoresced strongly in sulphuric acid and in methyl alcohol and weakly in water and in acetic acid.

Pyrylium Salts from Everninaldehyde (Orcylaldehyde 5-Methyl Ether).—Hoesch's orcylaldehyde monomethyl ether (everninaldehyde, *Ber.*, 1913, **46**, 886) (2 g.) was dissolved in methyl alcohol (10 c.c.) containing acetophenone (2 g.), and dry hydrogen chloride was passed into the cooled solution. A brown, crystalline precipitate (2·5 g.) separated after a few minutes. This was filtered off, washed with cold methyl alcohol, and recrystallised from hot dilute hydrochloric acid, thus giving needles, m. p. 173—174° (decomp.), of *7-methoxy-2-phenyl-5-methylbenzopyrylium chloride* containing $1\frac{1}{2}$ molecules of water of crystallisation (Found: C, 65·3; H, 6·05. $C_{17}H_{15}O_2Cl,1\frac{1}{2}H_2O$ requires C, 65·1; H, 5·8%). The *iodide* (red, microscopic needles, m. p. 191—192° decomp.) and the ferrichloride (needles or rectangular plates from acetic acid; m. p. 181—182° decomp., after softening at 177°) were prepared in the usual way from the chloride. All the salts gave an intense apple-green fluorescence in water, methyl alcohol, or sulphuric acid.

Everninaldehyde, when condensed in a similar manner with acetylanisole, gave *4': 7-dimethoxy-2-phenyl-5-methylbenzopyrylium chloride*, which crystallised from dilute hydrochloric acid in light

red needles, m. p. 214—215° (decomp.) (Found: C, 62·9; H, 5·9. $C_{18}H_{17}O_3Cl,1\frac{1}{2}H_2O$ requires C, 62·8; H, 5·8%). The *ferrichloride* crystallised from acetic acid in yellow needles, m. p. 177° (decomp.). The chloride and the ferrichloride gave a very intense apple-green fluorescence in all solvents.

Condensation of Orcylaldehyde 3-Methyl Ether with Acetylanisole.—When Gattermann's orcylaldehyde 3-methyl ether (m. p. 188°) (2 g.), acetylanisole (1·9 g.), and potassium hydroxide (2 g. in 3 c.c. of water) were heated on the water-bath for 3½ hours in methyl-alcoholic solution (20 c.c.), condensation occurred to give p-*anisyl 4-hydroxy-2-methoxy-6-methylstyryl ketone* (III). Addition of water then gave an oil (decomposition products) and from the decanted liquor, on cooling, crystals of the ketone separated in yellow needles, m. p. 194—195° (Found: C, 64·8; H, 6·5. $C_{18}H_{18}O_4,2H_2O$ requires C, 64·7; H, 6·6%). The action of hydriodic acid on this substance led to demethylation followed by condensation to a pyrylium salt which showed an intense green fluorescence in concentrated sulphuric acid.

5-*Methylcarbonato-orcylaldehyde 3-Methyl Ether*.—Orcylaldehyde 3-methyl ether (5 g.) was dissolved in 50 c.c. of acetone and treated with methyl chloroformate (4 c.c.). The solution was cooled in ice and shaken vigorously during the addition of 60 c.c. of *N*-sodium hydroxide. An oil separated which was washed several times with cold water and soon solidified. This material crystallised from dilute acetone in long, colourless, phototropic needles, m. p. 80—81° (Found: C, 58·8; H, 5·2. $C_{11}H_{12}O_5$ requires C, 58·9; H, 5·4%).

5-Methylcarbonato-orcylaldehyde 3-methyl ether (5 g.) dissolved in acetone (25 c.c.) was treated gradually with a solution of potassium permanganate (6 g. in 100 c.c. of water containing 5 g. of crystallised magnesium sulphate), the temperature being maintained at 45°. The precipitated oxides of manganese were then removed by means of sulphur dioxide in the usual way. A quantity of oil separated from the clear solution, followed by a slow crystallisation of 5-methyl-carbonato-orsellinic acid 3-methyl ether. Recrystallisation from ligroin–ethyl acetate gave the pure compound in colourless needles, m. p. 144° (yield, 2 g.). This substance yielded orsellinic acid 3-methyl ether when hydrolysed by Fischer and Hoesch's method (*loc. cit.*).

CCCXXXIV.—*The Nature of the Supposed Dimethiodide of Trimethylene Sulphide.*

By GEORGE MACDONALD BENNETT and ALFRED LOUIS HOCK.

IN reviewing the organic compounds of nitrogen and sulphur from the point of view of the octet theory, Langmuir (*J. Amer. Chem. Soc.*, 1920, **42**, 274) mentioned the dimethiodide of trimethylene sulphide (Grischkevitsch-Trochimovski, *J. Russ. Phys. Chem. Soc.*, 1916, **48**, 880) as the only substance known of the type $[SR_4]I_2$, the sulphur atom forming the centre of a positive bivalent ion. Although this compound can be satisfactorily formulated in accordance with the electronic theory of valency, no reason was apparent why this (together with the corresponding derivative of 2-methyltetramethylene sulphide) should have been the only dimethiodide of a sulphide to be isolated. We thought it desirable, therefore, to examine the substance in greater detail and to prepare other salts derived from this novel type of ion.

In the course of these experiments, we have found that the substance does not possess the structure $\left[CH_2<\begin{matrix}CH_2\\CH_2\end{matrix}>S<\begin{matrix}Me\\Me\end{matrix}\right]I_2$ attributed to it. It was stated explicitly by Grischkevitsch-Trochimovski that the two atoms of iodine in the molecule of the compound are equally ionic, but we were led to doubt this by the observation that only half the iodine is immediately precipitated by silver nitrate in cold aqueous solution, the rest being thrown down when the solution is boiled. This indicates the presence in the molecule of one atom of iodine in the ionic condition and a second atom highly reactive but not actually ionised. In agreement with this view, a solution of the supposed dimethiodide, after being shaken with an excess of silver chloride, yielded a *chloroplatinate*, $[CH_2I{\cdot}CH_2{\cdot}CH_2{\cdot}SMe_2]_2PtCl_6$, and a *chloroaurate*,

$$[CH_2I{\cdot}CH_2{\cdot}CH_2{\cdot}SMe_2]AuCl_4,$$

each with iodine still present in the molecule.

The compound produced by the addition of methyl iodide to trimethylene sulphide is therefore dimethyl-γ-iodopropylsulphonium iodide. Its formation is readily interpreted as due to reversible sulphonium salt formation (compare Bell, Bennett, and Hock, this vol., p. 1803). The strain in the four-membered ring will cause the monomethiodide, which must presumably be first formed, to pass over by intramolecular dissociation into methyl γ-iodopropyl sulphide, which will then combine with a second molecular proportion of methyl iodide:

$$C_3H_6S + MeI \longrightarrow \left[CH_2\langle\begin{matrix}CH_2\\CH_2\end{matrix}\rangle SMe\right]I \longrightarrow CH_2I\cdot CH_2\cdot CH_2\cdot SMe \longrightarrow [C_3H_6I\cdot SMe_2]I.$$

Independent confirmation of the structure of the compound in question has also been obtained by synthesis. Methyl γ-hydroxypropyl sulphide, prepared by methylating γ-hydroxypropyl mercaptan (Rojahn and Lemme, *Arch. Pharm.*, 1925, **263**, 612), yielded an oily methiodide which reacted rapidly with hydrogen iodide to yield dimethyl-γ-iodopropylsulphonium iodide, identical with the supposed dimethiodide of trimethylene sulphide.

It follows also that the " dimethiodide " of 2-methyltrimethylene sulphide is either dimethyl-γ-iodo-α-methylpropylsulphonium iodide or dimethyl-γ-iodo-*n*-butylsulphonium iodide.

There is thus no reason to believe that a dimethiodide of a sulphide can exist. Although the electronic formula of such a substance would be analogous to that of a sulphone, $R_2\overset{+}{\underset{+}{S}}\langle\begin{matrix}\bar{O}\\\bar{O}\end{matrix}$, the relative difficulty of formation of the former is easily understood. The conversion of a methiodide into a dimethiodide would be opposed by a large force, since it would involve the addition of a second equal charge to a sulphur atom already bearing a full free positive charge. This force must prevent the formation of a dimethiodide of a monosulphide, for similar forces make the addition of a second molecule of methyl iodide difficult or impossible even in the case of such substances as 1 : 4-dithian and pyrazine, where there are present in the molecule two distinct atoms of sulphur or nitrogen at which addition might occur. The relative ease with which a sulphoxide is converted into a sulphone, on the other hand, results from the diminution in these compounds of the field due to each positive charge by the influence of the free negative charge on the adjacent oxygen atom.

Experimental.

Preparation of Trimethylene Sulphide.—An improved yield of trimethylene sulphide was obtained thus : A solution of sodium sulphide (80 g. of the hydrate) in water (80 c.c.) and alcohol (100 c.c.) was divided into unequal portions, one-third being boiled in a flask under reflux whilst the remaining two-thirds and trimethylene dibromide (50 g.) were simultaneously introduced from dropping-funnels over a period of ½ hour. The mixture was boiled for a further ½ hour, cooled, diluted, and extracted with ether (5 times). The ethereal solution was dried, and distilled through a Widmer column (the sulphide being volatile with ether) (Yield : 7—9 g.).

The dimethiodide, produced by keeping a mixture of the sulphide and an excess of methyl iodide for 24 hours, crystallised well from absolute ethyl alcohol; m. p. 97—98° (Found: I, 70·4. Calc.: I, 70·9%). The proportion of iodine found by precipitation with an excess of silver nitrate in cold aqueous solution was 33·3, 33·6, and 41·6% after 5, 15, and 120 minutes, respectively, whilst rapid titration gave a mean value of 33·3% (Calc. for one atom of iodine per molecule, 35·4%).

Action of Silver Chloride on the Iodide.—The iodide (1·7 g.) dissolved in cold water (25 c.c.) was shaken with freshly precipitated silver chloride (2 mols.) for 15 minutes, and the solution filtered. Addition of platinic chloride then precipitated a *chloroplatinate*, as an ochre-coloured powder which evolved much iodine on heating (Found: Pt, 22·7, 22·3. $C_{10}H_{24}Cl_6I_2S_2Pt$ requires Pt, 22·4%), and of auric chloride a *chloroaurate*, as a canary-yellow powder which evolved much iodine on ignition (Found: Au, 34·5. $C_5H_{12}Cl_4ISAu$ requires Au, 34·6%).

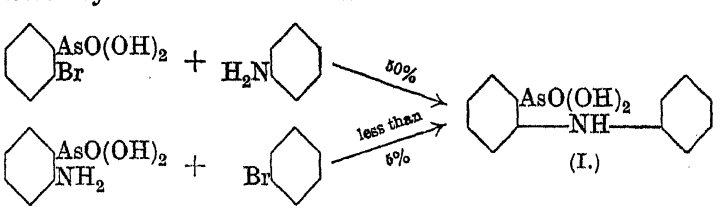
Attempts to isolate a crystalline picrate, mercuri-iodide, or oxalate were unsuccessful.

Action of Dimethylaniline on the Iodide.—When the iodide was heated at 100° with dimethylaniline (1 equiv. or more), a good yield of dimethylaniline methiodide, m. p. 215—217° (decomp.), was obtained (Found: I, 48·2. Calc.: I, 48·3%).

Synthesis of Dimethyl-γ-iodopropylsulphonium Iodide.—γ-Hydroxypropyl mercaptan (27 g.) was methylated by dissolving it in alkali (35 g. of sodium hydroxide in 150 c.c. of water) and adding methyl sulphate (44 g.). The mixture was heated at 100° for 1 hour, cooled, acidified with acetic acid, and extracted with ether. The extract was dried, evaporated, and finally fractionated under diminished pressure. *Methyl γ-hydroxypropyl sulphide* was thus obtained as a colourless oil, b. p. 102°/24 mm., $d_4^{20°}$ (vac.) 1·030 (Found: C, 45·05; H, 9·4. $C_4H_{10}OS$ requires C, 45·3; H, 9·4%). When this substance was dissolved in an excess of methyl iodide, heat was developed and an oil began at once to separate. After 6 hours, the excess of methyl iodide was decanted from the crude *dimethyl-γ-hydroxypropylsulphonium iodide*, which was not further purified. It was covered with dry xylene and dry hydrogen iodide was passed in at 100° for a short time. The xylene was then decanted, and the residue, when inoculated with a trace of the "dimethiodide" of trimethylene sulphide, crystallised at once. After crystallisation from alcohol, *dimethyl-γ-iodopropylsulphonium iodide* was obtained in colourless needles of m. p. 97·5°, not depressed by admixture of the "dimethiodide" of trimethylene sulphide

(Found: by precipitation in cold solution, I, 32·2; in boiling solution, 70·4. Calc.: I, 70·9%).

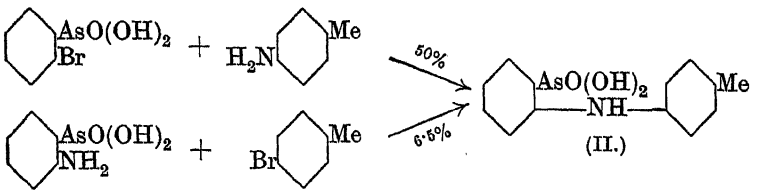
The authors wish to express their thanks to Mr. G. A. Birkett for translating the Russian memoir on which this work was based.



THE UNIVERSITY, SHEFFIELD. [*Received, August 11th*, 1927.]

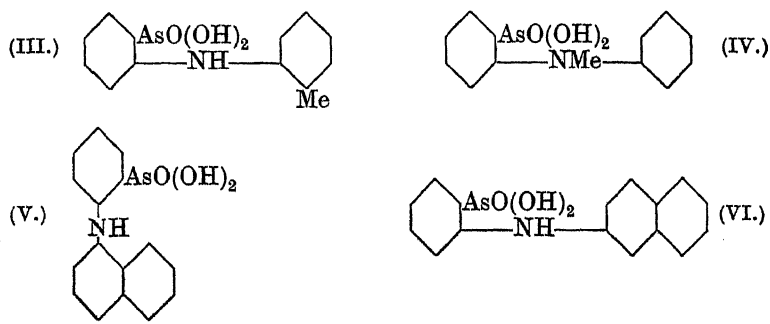
CCCXXXV.—10-*Chloro*-5 : 10-*dihydrophenarsazine and its Derivatives. Part V. The General Method of Synthesis and Determination of Constitution.*

By CHARLES STANLEY GIBSON and JOHN DOBNEY ANDREW JOHNSON.

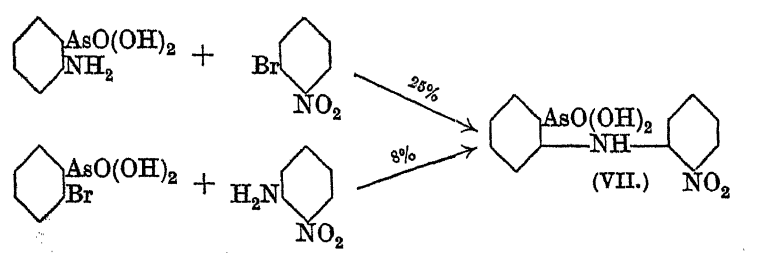


IT has been shown (J., 1927, 247) that carboxy-derivatives of 10-chloro-5 : 10-dihydrophenarsazine which are not accessible by the condensation of arsenious chloride with the corresponding substituted diphenylamines may be prepared by condensing *o*-bromophenylarsinic acid with aminobenzoic acids and subsequent ring closure. Further, it was shown (J., 1926, 2243) that certain substituted diphenylamines will not condense with arsenious chloride, although where at least two of the four ortho-positions in diphenylamine are unoccupied, there seemed reason to believe that the corresponding phenarsazine derivative should be capable of existence. By investigating in greater detail the conditions of the formation of various arsinic acids derived from diphenylamine and the conditions of ring closure to form the heterocyclic arsenic compound, it has been possible to study the properties of some of the compounds hitherto unprepared and to throw more light on the constitution of some already known compounds belonging to this series.

The preparation of *diphenylamine*-o-*arsinic acid* (I) has been effected by two methods as indicated:

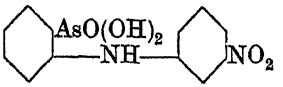


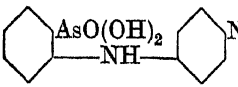
The condensations were carried out under identical conditions and it will be seen that the yield of the condensation product varied



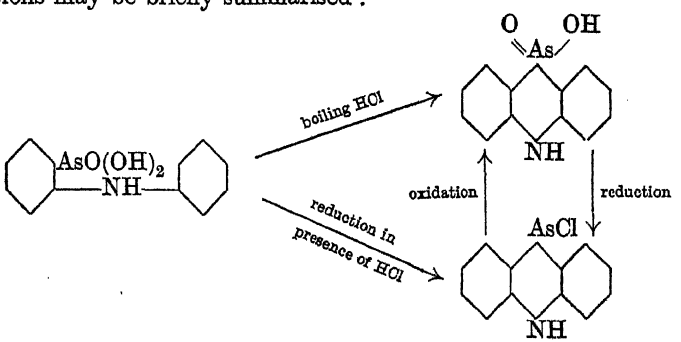
very considerably according as *o*-bromophenylarsinic acid or *o*-aminophenylarsinic acid was the initial material. A result of the same kind was obtained in the preparation by two methods of 4-*methyldiphenylamine*-6′-*arsinic acid* (II):

Since, in both cases, the use of *o*-bromophenylarsinic acid gave a higher yield of the desired arsinic acid, 2-*methyldiphenylamine*-6′-*arsinic acid* (III) (23% yield), N-*methyldiphenylamine*-o-*arsinic acid* (IV) (28% yield), 2-α-*naphthylaminophenylarsinic acid* (V) (81% yield), and 2-β-*naphthylaminophenylarsinic acid* (VI) (90% yield) were readily obtained by condensing *o*-bromophenylarsinic acid with the corresponding amine.





In the case of the production of 2-*nitrodiphenylamine*-6′-*arsinic acid* (VII), the higher yield was obtained when *o*-aminophenyl-

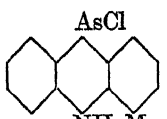


arsinic acid was used, and hence for the preparation of 3-*nitrodiphenylamine*-6′-*arsinic acid* (VIII) and of 4-*nitrodiphenylamine*-

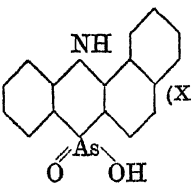
6′-*arsinic acid* (IX), *o*-aminophenylarsinic acid was condensed with the corresponding bromonitrobenzene.

(VIII.)   (IX.)

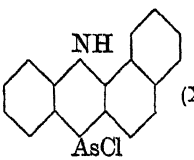
These results would indicate that the ease with which the reaction proceeds depends on the reactivity of the bromine atom, being slight in bromobenzene, greatest in *o*-bromonitrobenzene, and intermediate in the case of *o*-bromophenylarsinic acid.



With the exception of *N*-methyldiphenylamine-*o*-arsinic acid (IV), all the above acids can be converted into the corresponding heterocyclic arsenic compounds. Diphenylamine-*o*-arsinic acid (I), when boiled with concentrated hydrochloric acid, is converted rapidly first into an oil and then into the previously described hydrochloride of phenarsazinic acid (J., 1924, **125**, 2277). The same acid, when reduced by the alcohol–iodine–hydrochloric acid–sulphur dioxide method, is rapidly converted into 10-chloro-5 : 10-dihydrophenarsazine, which again can be oxidised to phenarsazinic acid. Incidentally, 10-chloro-5 : 10-dihydrophenarsazine has thus again been synthesised by a simpler method and its constitution further verified (compare Burton and Gibson, J., 1926, 452). These reactions may be briefly summarised :



When 4-methyldiphenylamine-6′-arsinic acid (II) was boiled with concentrated hydrochloric acid, similar effects were observed and the already described hydrochloride of 2-methylphenarsazinic acid (J., 1926, 469) was readily obtained. Also, by reduction with sulphur dioxide under the usual conditions, 10-chloro-2-methyl-5 : 10-dihydrophenarsazine was produced, which again was easily oxidised to the heterocyclic arsinic acid. Ring closure also took place on boiling the acid (II) with acetic anhydride. The synthesis of 10-chloro-2-methyl-5 : 10-dihydrophenarsazine has thus been effected and, incidentally, the *hydrobromide* of 2-methylphenarsazinic

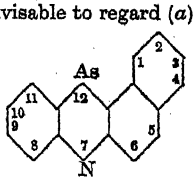


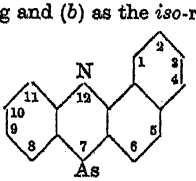
acid was prepared from the acid (II) by using hydrobromic acid instead of hydrochloric acid, and 10-*bromo*-2-*methyl*-5 : 10-*dihydrophenarsazine* was obtained from the acid (II) or from the corresponding phenarsazinic acid in the usual way.

Although the corresponding ring closure by means of hydrochloric acid took an appreciably longer time, 2-methyldiphenylamine-6′-arsinic acid (III) was converted into 4-*methylphenarsazinic acid hydrochloride* and 4-*methylphenarsazinic acid*. From both 2-methyldiphenylamine-6′-arsinic acid and 4-methylphenarsazinic acid, 10-*chloro*-4-*methyl*-5 : 10-*dihydrophenarsazine* (X) and also the corresponding *bromo*-compound have been prepared for the first time, since phenyl-*o*-tolylamine was not available when the condensation of arsenious chloride with various diphenylamines was being investigated.

(X.) 

(XI.)



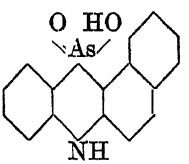


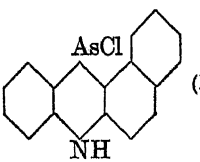
(XII.)

The formation of heterocyclic arsenic compounds from 2-α-naphthylaminophenylarsinic acid (V) can be accomplished very easily.

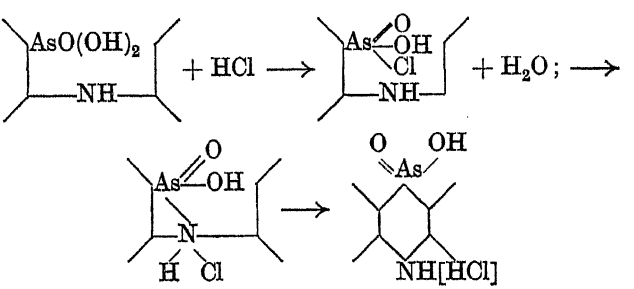
7 : 12-iso*Benzophenarsazinic acid* (XI) is easily produced by boiling the original acid for two minutes with concentrated hydrochloric acid containing a little alcohol, while the already described 7-chloro-7 : 12-dihydro*iso*benzophenarsazine * (XII) (Lewis and Hamilton, *J. Amer. Chem. Soc.*, 1921, **43**, 2218; Burton and Gibson, J., 1926, 467) is obtained very readily by the usual method of reduction. This synthesis effectively proves the correctness of the constitution assigned to the product of condensation of arsenious chloride and phenyl-α-naphthylamine.

* Previously called 7-chloro-7 : 12-dihydrobenzophenarsazine. It is considered advisable to regard (*a*) as the normal ring and (*b*) as the *iso*-ring, since





(*a*) 



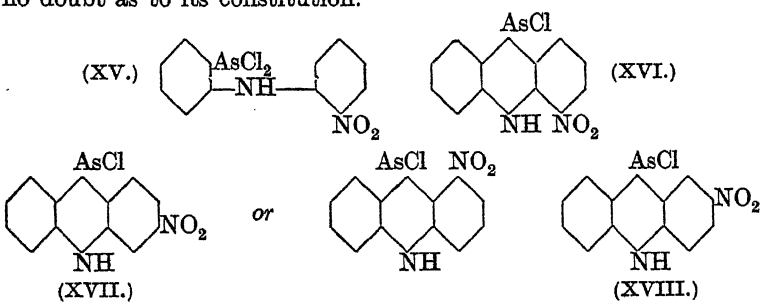
(*b*)

in (*b*) the hetero-atoms have to be numbered inversely to their accepted order on account of the geometry of the ring. This will avoid any confusion in the naming of the parent substances. The parent substance of compound (XII) will be 7 : 12-dihydro*iso*benzophenarsazine and of compound (XIV), 7 : 12-dihydrobenzophenarsazine.

The formation of the corresponding heterocyclic arsenic compounds from 2-β-naphthylaminophenylarsinic acid (VI) was just as readily accomplished. The *hydrochloride* of 7 : 12-*benzophenarsazinic acid* or the free acid (XIII) was readily produced by boiling 2-β-naphthylaminophenylarsinic acid with concentrated hydrochloric acid containing a little alcohol or by boiling it with acetic acid. Further, the previously described 12-chloro-7 : 12-dihydrobenzophenarsazine (XIV) (Burton and Gibson,* J., 1926, 2241) was easily obtained by the usual method of reduction from either 2-β-naphthylaminophenylarsinic acid or from the heterocyclic acid (XIII). On the assumption that the condensation goes in the α-position of the naphthalene nucleus, the constitution assigned previously to the condensation product of arsenious chloride and phenyl-β-naphthylamine is verified by the present work.

(XIII.)   (XIV.)

In several of the above cases when the ring closure was effected by boiling hydrochloric acid, an oily intermediate product possessing a characteristic acid chloride-like odour was formed prior to the formation of the crystalline hydrochloride of the heterocyclic arsinic acid. Although this intermediate product was never isolated, its repeated formation led us to believe that the condensation is preceded by the formation of an acid chloride and we suggest that the following scheme may represent the formation of the hydrochloride of the phenarsazinic acid :



When ring closure was effected by the alcohol–hydrochloric acid–iodine–sulphur dioxide method, in none of the above cases were

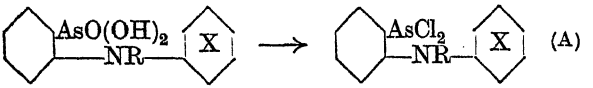
* There is a misprint on p. 2243 (line 4 from bottom) : " 12-chloro-7 : 12-dihydrophenarsazine " should be " 12-chloro-7 : 12-dihydrobenzophenarsazine."

we able to isolate the intermediate dichloroarsine; indeed, in only one case (described below) has this been possible.

When 2-nitrodiphenylamine-6′-arsinic acid (VII) was reduced for 5 minutes with sulphur dioxide in the presence of alcoholic hydrochloric acid and a trace of iodine, an oil was formed which, after solidification and recrystallisation, was obtained as deep red crystals of 2-*nitrodiphenylamine*-6′-*dichloroarsine* (XV), from which the original acid was regenerated by oxidation with hydrogen peroxide in acetic acid solution. When the dichloroarsine was boiled in acetic acid solution for 3 hours, 10-*chloro*-4-*nitro*-5 : 10-*dihydrophenarsazine* (XVI) crystallised in characteristic scarlet needles, m. p. 165°. The method of production of this compound leaves no doubt as to its constitution.

In the reduction of 3-nitrodiphenylamine-6′-arsinic acid (VIII) no intermediate dichloroarsine was obtained. From its method of formation, however, the homogeneous compound must be 10-*chloro*-3(or 1)-*nitro*-5 : 10-*dihydrophenarsazine* (XVII) and it was obtained in deep red, prismatic needles, m. p. 258—259° (decomp.). The corresponding 3(or 1)-*nitrophenarsazinic acid* and the 10-*bromo*-3(or 1)-*nitro*-5 : 10-*dihydrophenarsazine* were also isolated. [Previous work (J., 1926, 2241; compare Roberts and Turner, J., 1925, **127**, 2005) clearly suggests that the nitro-group in these compounds is probably in the 3 position.]

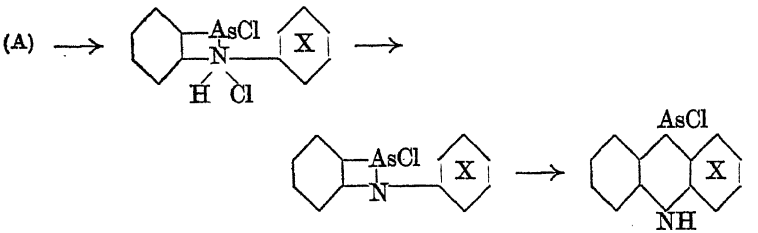
When 4-nitrodiphenylamine-6′-arsinic acid (IX) was reduced under similar conditions, no dichloroarsine was isolated, but there was no difficulty in isolating 10-*chloro*-2-*nitro*-5 : 10-*dihydrophenarsazine* (XVIII), m. p. 278° (decomp.), and the method of preparation leaves no doubt as to the constitution of this substance.



The synthesis and identification of these three nitro-derivatives have enabled us to clear up certain obscurities in the previous work on compounds of this series. 10-Chloro-4-nitro-5 : 10-dihydrophenarsazine (XVI) has been oxidised to the corresponding acid, and this reduced by ferrous hydroxide to the hydrochloride of 4-aminophenarsazinic acid, identical with the compound prepared

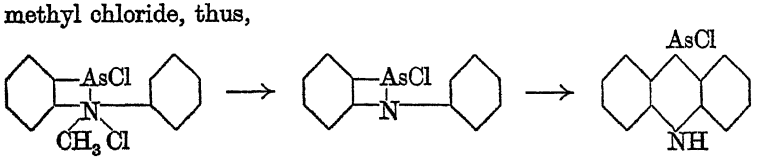
by Wieland and Rheinheimer (*Annalen*, 1921, **423**, 1). Although we expected a triazo-derivative might be formed, this compound is unaffected by nitrous acid at 5°.

Wieland and Rheinheimer obtained two mononitro-derivatives by the nitration of 10-chloro-5 : 10-dihydrophenarsazine. They concluded that the one produced in less quantity (brilliant scarlet needles) had the nitro-group in the ortho-position to the :NH group and although the melting point recorded by them is somewhat low (156°), the description shows that the compound actually was 10-chloro-4-nitro-5 : 10-dihydrophenarsazine (XVI), now synthesised and obtained by us in a pure condition, m. p. 165°. The other mononitro-derivative, Wieland and Rheinheimer rightly concluded was the para-isomeride, *viz.*, 10-chloro-2-nitro-5 : 10-dihydrophenarsazine (XVIII). They described it as crystallising in greenish-yellow scales, but did not record any melting point. On carefully repeating their work, we found that this compound was identical with the synthesised substance (XVIII), m. p. 278° (decomp.). Wieland and Rheinheimer further stated that this compound on oxidation was converted into the nitrophenarsazinic acid (the 2-nitro-acid) which is the by-product of the nitration of phenarsazinic acid, the main product, according to them, being 4-nitrophenarsazinic acid. We have found, however, that the main (*i.e.*, the more easily isolated) product of the nitration of phenarsazinic acid under the conditions described by Wieland and Rheinheimer is the 2-nitro-acid, for on repeating their work we isolated an acid which, on reduction by the sulphur dioxide–alcohol–hydrochloric acid–iodine method, gave 10-chloro-2-nitro-5 : 10-dihydrophenarsazine (XVIII) in a slightly impure form. Moreover, Burton and Gibson's "1-nitrophenarsazinic acid" (*loc. cit.*, p. 2243) is actually the 2-nitro-acid, for it gives the substance (XVIII) on reduction. As a result of the work now described, the conclusions drawn by Burton and Gibson as to the constitution of the corresponding amino-derivatives must be modified accordingly.



In view of the previous failure to prepare 10-chloro-5-methyl-5 : 10-dihydrophenarsazine (Burton and Gibson, J., 1926, 453; compare Wieland and Rheinheimer, *loc. cit.*), it is interesting to know that normal ring closure does not take place when *N*-methyldiphenylamine-*o*-arsinic acid (IV) is submitted to any of the treatments mentioned above for this purpose. Indeed, the only product which we have isolated by the alcohol–hydrochloric acid–iodine–sulphur dioxide reduction method was somewhat impure 10-chloro-5 : 10-dihydrophenarsazine in small quantity (compare Burton and Gibson, *loc. cit.*). Whilst we have again been unsuccessful in preparing 10-chloro-5-methyl-5 : 10-dihydrophenarsazine, the results

of the work indicate that ring closure effected by reduction by the sulphur dioxide method probably follows the course



(A)

Where R = H and X(*o*- or *p*-) = H or Me,

If X = NO_2 and R = H, the nitrogen atom will be less basic and arsenic–nitrogen ring closure will tend to take place with less ease, especially in the case of the 2-nitro-compound (VII). In this case we have actually isolated the dichloroarsine and it is possible that steric hindrance here plays some part (compare Roberts and Turner, *loc. cit.*). If R = Me and X = H, there will be less tendency for arsenic–nitrogen ring closure to take place. The small amount of the product of such ring closure will not be stable and should lose methyl chloride, thus,

with the formation of a small quantity of 10-chloro-5:10-dihydrophenarsazine, as found experimentally.

EXPERIMENTAL.

The method previously described for the preparation of *o*-bromophenylarsinic acid (J., 1926, 456) has been considerably modified, whereby a higher yield (56%) is obtained and economy in hydrobromic acid effected. *o*-Aminophenylarsinic acid (150 g.), dissolved in concentrated hydrochloric acid (210 c.c.) and water (210 c.c.), was diazotised below 5° with sodium nitrite (50 g.; water, 110 c.c.). Cuprous bromide (copper sulphate crystals, 150 g., in water, 500 c.c.; potassium bromide, 75 g., in water, 175 c.c.; the solution was reduced with sulphur dioxide, and the precipitate filtered off and washed with water) was dissolved in hydrobromic acid (of constant b. p.; 270 c.c.) and to this solution at the ordinary tem-

perature the diazo-solution was added with constant stirring. After stirring for 1 hour, the precipitated acid was dissolved in sodium hydroxide solution, and the solution was decolorised with charcoal and acidified with hydrochloric acid (Congo-red). The colourless crystals had m. p. 199—200° (decomp.).

o-Bromonitrobenzene may be obtained in 86% yield by the following modification of Ullmann's method (*Ber.*, 1896, **29**, 1880). *o*-Nitroaniline (138 g.), dissolved in concentrated hydrochloric acid (215 c.c.) and water (128 c.c.), was diazotised below 10° with sodium nitrite (75 g. in water, 150 c.c.). A solution of cuprous bromide in hydrobromic acid (of constant b. p.; 320 c.c.) was prepared from copper sulphate crystals (193 g. in water, 640 c.c.) and potassium bromide (96·5 g. in water, 210 c.c.) as described above, and the diazo-solution added to it at the ordinary temperature with constant stirring. The *o*-bromonitrobenzene, m. p. 43—44°, was isolated by steam distillation.

Diphenylamine-o-arsinic Acid, $C_6H_5{\cdot}NH{\cdot}C_6H_4{\cdot}AsO(OH)_2$ (I).—(*a*) A mixture of aniline (4·7 g.), *o*-bromophenylarsinic acid (14 g.), dry potassium carbonate (9·3 g.), amyl alcohol (38 c.c.), and a trace of copper powder was boiled for 5 hours. The volatile substances were removed by steam distillation and the residue was decolorised with charcoal. The filtrate on acidification with hydrochloric acid deposited a dark-coloured solid (7·1 g.), which was recrystallised from glacial acetic acid and then from dilute acetic acid.

(*b*) A mixture of bromobenzene (6·0 g.), *o*-aminophenylarsinic acid (6·75 g.), dry potassium carbonate (6·0 g.), amyl alcohol (35 c.c.), and a trace of copper powder was treated in a similar manner. Only 0·4 g. of product was obtained.

Diphenylamine-o-arsinic acid forms colourless, felted needles, m. p. 166° (slight decomp.). It cannot be titrated with 0·1*N*-sodium hydroxide and phenolphthalein, the end-point varying with the concentration; but its basicity is greater than unity (Found: As, 25·5. $C_{12}H_{12}O_3NAs$ requires As, 25·6%).

Conversion of Diphenylamine-o-arsinic Acid into Phenarsazinic Acid and 10-Chloro-5 : 10-dihydrophenarsazine.—(*a*) Diphenylamine-*o*-arsinic acid (1 g., either crude or pure) was boiled with concentrated hydrochloric acid (7 c.c.). An oil having a characteristic odour was first formed, but it rapidly disappeared and after 2 minutes' boiling the liquid became filled with crystals of phenarsazinic acid hydrochloride identical with an authentic specimen, m. p. 203—205° (decomp.). This hydrochloride dissolved in an excess of aqueous sodium hydroxide, from which solution phenarsazinic acid was precipitated on addition of acetic acid. The phenarsazinic acid was dissolved in hot alcohol–hydrochloric acid

and reduced with sulphur dioxide after addition of a trace of iodine. 10-Chloro-5:10-dihydrophenarsazine, m. p. 191°, identical with an authentic specimen, was obtained (Found: Cl, 12·9. Calc.: Cl, 12·8%).

(*b*) Diphenylamine-*o*-arsinic acid (1 g., either crude or pure), dissolved in a hot mixture of alcohol (5 c.c.) and concentrated hydrochloric acid (5 c.c.), deposited 10-chloro-5:10-dihydrophenarsazine, m. p. 191° (after recrystallisation from benzene), on reduction with sulphur dioxide after addition of a trace of iodine. The chloro-compound, on oxidation with chloramine-T in aqueous acetone (Burton and Gibson, J., 1924, **125**, 2276), was converted into phenarsazinic acid.

4-*Methyldiphenylamine*-6′-*arsinic Acid*,

$$C_6H_4Me{\cdot}NH{\cdot}C_6H_4{\cdot}AsO(OH)_2 \quad (II).$$

—(*a*) The product obtained from *p*-toluidine (4·9 g.) and *o*-bromophenylarsinic acid (12·9 g.), worked up as described above, amounted to 10 g. (*b*) The amount obtained from *p*-bromotoluene (8·6 g.) and *o*-aminophenylarsinic acid (10·9 g.) was only 1·0 g. Pure 4-*methyldiphenylamine*-6′-*arsinic acid*, m. p. 160—165° (decomp.), was obtained as a cream-coloured solid by recrystallising the product from dilute acetic acid (Found: As, 24·1. $C_{13}H_{14}O_3NAs$ requires As, 24·4%). It is soluble in hot alcohol or hot glacial acetic acid and only slightly soluble in water.

4-Methyldiphenylamine-6′-arsinic acid (10 g. of crude acid) was boiled with concentrated hydrochloric acid (40 c.c.). An oil was formed and the mixture vigorously stirred during the heating. After about 2 minutes the solution became homogeneous and then suddenly filled with crystals (8·5 g.) of 2-methylphenarsazinic acid hydrochloride, m. p. 200—204° (decomp.), which was identical with an authentic specimen (J., 1926, 469). On treatment with sodium hydroxide, the sodium salt, which is sparingly soluble in cold water, was obtained, and from this 2-methylphenarsazinic acid, m. p. 306° (decomp.), was isolated by acidification with glacial acetic acid. This was identical with a specimen made by oxidising the condensation product of arsenious chloride and phenyl-*p*-tolylamine. The hydrochloride, m. p. 208° (decomp.), was readily re-formed on dissolving the acid in a hot mixture of equal volumes of alcohol and concentrated hydrochloric acid and allowing the solution to cool (Found: Cl, 11·2. Calc.: Cl, 10·9%).

A boiling solution of 4-methyldiphenylamine-6′-arsinic acid (1 g.) in alcohol (7 c.c.) and concentrated hydrochloric acid (7 c.c.) containing a trace of iodine was treated with sulphur dioxide; reduction was complete after 5 minutes. The product, recrystallised from benzene, gave 10-chloro-2-methyl-5:10-dihydrophenarsazine

in orange-yellow needles, m. p. 199—200°, which did not depress the melting point of an authentic specimen (Found: Cl, 12·2. Calc.: Cl, 12·2%). On oxidation with chloramine-T in aqueous acetone, it was converted into the colourless 2-methylphenarsazinic acid, m. p. 306—308° (decomp.), identical with an authentic specimen.

4-Methyldiphenylamine-6′-arsinic acid (3 g.) was boiled with acetic anhydride (15 c.c.) for 2 hours. The solution remaining after half of the anhydride had been distilled off was deep blue and deposited 0·6 g. of colourless, crystalline material. This was washed with alcohol and had m. p. 308° (decomp.). On reduction with sulphur dioxide under the usual conditions, it was converted into 10-chloro-2-methyl-5 : 10-dihydrophenarsazine. 2-Methylphenarsazinic acid under the same conditions was not acetylated.

2-*Methylphenarsazinic acid hydrobromide*,

$$NH\langle\begin{matrix}C_6H_3Me\\C_6H_4\end{matrix}\rangle AsO(OH),HBr,$$

was prepared by dissolving 2-methylphenarsazinic acid (1 g.) in a hot mixture of alcohol (5 c.c.) and hydrobromic acid (of constant b. p.; 6 c.c.) and allowing the solution to cool. It crystallised as an almost colourless, granular powder, which turned orange-coloured on heating above 100° and had m. p. 208—210° (decomp.) (Found: Br, 21·3. $C_{13}H_{13}O_2NBrAs$ requires Br, 21·6%). It was also formed by boiling 4-methyldiphenylamine-6′-arsinic acid (1 g.) with hydrobromic acid (of constant b. p.; 8 c.c.) for a few minutes, but the reaction did not take place so smoothly as in the formation of the hydrochloride: the tarry matter formed was removed by washing the precipitate with a mixture of hydrobromic acid and alcohol.

10-*Bromo*-2-*methyl*-5 : 10-*dihydrophenarsazine*,

$$NH\langle\begin{matrix}C_6H_3Me\\C_6H_4\end{matrix}\rangle AsBr,$$

was prepared by dissolving 2-methylphenarsazinic acid or 4-methyldiphenylamine-6′-arsinic acid (1 g.) in a hot mixture of alcohol (5 c.c.) and hydrobromic acid (of constant b. p.; 5 c.c.) and reducing the product in the usual way; it crystallised from benzene in rosettes of hard, orange-red needles, m. p. 180° (decomp.) (Found: Br, 23·9. $C_{13}H_{11}NBrAs$ requires Br, 23·8%).

2-*Methyldiphenylamine*-6′-*arsinic Acid*,

$$C_6H_4Me\cdot NH\cdot C_6H_4\cdot AsO(OH)_2 \text{ (III)}.$$

—*o*-Toluidine (15 g.), *o*-bromophenylarsinic acid (39 g.), dry potassium carbonate (30 g.), amyl alcohol (120 c.c.), and a trace of copper powder were boiled for 7 hours and worked up as before. On acidifying the solution of the potassium salt, 2-methyldiphenyl-

amine-6′-arsinic acid (10 g.) was obtained as a light cream-coloured solid. It was difficult to purify, but from dilute acetic acid it was obtained as a slightly discoloured solid of indefinite melting point (130—140°) (Found: As, 24·2. $C_{13}H_{14}O_3NAs$ requires As, 24·4%).

4-*Methylphenarsazinic acid hydrochloride* was formed on boiling the preceding compound (crude) with concentrated hydrochloric acid as described for the isomeride, but the time elapsing before the separation of the hydrochloride was almost twice as long. The crude salt had m. p. 187—189° (decomp.). 4-*Methylphenarsazinic acid* was formed from the crude hydrochloride by treatment with an excess of sodium hydroxide solution and then acidification with acetic acid. The precipitated acid was recrystallised from dilute acetic acid and then had m. p. 309—310° (decomp.) (Found: As, 25·7. $C_{13}H_{12}O_2NAs$ requires As, 25·9%). This acid tends to form an unstable acetate, since, when it was recrystallised from glacial acetic acid and air-dried for 2 days, it still retained 5·61% of acetic acid (Calc. for 1 mol. of $C_2H_4O_2$, 17·2%). 4-Methylphenarsazinic acid resembles the 2-isomeride in most of its properties: the sodium salt is not very soluble in cold water and it is readily converted into the *hydrochloride*, colourless needles, m. p. 199° (decomp.), by the usual method (Found: Cl, 10·9. $C_{13}H_{13}O_2NClAs$ requires Cl, 10·9%).

10-*Chloro*-4-*methyl*-5:10-*dihydrophenarsazine* (X). — 4-Methylphenarsazinic acid or crude 2-methyldiphenylamine-6′-arsinic acid was reduced as described for the 2-isomeride. Recrystallised from benzene, the product formed yellow needles (occasionally greenish-yellow), m. p. 191° (decomp.). The yield was almost quantitative (Found: Cl, 12·3. $C_{13}H_{11}NClAs$ requires Cl, 12·2%).

10-*Bromo*-4-*methyl*-5:10-*dihydrophenarsazine* was prepared in an analogous manner from 4-methylphenarsazinic acid. It was recrystallised from benzene and obtained in light yellow needles, m. p. 190° (slight decomp.) (Found: Br, 24·0. $C_{13}H_{11}NBrAs$ requires Br, 23·8%). Both these compounds were converted into 4-methylphenarsazinic acid on oxidation with chloramine-T in aqueous acetone.

N-*Methyldiphenylamine*-o-*arsinic Acid* (IV).—Monomethylaniline* (15 g.), *o*-bromophenylarsinic acid (39 g.), dry potassium carbonate (30 g.), amyl alcohol (120 c.c.), and a trace of copper powder were boiled for 5 hours. The product was worked up in the usual manner, and the N-*methyldiphenylamine*-o-*arsinic acid* (12 g.) obtained as a colourless, crystalline solid, m. p. 182—184°

* Purified through its *p*-toluenesulphonyl derivative. It had b. p. 196°/764 mm., and gave quantitative yields of its acetyl and *p*-toluenesulphonyl derivatives (m. p.'s 101° and 94°, respectively).

(decomp.) after recrystallisation from dilute acetic acid. It was difficult to purify (Found: As, 24·2. $C_{13}H_{14}O_3NAs$ requires As, 24·4%). Boiling with concentrated hydrochloric acid for 5 minutes caused no separation of crystalline matter, but some decomposition took place and the characteristic odour, which we attribute to the intermediate formation of an acid chloride, was observed. On cooling, treatment with sodium hydroxide, and acidification with acetic acid, only an impure acid was precipitated. When hydrobromic acid was used instead of hydrochloric acid, marked decomposition took place.

N-Methyldiphenylamine-*o*-arsinic acid (8 g.) was reduced in hot alcoholic-concentrated hydrochloric acid solution in the manner already described, but the product of the reduction was a heavy, dark-coloured oil. A small amount of yellowish-brown solid separated from the oily matter on cooling. This was recrystallised from benzene and melted at 175—177°. The melting point was raised (187—188°) by admixture with pure 10-chloro-5 : 10-dihydrophenarsazine, but the quantity obtained was too small for further purification and attempts to work up the oil were unavailing. 10-Chloro-5-methyl-5 : 10-dihydrophenarsazine therefore cannot be prepared by this method and it was also found impossible to prepare the corresponding bromo-compound.

2-α-*Naphthylaminophenylarsinic Acid* (V).—On mixing α-naphthylamine (16·0 g.), *o*-bromophenylarsinic acid (28·2 g.), dry potassium carbonate (19·0 g.), amyl alcohol (80 c.c.), and a trace of copper powder an almost solid mass was produced. The mixture was boiled for 6½ hours and the product isolated (28 g., crude) in the usual way. The acid recrystallised from dilute acetic acid had m. p. 165° (Found: As, 21·6. $C_{16}H_{14}O_3NAs$ requires As, 21·9%).

2-α-Naphthylaminophenylarsinic acid (10 g.) was dissolved as rapidly as possible in a hot mixture of alcohol (50 c.c.) and concentrated hydrochloric acid (50 c.c.) and reduced with sulphur dioxide after addition of a trace of iodine. The precipitated 7-*chloro*-7 : 12-*dihydroisobenzophenarsazine* (XII) was filtered off from the cold liquid and recrystallised from toluene. The short, yellow needles, m. p. 219°, were identical with an authentic specimen (Found: Cl, 10·7. $C_{16}H_{11}NClAs$ requires Cl, 10·8%).

7 : 12-iso*Benzophenarsazinic Acid Hydrochloride*.—2-α-Naphthylaminophenylarsinic acid (3·5 g.) was dissolved in a mixture of alcohol (15 c.c.) and concentrated hydrochloric acid (15 c.c.), and the mixture rapidly heated on the water-bath. After 2 minutes and while the solution was still hot, small, colourless plates of the *hydrochloride* of 7 : 12-*iso*benzophenarsazinic acid began to separate. It has m. p. 232° (decomp.) (Found: Cl, 10·0. $C_{16}H_{13}O_2NClAs$

requires Cl, 9·8%). This, on treatment with warm dilute sodium hydroxide solution followed by acidification with acetic acid, was converted into colourless 7:12-*iso*benzophenarsazinic acid (XI), which was recrystallised from dilute acetic acid (Found: As, 22·9. Calc.: As, 23·1%). The sodium salt had the properties described by Lewis and Hamilton (*J. Amer. Chem. Soc.*, 1921, **43**, 2218).

2-β-*Naphthylaminophenylarsinic Acid* (VI).—β-Naphthylamine was condensed with *o*-bromophenylarsinic acid, the quantities taken and the conditions of the reaction being the same as in the preparation of the isomeric substance. The crude acid (31 g.) was deposited in colourless needles, m. p. 181°, after the solution in hot alcohol had been decolorised with charcoal (Found: As, 21·6. $C_{16}H_{14}O_3NAs$ requires As, 21·9%). 12-Chloro-7:12-dihydrobenzophenarsazine (XIV) was prepared from this compound (10 g.) by the method used for the preparation of the isomeride. It was recrystallised from *s*-tetrachloroethane and obtained in yellow leaflets, m. p. 254°, identical in every respect with the compound formed by the condensation of arsenious chloride with phenyl-β-naphthylamine. Yield, 7 g. (Found: Cl, 10·85. Calc.: Cl, 10·8%).

7:12-*Benzophenarsazinic Acid* (XIII).—When a solution of the preceding compound (25 g.) in hot glacial acetic acid (200 c.c.) was rapidly cooled and treated with hydrogen peroxide (20 vols.; 130 c.c.) and then heated almost to boiling to complete the oxidation, 7:12-benzophenarsazinic acid was precipitated as a brown, amorphous solid. It was recrystallised from dilute acetic acid after decoloration with charcoal and obtained in small, colourless needles, m. p. above 325°. Yield, 18 g. (Found: As, 22·8. $C_{16}H_{12}O_2NAs$ requires As, 23·1%). The same acid was produced when a solution of 12-chloro-7:12-dihydrobenzophenarsazine was oxidised with an aqueous solution of chloramine-T. It was also obtained when a solution of 2-β-naphthylaminophenylarsinic acid in the minimum quantity of boiling glacial acetic acid was heated on the water-bath for 30 minutes. The acid crystallised on cooling and the filtrate contained a small quantity of unchanged 2-β-naphthylaminophenylarsinic acid.

7:12-*Benzophenarsazinic acid hydrochloride* was obtained by dissolving 2-β-naphthylaminophenylarsinic acid (0·3 g.) in a hot mixture of alcohol (5 c.c.) and concentrated hydrochloric acid (5 c.c.). After a few minutes the compound, m. p. 234° (decomp.), separated in fine needles (Found: Cl, 10·0. $C_{16}H_{13}O_2NClAs$ requires Cl, 9·8%). It was converted into 7:12-benzophenarsazinic acid in the usual way. The sodium salt (colourless needles) of 7:12-benzophenarsazinic acid is not very soluble in cold water;

the ammonium salt crystallises in glistening plates from water; the barium, silver, and mercuric salts are produced as heavy, white precipitates; the ferric salt is brown and somewhat gelatinous; the copper salt is pale greenish-blue; the cobalt salt is pale blue, and the calcium salt forms fine, colourless needles.

12-*Bromo*-7 : 12-*dihydrobenzophenarsazine* was prepared by reducing 7 : 12-benzophenarsazinic acid in alcohol–hydrobromic acid solution in the usual way. It forms short, deep orange-coloured needles, m. p. 251—252° (decomp.), from toluene (Found : Br, 21·7. $C_{16}H_{11}NBrAs$ requires Br, 21·5%).

2-*Nitrodiphenylamine*-6′-*arsinic Acid* (VII). — A mixture of *o*-aminophenylarsinic acid (47·2 g.), *o*-bromonitrobenzene (49·0 g.), dry potassium carbonate (42 g.), amyl alcohol (245 c.c.), and a trace of copper powder was boiled for 6 hours. The product was worked up as usual, washed with dilute hydrochloric acid and water to remove unchanged *o*-aminophenylarsinic acid, and recrystallised from aqueous alcohol, forming golden-yellow needles, m. p. 238—240° (decomp.). Yield of pure acid, 25% (Found : N, 7·95. $C_{12}H_{11}O_5N_2As$ requires N, 8·3%). *o*-Bromophenylarsinic acid and *o*-nitroaniline, condensed in a similar manner, gave a 7·7% yield of the same product.

The acid is slightly soluble in water and is soluble in alcoholic hydrochloric acid, but a hydrochloride could not be isolated. Solutions of the sodium and potassium salts are deep red in contrast to that of the acid, which is deep yellow.

2-*Nitrodiphenylamine*-6′-*dichloroarsine* (XV).—The preceding compound (3·1 g.) was dissolved in a hot mixture of alcohol (20 c.c.) and concentrated hydrochloric acid (25 c.c.), and sulphur dioxide passed into the solution for 5 minutes only, after addition of a trace of iodine. The oil which separated quickly solidified on cooling. The solid crystallised from benzene–light petroleum (b. p. 60—80°) in deep red crystals, m. p. 110° (Found : Cl, 19·95. $C_{12}H_9O_2N_2Cl_2As$ requires Cl, 19·8%). On oxidation with hydrogen peroxide (20 vol.) in acetic acid solution, the above 2-nitrodiphenylamine-6′-arsinic acid was obtained.

10-*Chloro*-4-*nitro*-5 : 10-*dihydrophenarsazine* (XVI).—After a solution of 2-nitrodiphenylamine-6′-dichloroarsine (1·5 g.) in glacial acetic acid (25 c.c.) had been boiled for 3 hours, beautiful scarlet needles of 10-chloro-4-nitro-5 : 10-dihydrophenarsazine were deposited on cooling. It was recrystallised from glacial acetic acid and then had m. p. 165° (Wieland and Rheinheimer, *loc. cit.*, give m. p. 156°) (Found : Cl, 10·8. Calc. : Cl, 11·0%).

This compound was oxidised by hydrogen peroxide (20 vol.) in glacial acetic acid solution, whereby it was converted into 4-nitro-

phenarsazinic acid. This acid was reduced by ferrous hydroxide (Burton and Gibson, *loc. cit.*) and converted into the 4-aminophenarsazinic acid, which was conveniently isolated as the hydrochloride. The hydrochloride, suspended in excess of dilute hydrochloric acid, was unaffected by sodium nitrite at 5°.

3-*Nitrodiphenylamine*-6'-*arsinic acid* (VIII) was prepared from *o*-aminophenylarsinic acid (20·9 g.) and *m*-bromonitrobenzene (21·7 g.) in a similar manner to the isomeride, the boiling, however, being continued for 7 hours. The product (16 g.) crystallised from dilute acetic acid in light yellow needles, m. p. 202° (decomp.) (Found: As, 21·7. $C_{12}H_{11}O_5N_2As$ requires As, 22·2%). The solutions of the sodium and potassium salts are deep red.

10-*Chloro*-3(or 1)-*nitro*-5:10-*dihydrophenarsazine* (XVII).—The compound just described (20 g.) was reduced in the usual manner for 15 minutes by sulphur dioxide; a deep red, crystalline substance soon filled the liquid. The product was fractionally crystallised from glacial acetic acid and only one substance, which formed glistening, thin prisms, m. p. 258—259° (decomp.), was obtained (Found: As, 22·8; Cl, 11·2. $C_{12}H_8O_2N_2ClAs$ requires As, 23·2; Cl, 11·0%).

3(or 1)-*Nitrophenarsazinic Acid*.—The preceding compound (4 g.) was boiled with glacial acetic acid (60 c.c.) and rapidly cooled, and to the solution-suspension hydrogen peroxide (20 vol.; 40 c.c.) was added. The colour of the solution rapidly changed and a yellowish-brown acid was precipitated; the reaction was completed by gentle warming. The product was recrystallised from dilute acetic acid. The yellow substance did not melt below 320° (Found: N, 8·8; As, 23·0. $C_{12}H_9O_4N_2As$ requires N, 8·7; As, 23·4%). It was insoluble in water and most organic solvents, but dissolved in aqueous sodium hydroxide, and from a strong solution of the latter the sodium salt (brown) crystallised.

10-*Bromo*-3(or 1)-*nitro*-5:10-*dihydrophenarsazine* was prepared by reducing 3(or 1)-nitrophenarsazinic acid in the presence of hydrobromic acid in the usual way. When recrystallised from benzene, it was obtained in short, reddish-brown needles, m. p. 234° (decomp.) (Found: Br, 22·15. $C_{12}H_8O_2N_2BrAs$ requires Br, 21·8%).

4-*Nitrodiphenylamine*-6'-*arsinic acid* (IX) was prepared from *p*-bromonitrobenzene (52·2 g.) and *o*-aminophenylarsinic acid (50·3 g.) in a similar manner to the isomeric compounds, the boiling, however, being continued in this case for 7½ hours. The crude product (35 g.) was recrystallised from dilute acetic acid, and the pure acid obtained as a pale yellow, microcrystalline substance, m. p. 223° (decomp.) (Found: N, 8·3. $C_{12}H_{11}O_5N_2As$ requires N, 8·3%). The alkali salts are deep orange-red in aqueous solution.

10-*Chloro*-2-*nitro*-5 : 10-*dihydrophenarsazine* (XVIII) was prepared from the preceding compound (8 g.) by reduction in the presence of hydrochloric acid in the usual way. The product (6·1 g.) was recrystallised from glacial acetic acid, in which it was somewhat sparingly soluble. It seems to be dimorphous, for it separated first in soft, yellow needles which, on standing or when the solution was stirred, changed into compact, small, orange-yellow, prismatic needles. On heating, the substance turned dark red at about 194—197° and had m. p. 276—278° (decomp.) (Found : Cl, 10·8; As, 22·95. $C_{12}H_8O_2N_2ClAs$ requires Cl, 11·0; As, 23·2%).

Phenarsazinic acid (20 g.) was nitrated under the conditions described by Burton and Gibson (J., 1926, 2244), and the nitro-acid purified as described through the sodium and barium salts. This acid, on reduction in the usual way in the presence of hydrochloric acid, gave a chloro-compound which was identical in every way with the above compound. It was obtained in soft, yellow needles which were converted into the compact, orange-yellow prisms; on heating, the behaviour was the same as that already described (Found : As, 23·05. Calc. : As, 23·2%). It must have been formed from 2-nitrophenarsazinic acid.

Phenarsazinic acid (10 g.) was nitrated as far as possible under the conditions described by Wieland and Rheinheimer (*loc. cit.*). The mixture was kept for 1½ hours after the addition of the nitric acid (*d* 1·5) was completed. The nitro-acid obtained from the sodium salt was recrystallised twice from 50% acetic acid and was then dark yellow to orange. It was reduced in the presence of hydrochloric acid in the usual way, and the product had a very indefinite melting point, melting and decomposition not being complete at 250°. After this had been further recrystallised from glacial acetic acid, it melted at 265—267° (decomp.), and although even then it was not quite pure, its behaviour when admixed with pure 10-chloro-2-nitro-5 : 10-dihydrophenarsazine showed that it was chiefly composed of this substance.

We are therefore justified in concluding that the most easily isolated product of the nitration of phenarsazinic acid is 2-nitrophenarsazinic acid, and not 4-nitrophenarsazinic acid as stated by Wieland and Rheinheimer.

10-Chloro-5 : 10-dihydrophenarsazine was also nitrated under the conditions described by Wieland and Rheinheimer. The mononitro-derivative obtained in the larger amount (for which they quoted no melting point) was oxidised by means of hydrogen peroxide (20 vol.) in glacial acetic acid solution. The product was recrystallised from glacial acetic acid and then reduced in the presence of hydrochloric acid in the usual way, being thus con-

verted into 10-chloro-2-nitro-5 : 10-dihydrophenarsazine, m. p. 276° (decomp.), identical with the product described above.

The various nitro-derivatives of 10-chloro-5 : 10-dihydrophenarsazine can be readily distinguished from 2-nitrodiphenylamine-6′-arsinic acid, since the latter dissolves in concentrated sulphuric acid to form a characteristic deep red solution, whilst the former compounds yield deep violet solutions. All the solutions change to an olive-green colour on addition of a drop of concentrated nitric acid.

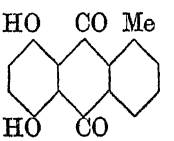
[*Received, August 26th*, 1927.]

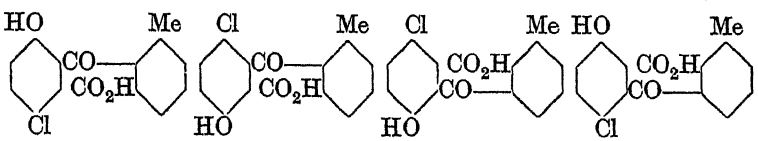


CCCXXXVI.—*A New Isomerism of Halogenohydroxybenzoyltoluic Acids.*

By MOSUKE HAYASHI.

THE roots of *Lithospermum Erythrorhizon*, commonly known as Shikon, were used in ancient Japan as an important violet dye. A few years ago the main constituent of this colouring matter was isolated by Majima and Kuroda (*Acta Phytochim.*, 1922, **1**, 43) and found to be a monoacetyl compound of a hydroxynaphthaquinone derivative. This derivative, which has been termed *shikonin* from the Japanese name of the plant, melts at 147° and has the molecular formula $C_{16}H_{16}O_5$; its constitutional formula, representing it as 2 : 5 : 8-trihydroxy-3-δ-methyl-Δ$^{\gamma}$-pentenyl-1 : 4-naphthaquinone (I), was deduced from the results of careful investigations.

(I.)



(II.)

One of the most characteristic properties of shikonin is the formation of a red sublimate on heating; this decomposition product, termed *shikizarin*, m. p. 232°, has the molecular formula $C_{15}H_{10}O_4$. Whereas shikonin itself, as a naphthaquinone derivative, is relatively unstable, shikizarin is stable enough to be regarded as an anthraquinone derivative; it gives 3-methylphthalic anhydride on oxidation with potassium permanganate. From these results, shikizarin (II) seems to be 8-methylquinizarin, formed by the extrusion of a molecule of hydrogen and of the elements of methyl alcohol from shikonin.

To decide the constitution of shikizarin, 8-methylquinizarin was synthesised by Majima by condensing 3-methylphthalic anhydride with quinol dimethyl ether and heating the dihydroxybenzoyltoluic acid thus formed with concentrated sulphuric acid.* It was identical with shikizarin, and strong support was thus obtained for the constitution of shikonin. The yield of the dihydroxybenzoyltoluic acid was, however, very poor, so the synthesis was attempted in another way by Sakurai in the same laboratory, but without much improvement in the result.* Yet another synthesis was carried out by the present author by condensing 3-methylphthalic anhydride with *p*-chloroanisole in acetylene tetrachloride solution in the presence of aluminium chloride (compare Ullmann and Schmidt, *Ber.*, 1919, **52**, 2098). Thereby chlorohydroxybenzoyltoluic acid was obtained in good yield, the methoxyl group being hydrolysed at the same time. 8-Methylquinizarin was then produced by treating this intermediate substance with concentrated sulphuric acid and heating the chlorohydroxymethylanthraquinone thus formed with a solution of boric acid in sulphuric acid. The yield was about 50% of the chlorohydroxymethylanthraquinone.

The stage of the reaction resulting in the formation of chlorohydroxymethylanthraquinone was, however, not at all simple and the action of concentrated sulphuric acid on the chlorohydroxybenzoyltoluic acid gave rise, in addition to chlorohydroxymethylanthraquinone, to an interesting isomeric change, which has been studied in some detail. The above-mentioned chlorohydroxybenzoyltoluic acid, m. p. 238—239°, may have one of the formulæ III, IV, V, and VI. Many authors (Nourrisson, *Ber.*, 1886, **19**,

(III.) (IV.) (V.) (VI.)

2103; Logodzinski, *Ber.*, 1895, **28**, 116; *Annalen*, 1905, **342**, 90; Bistrzycki and Schepper, *Ber.*, 1898, **31**, 2790; Ullmann and Schmidt, *Ber.*, 1919, **52**, 2098; Simonsen and Rau, J., 1921, **119**, 1339; Simonsen, J., 1924, **125**, 721; Eder and his co-workers, *Helv. Chim. Acta*, 1922, **5**, 3; 1923, **6**, 419, 966; 1925, **8**, 126; Bistrzycki and Krauer, *Helv. Chim. Acta*, 1923, **6**, 750; Adams and his collaborators, *J. Amer. Chem. Soc.*, 1923, **45**, 2439, 2455; 1925, **47**, 283; compare also Bentley, Gardner, and Weizmann, J., 1907, **91**, 1626) have shown that phthalic anhydride and its derivatives condense with phenolic ethers in the *p*-position to the alkyloxy-

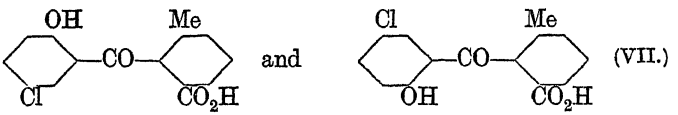
* The details of these experiments have not yet been published.

group, provided that position is open, and with phenols in the *o*-position to the hydroxy-group, and that no condensation in the *m*-position to the alkyloxy- or hydroxy-group can be effected. The constitutional formula of the chlorohydroxybenzoyltoluic acid may therefore be either (III) or (V). As α-substituted phthalic anhydrides usually condense with phenol and its ethers through the carbonyl group adjacent to the substituent (Bistrzycki and Schepper; Simonsen and Rau; Simonsen; Eder and his co-workers; Bistrzycki and Krauer; Adams and his collaborators; *locc. cit.*), it is highly probable that the chlorohydroxybenzoyltoluic acid is 5′-chloro-2′-hydroxy-2-benzoyl-*m*-toluic acid (III).

By the action of concentrated sulphuric acid (98·25%) on the chlorohydroxybenzoyltoluic acid, an anthraquinone derivative, m. p. 223—224°, was obtained, and this should be 5-chloro-8-hydroxy-1-methylanthraquinone.

When 5′-chloro-2′-hydroxy-2-benzoyl-*m*-toluic acid was treated with concentrated sulphuric acid on the steam-bath, the greater part of the product was soluble in aqueous sodium carbonate. Two isomeric substances, differing in solubility, crystalline form, and in the amount of water of crystallisation of their salts, were obtained by fractional crystallisation of the recovered acids from alcohol; one melted at 171—171·5° and the other at 238—239°. The latter was proved to be identical with the initial substance by the mixed melting point method. These two isomerides are designated α- and β-5′-chloro-2′-hydroxy-2-benzoyl-*m*-toluic acid, respectively.

After the isolation of the α- and β-acids from the material soluble in sodium carbonate, the residue (C) melted at about 160—165° and was difficult to purify by further fractional crystallisation.



The α-acid (m. p. 171—171·5°) was treated with concentrated sulphuric acid, and the isolation of the products carried out, as in the case of the β-acid; the anthraquinone derivative, the β-acid, unchanged α-acid, and the residue (C′), from which it was difficult to separate the α- and β-acids by further fractional crystallisation, were then obtained.

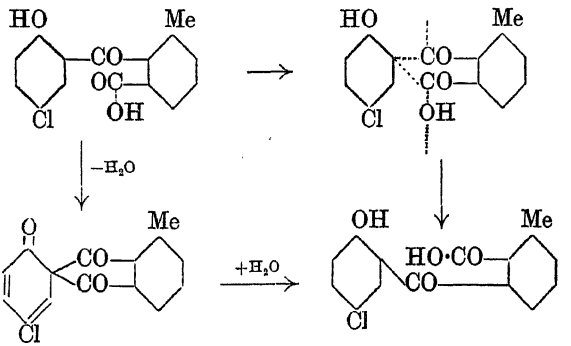
When treated with concentrated sulphuric acid on the steam-bath, the residue C or C′ gave essentially the same results as those obtained from the α- or the β-acid. Therefore the residues C and C′ seem to consist of somewhat impure mixtures of the α- and β-acids, and the percentages of these acids in them can be approximately deduced from a table of melting points of mixtures of the two acids.

On treating the α-acid, the β-acid, the residue C and the residue C′ separately with concentrated sulphuric acid at room temperature, the anthraquinone derivative was not obtained, but in each case

the α- and β-acids could be isolated. Consequently the production of the anthraquinone derivative from the α- or the β-acid is preceded by a reversible change between these acids.

The α- and the β-acid, being so readily interconvertible on treatment with concentrated sulphuric acid, are probably stereoisomeric, and this view is supported by the great similarity of their ultra-violet absorption curves. This theory of the isomerism may be illustrated by the following formulæ :

(VII.)



At present there is no diagnostic reaction which will enable us to apportion these configurations, but since in an equilibrium mixture of the two acids at about 100° the amount of the β-acid is very small and that of the α-acid is great, whilst the yield of the anthraquinone derivative is relatively small, it seems probable that the configuration (VII) is that of the α-acid.

The Kaufler diphenyl configuration (*Annalen*, 1907, **351**, 151; *Ber.*, 1907, **40**, 3250) has been employed by Cain and his collaborators (J., 1914, **105**, 1437, 1442, etc.), by Turner (J., 1915, **107**, 1495), by Kenner and his co-workers (J., 1922, **121**, 614; 1923, **123**, 779, 1043, 1948), by Brady and McHugh (J., 1923, **123**, 2047), by Bullock and Wilson (*J. Amer. Chem. Soc.*, 1923, **45**, 521), and by many other chemists to account for the stereoisomerism of diphenyl derivatives.* Moreover, Kaufler and Basel (*Ber.*, 1907, **40**, 3253) and Kenner (J., 1922, **121**, 614) expected the existence of stereoisomerides of the same kind in derivatives of diphenylmethane and diphenylethane, but so far as the author is aware, their existence has not been reported. In the case of 5′-bromo-2′-hydroxy-2-benzoyl-*m*-toluic acid, the author obtained results similar to those described above in connexion with the chloro-derivatives.

When 5′-chloro-2′-hydroxy-*o*-benzoylbenzoic acid, obtained by condensing phthalic anhydride with *p*-chloroanisole or *p*-chlorophenol, was heated with concentrated sulphuric acid (98·25%) on the steam-bath, 4-chloro-1-hydroxyanthraquinone was easily obtained in 90% yield (compare Ullmann, D.R.-P. 282,493), but interaction over-night at room temperature gave only a 5% yield

* More recent investigations have shown that the conception is not even necessary for the satisfactory explanation of the chemistry of the diphenyl group, and as a result of these developments in the period following the writing of this communication the author feels that the alternative structural explanation of his results requires all the more careful consideration.

of the anthraquinone, 92% of the original substance being recovered. In these experiments, two isomerides of 5′-chloro-2′-hydroxy-*o*-benzoylbenzoic acid, anticipated from the analogy with the above-mentioned benzoyltoluic acids, were not encountered. This circumstance lends some colour to the view that the isomerism of these substituted benzoylbenzoic acids is, after all, structural in accordance with one of the schemes :

Obviously, in this case the shikizarin ultimately obtained would be a homogeneous product, whereas the chlorohydroxymethylanthraquinone might consist of two isomerides. Experience in the anthraquinone group suggests that such a mixture might simulate the behaviour of a pure substance.

The investigation of the analogous isomerism of other derivatives of benzoylbenzoic acid is in progress with the object of deciding between the two possible interpretations of the results.

Experimental.

β-5′-*Chloro*-2′-*hydroxy*-2-*benzoyl*-m-*toluic Acid*.—3-Methylphthalic anhydride (10 g., m. p. 115·5—116·5°) was dissolved in acetylene tetrachloride (50 c.c.), mixed with *p*-chloroanisole (10 g.), and finely powdered aluminium chloride (25 g.) gradually added in the course of 1—1½ hours, with frequent shaking, the temperature being maintained at 115—120° (oil-bath) during the addition and thereafter at 120—130° for 3 hours. The product was cooled, mixed with ice-water and, after the addition of an excess of hydrochloric acid, distilled in steam in order to remove *p*-chloroanisole and acetylene tetrachloride. The solid residue was extracted several times with boiling ammonia solution,* and the ammoniacal extracts

* Chlorohydroxymethylanthraquinone (7% of the theoretical) was isolated from the part insoluble in ammonia, and proved to be identical with the anthraquinone derivative, which was obtained from the α- or β-5′-chloro-2′-hydroxybenzoyltoluic acid, by the method of mixed melting points.

were freed from ammonia and cooled; the resinous substance that separated was removed. On acidification of the filtrate, impure β-5′-chloro-2′-hydroxy-2-benzoyl-*m*-toluic acid, m. p. about 210—220°, separated in 75% yield. The acid was redissolved in caustic alkali or in ammonia and the solution was boiled with animal charcoal, filtered, and acidified with hydrochloric acid; the almost colourless material thus precipitated was washed with water and crystallised from alcohol or glacial acetic acid (Found: C, 61·7; H, 4·0; Cl, 12·4; *M*, in camphor by Rast's method, 285. $C_{15}H_{11}O_4Cl$ requires C, 62·0; H, 3·8; Cl, 12·2%; *M*, 291). This acid melts at 238—239°, and dissolves readily in hot alcohol or glacial acetic acid, but is sparingly soluble in the cold solvents. It is easily soluble in acetone, slightly soluble in benzene, carbon tetrachloride, carbon disulphide or chloroform, and very sparingly soluble in light petroleum or water. The yellow solution in concentrated sulphuric acid develops a deep red colour. The crystalline form: rhombic system, ∝ P (from alcohol). The ultra-violet absorption curve of this acid, determined with a Hilger quartz spectrograph, shows two bands with heads at λ 3350 and 2860 Å.U.

In an experiment similar to that described above but starting from 3-methylphthalic anhydride (10 parts) and *p*-chlorophenol (9 parts), a substance, m. p. 215—225°, was isolated in 70% yield. (Chlorohydroxymethylanthraquinone, 7% of the theoretical quantity, was also isolated from the part insoluble in ammonia.) This was purified and identified as β-5′-chloro-2′-hydroxy-2-benzoyl-*m*-toluic acid, since its m. p. was not depressed on admixture with the β-acid.

The *sodium* and *barium* salts were prepared by neutralising hot alcoholic solutions of the acid with solutions of the corresponding bases, and recrystallised from water by cooling their solutions with ice. The specimens were kept in a balance room until the weight was constant for a few hours [Found for the sodium salt (temperature of the room, 12°; relative humidity, 85%): loss at 105°/10 mm., 25·6; Na, 5·4. $C_{15}H_{10}O_4ClNa,6H_2O$ requires H_2O, 25·7; Na, 5·5%. Found for the barium salt (temperature of the room, 11°; relative humidity, 84%): loss at 105°/10 mm., 16·6; Ba, 15·7. $(C_{15}H_{10}O_4Cl)_2Ba,8H_2O$ requires H_2O, 16·7; Ba, 16·0%]. On standing in the atmosphere, the water of crystallisation was gradually lost, the more quickly the higher the room temperature. The sodium salt is readily soluble and the barium salt moderately easily soluble in water.

α-*5′-Chloro-2′-hydroxy-2-benzoyl*-m-*toluic Acid.*—The β-acid (1 g.) was heated with sulphuric acid (6 c.c.; 98·25%) in a boiling water-bath for about 1 hour. On pouring the product into ice-water, a

dirty green, sticky precipitate separated and after warming for a few minutes this was collected, washed with water by decantation, and stirred with an excess of dilute aqueous sodium carbonate; a yellow substance (20—25% yield), m. p. 220—222°, remained undissolved. This substance was recrystallised several times from glacial acetic acid and proved to be chlorohydroxymethylanthraquinone (see p. 2524). From the yellow filtrate, acidified with hydrochloric acid, a sticky substance was precipitated which crystallised on being warmed for a few minutes or kept at the ordinary temperature for several days. The solid was collected, washed with water, and dried over sulphuric acid in a vacuum desiccator, a faintly yellow, crystalline mass being obtained (yield, 55—75%). It sintered at about 160° and melted to a clear liquid at about 170°. On fractional crystallisation from alcohol, two forms were separated. The residue (C), from which nothing definite could be isolated by further recrystallisation, melted at 160—165° (yield, 10—30% of the β-acid). The less soluble fraction (yield, about 1%), m. p. 220—235°, was recrystallised from alcohol and proved to be identical with the β-acid by the mixed melting point method. The more soluble fraction (yield, 35—50%) melted at 169—171° and was recrystallised several times from aqueous alcohol (Found: C, 61·8; H, 3·8; Cl, by Nomura and Murai's method, 11·9; *M*, in camphor by Rast's method, 287. $C_{15}H_{11}O_4Cl$ requires C, 62·0; H, 3·8; Cl, 12·2%; *M*, 291). The substance is moderately easily soluble in benzene, dissolves to some extent in water, and is readily soluble in alcohol or glacial acetic acid. It dissolves in concentrated sulphuric acid to a deep red solution, a little heat being developed. Like the β-isomeride, it is soluble in dilute aqueous caustic alkali to a yellow solution. Crystalline form: rhombic system, ∞ P, P (from a mixture of alcohol and water). This acid has two absorption bands with heads at λ 3390 and 2860.

α-5′-Chloro-2′-hydroxy-2-benzoyl-*m*-toluic acid was treated with sulphuric acid (98·25%) under the same conditions as in the case of the β-acid, and the separation and identification of the reaction products were carried out as before. In this separation the chlorohydroxymethylanthraquinone and the β-acid, together with the initial substance, were isolated. Nothing definite could be isolated, by further recrystallisation, from the residue (C′).

However, the α- and β-acids and the chlorohydroxymethylanthraquinone were isolated from the residue (C or C′) by applying the same method as in the preceding cases, after treatment with concentrated sulphuric acid (98·25%).

In the latter three cases, the percentages of the α- and β-acids

and of the chlorohydroxymethylanthraquinone thus formed were almost the same as in the case of the β-acid. The details are given below in tabular form.

TABLE I.

Action of 98·25% Sulphuric Acid at about 95°.

Initial substance.	Insoluble in dil. Na_2CO_3 soln. (crude anthraquinone derivative). M. p.	%	Soluble in dilute sodium carbonate solution. M. p.	%		M. p.	%
β-Acid	220—222°	20—25	160—170°	55—75	Crude α-acid	169—171°	35—50
					Crude β-acid	220—235	1
					Residue (C)	160—165	10—30
α-Acid	219—222	20—25	158—170	60—70	Crude α-acid	168—170	30—50
					Crude β-acid	220—230	trace
					Residue (C′)	160—165	20—30
Residue C or C′	210—220	20—25	158—170	60—70	Crude α-acid	169—170	30—50
					Crude β-acid	220—235	
					Residue	160—165	10—30

The anthraquinone derivative was not obtained when a solution of the α- or the β-acid or of the residue (C or C′) in concentrated sulphuric acid (98·25%) was kept over-night at room temperature (see Table II). This method is preferable for the preparation of the α-acid from the β-acid.

TABLE II.

Action of 98·25% Sulphuric Acid at Room Temperature.

Initial substance.	Soluble in dilute sodium carbonate solution. M. p.	%		M. p.	%
β-Acid	168—170·5°	95—98	Crude α-acid	170—171°	70—80
			Crude β-acid	could not be separated	
			Residue (D)	163—168	15—25
α-Acid	,,	,,	Crude α-acid	169—171°	70—80
			Crude β-acid	could not be separated	
			Residue (D′)	163—168	20—25
Residue C or C′	,,	,,	Crude α-acid	169—171°	60—80
			Crude β-acid	could not be separated	
			Residue	160—166	15—20

It is clear from the data in Table III that the velocity of the reaction by which the β-acid changes to the α-acid is extremely rapid.

TABLE III.

The β-acid (0·1 g.) was treated with 98·25% sulphuric acid (1 c.c.) at 24° for the times stated.

9·5	90·5	163—167	40·4	59·6	162—215
13·4	86·6	163—167	49·5	50·5	162—220

The *sodium* and *barium* salts of the α-acid were prepared and analysed under conditions similar to those described for the sodium and barium salts of the β-acid. The *sodium* salt is readily soluble in water and closely resembles the sodium salt of the β-acid (Found: loss at 105°/10 mm., 19·0; Na, 5·9. $C_{15}H_{10}O_4ClNa,4H_2O$ requires H_2O, 18·7; Na, 6·0%). The *barium* salt is moderately easily soluble in water and does not effloresce at about 12° [Found: loss at 105°/10 mm., 4·7; Ba, 18·4. $(C_{15}H_{10}O_4Cl)_2Ba,2H_2O$ requires H_2O, 4·8; Ba, 18·3%]. The solubility of the α-acid and its salts is generally greater than that of the β-acid and its salts.

Chlorohydroxymethylanthraquinone.—A mixture of α- or β-5′-chloro-2′-hydroxy-2-benzoyl-*m*-toluic acid (1 g.) and sulphuric acid (6 c.c.; 98·25%) was heated at 115—120° for about an hour, cooled, and added to ice-water, and the green precipitate that separated was collected and treated with an excess of dilute sodium carbonate solution. A yellow substance (yield, 65%), m. p. 220—222°, remained undissolved; after several recrystallisations from glacial acetic acid it melted at 223—224° (Found: C, 65·8; H, 3·6; Cl, 13·3. $C_{15}H_9O_3Cl$ requires C, 66·1; H, 3·3; Cl, 13·0%). This substance is easily soluble in hot benzene, appreciably soluble in hot glacial acetic acid, and sparingly soluble in hot alcohol. It dissolves with difficulty in caustic alkalis and easily in concentrated sulphuric acid, giving a red solution in each case.

5 : 8-*Dihydroxy*-1-*methylanthraquinone* (8-*Methylquinizarin*).—Chlorohydroxymethylanthraquinone (1 g.) was gradually added to a solution of boric acid (2·4 g.) in concentrated sulphuric acid (10 c.c.) at 140—150°, and the whole was heated at 150—160° until the evolution of hydrogen chloride ceased. After cooling, the product was poured into ice-water, and the reddish-black precipitate was collected, and well washed with hot water. The substance was purified by dissolution in caustic soda and reprecipitation (yield, about 50%) and then by crystallisation several times from *iso*butyl alcohol or glacial acetic acid (Found: C, 70·6; H, 4·0. Calc., C, 70·9; H, 4·0%). The dark red crystals melted at 233—234° and at the same temperature when mixed with a specimen of

8-methylquinizarin (m. p. 232—233°) obtained from shikonin by Majima and Kuroda (*loc. cit.*).

β-5′-*Bromo*-2′-*hydroxy*-2-*benzoyl*-m-*toluic Acid.*—Aluminium chloride (12·5 g.) was gradually added to a solution of 3-methylphthalic anhydride (5 g.) and *p*-bromophenol (7·5 g.) in acetylene tetrachloride (20 c.c.), and the subsequent treatment and the separation of the reaction products were carried out as in the case of the chloro-derivative. Impure β-5′-*bromo*-2′-*hydroxy*-2-*benzoyl*-m-*toluic acid*, m. p. about 220—230°, was obtained in 75% yield from the part soluble in ammonia, and bromohydroxymethylanthraquinone in about 6% yield from the insoluble part. The former, after several crystallisations from alcohol, had m. p. 246—246·5° (Found: C, 53·8; H, 3·5; Br, by Nomura and Murai's method, 23·8. $C_{15}H_{11}O_4Br$ requires C, 53·7; H, 3·3; Br, 23·8%). It is easily soluble in hot alcohol, hot glacial acetic acid or hot acetone, and sparingly soluble in carbon disulphide, carbon tetrachloride or benzene. It is very sparingly soluble in water or light petroleum. The solution of this acid in concentrated sulphuric acid is at first yellow, but soon becomes deep red. The acid is also soluble in dilute caustic alkali to a yellow solution. It exhibits an absorption band with a head at λ 3335.

The bromohydroxymethylanthraquinone mentioned above was proved to be identical with bromohydroxymethylanthraquinone, which was obtained from α- or β-5′-bromo-2′-hydroxy-2-benzoyl-*m*-toluic acid, by the mixed melting point method.

α-5′-*Bromo*-2′-*hydroxy*-2-*benzoyl*-m-*toluic Acid.*—After a solution of β-5′-bromo-2′-hydroxy-2-benzoyl-*m*-toluic acid in sulphuric acid (6 c.c.; 98·25%) had been heated in the boiling water-bath for ½ hour, the reaction products were treated with an excess of dilute sodium carbonate solution, bromohydroxymethylanthraquinone, a yellow substance, m. p. 187—195°, remaining undissolved (yield, 8—10%); a crystalline mass, m. p. 157—162° (yield, 70—85%) was obtained from the yellow filtrate on acidification with hydrochloric acid. On repeated crystallisation from alcohol, two fractions were isolated. The less soluble crystals (about 1%) melted at 240—243°, and the more soluble ones (50—70%) at 161—164°. The former fraction was recrystallised from alcohol and proved to be identical with β-5′-bromo-2′-hydroxy-2-benzoyl-*m*-toluic acid by the mixed melting point method. The latter was recrystallised from aqueous alcohol (Found: C, 53·7; H, 3·5; Br, by Nomura and Murai's method, 24·1. $C_{15}H_{11}O_4Br$ requires C, 53·7; H, 3·3; Br, 23·8%). This isomeride melts at 163·5—164°, and is readily soluble in alcohol, glacial acetic acid, or acetone, moderately readily soluble in benzene, carbon disulphide, or carbon tetrachloride, and

very sparingly soluble in light petroleum or water. Its solubility is generally greater than that of the β-acid. It dissolves in concentrated sulphuric acid and in dilute aqueous caustic alkali, giving a red and a yellow solution, respectively. This acid has an absorption band with a head at λ 3345.

The α-acid was treated with sulphuric acid (98·25%) at 100°, and bromohydroxymethylanthraquinone and the α- and β-acids were then separated by applying the method used in the case of the β-acid. The same results were obtained from the residue (R or R′) (see Table V).

The Sodium and Potassium Salts of α- *and* β-5′-*Bromo*-2′-*hydroxy*-2-*benzoyl*-m-*toluic Acids*.—These salts were prepared by neutralising hot alcoholic solutions of the acids with solutions of the corresponding alkali hydroxides, and recrystallised from water by cooling in ice. After standing in a balance room until the weight was constant for a few hours, they were analysed (Temp. of room, 6°; relative humidity, 87%. Found for sodium salts of α-acid and of β-acid, respectively: loss at 105°/10 mm., 17·0 and 23·5; Na, 5·4 and 5·0. $C_{15}H_{10}O_4BrNa,4H_2O$ and $C_{15}H_{10}O_4BrNa,6H_2O$ respectively require H_2O, 16·8 and 23·2; Na, 5·4 and 4·9%. Temp. of room, 11°; relative humidity, 83%. Found for potassium salts of α-acid and of β-acid, respectively: loss at 105°/10 mm., 4·3 and 12·4; K, 9·8 and 9·1. $C_{15}H_{10}O_4BrK,H_2O$ and $C_{15}H_{10}O_4BrK,3H_2O$ respectively require H_2O, 4·6 and 12·7; K, 10·0 and 9·2%). The two sodium salts and the β-potassium salt gradually lost their water of crystallisation in the air.

Bromohydroxymethylanthraquinone.—The above-mentioned anthraquinone derivatives obtained from α- and β-5′-bromo-2′-hydroxy-2-benzoyl-*m*-toluic acids and the residues (R and R′) crystallised separately from *iso*butyl alcohol in yellow crystals, m. p. 198—198·5°, and were proved to be identical with each other by the mixed melting point method (Found: C, 56·7; H, 3·0; Br, by Nomura and Murai's method, 25·15. $C_{15}H_9O_3Br$ requires C, 56·8; H, 2·9; Br, 25·2%). This bromohydroxymethylanthraquinone is

easily soluble in benzene, glacial acetic acid, *iso*butyl alcohol, carbon disulphide, carbon tetrachloride, and acetone when the solvents are hot. It is moderately readily soluble in alcohol and sparingly soluble in light petroleum. It dissolves to a slight extent in dilute aqueous caustic alkali and easily in concentrated sulphuric acid, giving red solutions.

In conclusion, the author wishes to express his gratitude to Professor Rikô Majima, at whose suggestion this investigation was made, for his advice and helpful criticism, to Dr. Hiroshi Nomura for the micro-analyses, to Saichirô Nagami Rg. s. for the spectrographic investigation, and to Kenjirô Katô Rg. s. for the crystallographic measurements.

CCCXXXVII.—*Reactions of Thiosemicarbazones. Part III.*

By WILLIAM BAIRD, ROBERT BURNS, and FORSYTH JAMES WILSON.

IT has been found that the sodium derivative of acetonethiosemicarbazone reacts with ethyl, propyl, allyl, and butyl halides, also with ethyl ω-bromo-*o*-toluate, to give *S*-alkyl compounds of the type $CMe_2{:}N{\cdot}N{:}C(SR){\cdot}NH_2$. Whilst *S*-benzylthiosemicarbazide (J., 1922, **121**, 870) gave a monohydrochloride only and the benzylidene derivative was non-basic, the *S*-alkylthiosemicarbazides described in this paper are diacid bases giving dihydrochlorides of the type $NH_2{\cdot}N{:}C(SR){\cdot}NH_2,2HCl$, which were obtained from the parent compounds by hydrolysis with acid. The benzylidene derivatives are monoacid bases and were obtained as monohydrochlorides, $CHPh{:}N{\cdot}N{:}C(SR){\cdot}NH_2,HCl$. These acetone- and benzaldehyde-*S*-alkylthiosemicarbazones melt at much lower temperatures than the thiosemicarbazones themselves and it therefore appears probable that the thiosemicarbazones contain the group $-C{:}S$ and not $-C{\cdot}SH$.

Whilst the sodium derivative of acetonethiosemicarbazone reacts with esters of α-halogenated monobasic acids to produce cyclic compounds (J., 1923, **123**, 799), esters of β- and γ-halogenated monobasic acids behave quite differently. With ethyl β-chloro-*n*-butyrate and ethyl β-bromo-β-phenylpropionate, elimination of hydrogen halide as sodium halide occurred with formation of acetonethiosemicarbazone and the unsaturated ester, ethyl croton-

ate and ethyl cinnamate, respectively: ethyl γ-chloro-*n*-butyrate, ethyl γ-chloro-*n*-valerate, and ethyl γ-chloro*iso*hexoate reacted in a similar way. These reactions were carried out in alcoholic solution; in benzene suspension, no reaction took place even after several hours' boiling.

The interaction of thiosemicarbazones and primary amines, when hot, takes place according to the scheme $CRR':N\cdot NH\cdot CS\cdot NH_2 + R''NH_2 = CRR':N\cdot NH\cdot CS\cdot NHR'' + NH_3$, yielding δ-substituted thiosemicarbazones with the alkyl or aryl group attached, not to sulphur as in the preceding cases, but to nitrogen. The reaction is similar to that between semicarbazones and primary amines investigated by Borsche and others (*Ber.*, 1901, **34**, 4299; 1904, **37**, 3177; 1905, **38**, 83) and by workers in these laboratories; thiosemicarbazones, however, react much more slowly. Acetonethiosemicarbazone was chiefly employed, the amines being benzylamine, α-phenylethylamine, aniline, β-naphthylamine, and *n*-heptylamine. These δ-substituted thiosemicarbazones on hydrolysis with dilute hydrochloric acid yielded the corresponding thiosemicarbazide hydrochlorides, $NH_2\cdot NH\cdot CS\cdot NHR'',HCl$, with the exception of the β-naphthyl derivative, which suffered further decomposition; from these hydrochlorides the thiosemicarbazides were obtained. That these compounds contain the substituent in the δ-position is evident from the fact that acetonethiosemicarbazone and aniline yielded a product identical with a specimen of acetone-δ-phenylthiosemicarbazone prepared in the usual way; also δ-benzylthiosemicarbazide, synthesised from benzylthiocarbimide and hydrazine hydrate, $CH_2Ph\cdot NCS + NH_2\cdot NH_2 = CH_2Ph\cdot NH\cdot CS\cdot NH\cdot NH_2$ (a general reaction for the preparation of such substances), was identical with the compound obtained by us.

It is hoped to prepare the optically active δ-α-phenylethylthiosemicarbazides and to investigate possible applications of these compounds.

EXPERIMENTAL.

The Reaction between the Sodium Derivative of Acetonethiosemicarbazone and Alkyl Halides.—Procedure. Alcoholic solutions of acetonethiosemicarbazone and sodium ethoxide (equimolecular quantities) were mixed, boiled for 10 minutes, and cooled, the alkyl halide (1 mol.) was then added, and after 12 hours the mixture was heated under reflux for 15 minutes. The solution was then evaporated to dryness under reduced pressure and the acetone-*S*-alkylthiosemicarbazone was separated from the sodium halide and acetonethiosemicarbazone by dissolving it in ether; after evaporation of the ether, it was recrystallised from light petroleum. These compounds were readily soluble in the usual organic solvents.

Hydrolysis was effected by boiling under reflux for 15 minutes with 0·5*N*-hydrochloric acid; unchanged substance and any mercaptan formed were then removed by extraction with ether, the acid solution was concentrated under reduced pressure, and the *S*-alkylthiosemicarbazide dihydrochloride obtained in the solid form by keeping the residual syrup over sulphuric acid or phosphorus pentoxide in an evacuated desiccator. These dihydrochlorides were very hygroscopic and very soluble in water.

The benzylidene monohydrochloride was obtained by shaking an aqueous solution of the dihydrochloride with a little benzaldehyde, washing the product with a little ether, and then precipitating it from alcoholic solution by addition of ether. These compounds were readily soluble in alcohol and sparingly soluble or insoluble in benzene, ether, and water. The benzylidene derivative itself was obtained by treating the monohydrochloride with the necessary quantity of sodium carbonate in aqueous-alcoholic solution, evaporating the solution to dryness under reduced pressure, extracting the residue with ether, and, after evaporation of the ether, recrystallising the product from light petroleum. These derivatives were soluble in the usual organic solvents.

With ethyl bromide. *Acetone*-S-*ethylthiosemicarbazone* formed flat, transparent prisms, m. p. 55°, having a slight, unpleasant odour (yield, 65—70%) (Found: N, 26·4. $C_6H_{13}N_3S$ requires N, 26·4%). S-*Ethylthiosemicarbazide dihydrochloride* was obtained as a white powder after being kept for several weeks over phosphorus pentoxide; it melted indefinitely at about 60° (Found: HCl, 37·7. $C_3H_9N_3S,2HCl$ requires HCl, 38·0%). *Benzaldehyde*-S-*ethylthiosemicarbazone hydrochloride* formed fine, colourless needles, m. p. 195° (Found: N, 17·2. $C_{10}H_{13}N_3S,HCl$ requires N, 17·2%); *benzaldehyde*-S-*ethylthiosemicarbazone* formed flat prisms, m. p. 66° (Found: N, 20·2. $C_{10}H_{13}N_3S$ requires N, 20·3%).

With propyl bromide. *Acetone*-S-*propylthiosemicarbazone* distilled at 121°/7 mm.; the distillate solidified on cooling in carbon dioxide and ether and then melted at 26—27° (Found: N, 24·2. $C_7H_{15}N_3S$ requires N, 24·3%). S-*Propylthiosemicarbazide dihydrochloride* was a thick syrup which would not solidify (Found: HCl, 35·3. $C_4H_{11}N_3S,2HCl$ requires HCl, 35·4%). *Benzaldehyde*-S-*propylthiosemicarbazone hydrochloride* formed lustrous needles, m. p. 209° (Found: N, 16·3. $C_{11}H_{15}N_3S,HCl$ requires N, 16·3%); *benzaldehyde*-S-*propylthiosemicarbazone* formed short prisms, m. p. 54° (Found: N, 18·9. $C_{11}H_{15}N_3S$ requires N, 19·0%).

With allyl iodide. *Acetone*-S-*allylthiosemicarbazone* crystallised in flat, transparent prisms (yield, 75%), m. p. 51° (Found: N, 24·5. $C_7H_{13}N_3S$ requires N, 24·6%). S-*Allylthiosemicarbazide di-*

hydrochloride, a crystalline mass, melted at 75° (Found : HCl, 35·4. $C_4H_9N_3S,2HCl$ requires HCl, 35·9%). *Benzaldehyde*-S-*allylthiosemicarbazone hydrochloride* formed lustrous plates, m. p. 190° (Found : HCl, 14·2; N, 16·2. $C_{11}H_{13}N_3S,HCl$ requires HCl, 14·3; N, 16·4%); *benzaldehyde*-S-*allylthiosemicarbazone* formed transparent, rhombic prisms, m. p. 42° (Found : N, 19·0. $C_{11}H_{13}N_3S$ requires N, 19·2%).

With n-*butyl bromide*. *Acetone*-S-*butylthiosemicarbazone*, a colourless oil of b. p. 146°/16 mm., did not solidify when strongly cooled and became slightly coloured on standing (Found : N, 22·4. $C_8H_{17}N_3S$ requires N, 22·5%). S-*Butylthiosemicarbazide dihydrochloride* formed a crystalline mass, m. p. 100—101° (decomp.) (Found : HCl, 33·1; N, 19·1. $C_5H_{13}N_3S,2HCl$ requires HCl, 33·2; N, 19·1%). *Benzaldehyde*-S-*butylthiosemicarbazone* was obtained as a viscid oil which solidified on cooling in ether and carbon dioxide; the solid, after being pressed on porous tile, crystallised from light petroleum in transparent prisms, m. p. 50° (Found : N, 17·8. $C_{12}H_{17}N_3S$ requires N, 17·9%).

With ethyl ω-*bromo*-o-*toluate*. *Acetone*-S-o-*carbethoxybenzylthiosemicarbazone*, $CMe_2{:}N{\cdot}N{:}C(S{\cdot}CH_2{\cdot}C_6H_4{\cdot}CO_2Et){\cdot}NH_2$, formed pale yellow, transparent prisms, m. p. 66°, from light petroleum containing a little benzene; yield, 70% (Found : N, 14·3. $C_{14}H_{19}O_2N_3S$ requires N, 14·3%). S-o-*Carbethoxybenzylthiosemicarbazide dihydrochloride*, $NH_2{\cdot}N{:}C(S{\cdot}CH_2{\cdot}C_6H_4{\cdot}CO_2Et){\cdot}NH_2,2HCl$, a crystalline mass, melted at 125—130° (decomp.) (Found : HCl, 22·2; N, 12·7. $C_{11}H_{15}O_2N_3S,2HCl$ requires HCl, 22·4; N, 12·9%). *Benzaldehyde*-S-o-*carbethoxybenzylthiosemicarbazone hydrochloride* formed lustrous, white plates, m. p. 115°, containing $1H_2O$ (Found : HCl, 8·7; N, 10·5. $C_{18}H_{19}O_2N_3S,HCl,H_2O$ requires HCl, 9·2; N, 10·6%); *benzaldehyde*-S-o-*carbethoxybenzylthiosemicarbazone* crystallised from light petroleum, containing a little benzene, in short, transparent prisms, m. p. 74° (Found : N, 12·2. $C_{18}H_{19}O_2N_3S$ requires N, 12·3%).

Interaction of Thiosemicarbazones and Primary Amines when Hot.—Procedure. With one exception (acetophenonethiosemicarbazone, as noted below), acetonethiosemicarbazone was used throughout. Equimolecular quantities of the reactants were heated under reflux in toluene solution or suspension at 125—130° until evolution of ammonia ceased; if necessary, the solution was then evaporated under reduced pressure. Hydrolysis was effected by refluxing with 6% hydrochloric acid, followed, if necessary, by evaporation under reduced pressure.

With benzylamine (20 hours). On cooling, *acetone*-δ-*benzylthiosemicarbazone* and a little unchanged substance separated. The product was crystallised from alcohol (prismatic needles) and then from benzene (plates); it melted at 147—148°, had a slightly

creamy tint, and was insoluble in ether and light petroleum (yield, 65%) (Found: N, 18·9; S, 14·4. $C_{11}H_{15}N_3S$ requires N, 19·0; S, 14·5%). After hydrolysis (1 g.; 20 c.c. of acid; 20 minutes) the solution, which contained acetone as shown by distillation, was filtered from a small amount of insoluble matter and evaporated after removal of the crystals which separated on cooling. The residue and the crystals were united and extracted with absolute alcohol to remove hydrazine hydrochloride; the alcoholic extract on cooling deposited *δ-benzylthiosemicarbazide hydrochloride* in colourless plates, of m. p. 189° (decomp.) after recrystallisation (yield, 87%). It was insoluble in ether and benzene, but soluble in warm water (Found: Cl, 16·2. $C_8H_{11}N_3S,HCl$ requires Cl, 16·3%). The formation of hydrazine hydrochloride and an odour of cress (due probably to thiocarbimide) after the hydrolysis showed that some decomposition had occurred. *δ-Benzylthiosemicarbazide* was obtained by boiling 0·8 g. of the hydrochloride with 20 c.c. of water for 5 minutes (an odour of thiocarbimide was apparent); the base deposited on cooling was recrystallised from absolute alcohol and then from benzene. It formed glistening leaves (yield, 76%), m. p. 130°, insoluble in light petroleum and slightly soluble in ether and water. The aqueous solution gave a white precipitate with silver nitrate (Found: N, 23·2. $C_8H_{11}N_3S$ requires N, 23·2%). The *benzylidene* derivative, prepared from benzaldehyde and the base or the hydrochloride in aqueous-alcoholic solution, crystallised from light petroleum–alcohol in long, matted needles, m. p. 133—134° (Found: N, 15·7. $C_{15}H_{15}N_3S$ requires N, 15·6%). δ-Benzylthiosemicarbazide, identical with the specimen just described (mixed m. p. test), was prepared in good yield by mixing equimolecular quantities of benzylthiocarbimide and hydrazine hydrate in ice-cold alcoholic solution. Heat was developed and the substance, which soon separated, was recrystallised from alcohol (tabular prisms) and then from benzene (leaves); both forms melted at 130°.

Acetophenonethiosemicarbazone and benzylamine reacted much more slowly (42 hours). *Acetophenone-δ-benzylthiosemicarbazone*, which separated on cooling (a little more was obtained by evaporation), crystallised from benzene as a mass of fine, colourless needles, m. p. 157—159°, and from alcohol in colourless plates, m. p. 160—161° (yield, 85%) (Found: N, 14·9; S, 11·2. $C_{16}H_{17}N_3S$ requires N, 14·8; S, 11·3%). The hydrolysis (1 g.; 20 c.c. of acid; 4½ hours), which was slow and incomplete, gave acetophenone and δ-benzylthiosemicarbazide hydrochloride besides hydrazine hydrochloride and benzylthiocarbimide.

With α-phenylethylamine (35½ hours). The solution after filtration

from a small quantity of insoluble matter and evaporation left a viscid oil which set to a transparent resin on cooling. The solution of this in a little hot absolute alcohol deposited crystals of *acetone-δ-α-phenylethylthiosemicarbazone* after cooling and scratching; recrystallisation from alcohol gave colourless, tabular prisms, m. p. 89—90° (yield, 66%) (Found: N, 18·0; S, 13·8. $C_{12}H_{17}N_3S$ requires N, 17·9; S, 13·6%). The substance was fairly soluble in benzene, sparingly soluble in light petroleum, and could be crystallised from a mixture of these solvents. The solution obtained by hydrolysis (1 g.; 20 c.c. of acid; 17 minutes) contained acetone and had an odour of thiocarbimide; a small quantity of an oil which was deposited on cooling was removed. The residue obtained by evaporation of the solution was dissolved in hot alcohol–benzene, and concentration in a vacuum then gave small, colourless plates of *δ-α-phenylethylthiosemicarbazide hydrochloride*, m. p. 157—158° (yield, 80%) (Found: Cl, 15·5. $C_9H_{13}N_3S,HCl$ requires Cl, 15·3%). The *benzylidene* derivative, prepared in the usual way, tended to separate as an oil but formed colourless plates, m. p. 128—129°, from light petroleum (Found: N, 15·0. $C_{16}H_{17}N_3S$ requires N, 14·8%). An aqueous solution of the hydrochloride was boiled with barium carbonate, and the residue obtained by evaporation of the filtrate under reduced pressure was extracted with benzene. This extract, after drying and spontaneous evaporation in a vacuum, gave an oil which solidified on standing; recrystallisation from alcohol–light petroleum gave a crystalline mass of *δ-α-phenylethylthiosemicarbazide*, m. p. 84°, which was extremely soluble in alcohol and sparingly soluble in light petroleum (Found: N, 21·6. $C_9H_{13}N_3S$ requires N, 21·5%).

With aniline (20 hours at 120—125° and 17 hours at 130—135°). Some hydrogen sulphide was evolved and a small amount of insoluble matter separated. After cooling and filtration, the toluene was evaporated, leaving a viscid oil which solidified on cooling and scratching. Recrystallisation from alcohol gave plates (yield, only 30%) of acetone-δ-phenylthiosemicarbazone, which was identified by comparison with an authentic specimen. The insoluble matter after recrystallisation from alcohol gave glistening leaves, softening at about 235° and melting at 245°. The quantity obtained was too small for identification.

With β-naphthylamine (18 hours). An appreciable quantity of an insoluble substance was formed, and hydrogen sulphide and ammonia were evolved. The substance was collected and after extraction with boiling absolute alcohol was crystallised from alcohol–pyridine. The colourless crystals softened and darkened at about 266° and melted at about 275° (Found: N, 15·5%).

This substance may be *di-β-naphthyliminotetrahydrothiodiazole* ($C_{22}H_{16}N_4S$ requires N, 15·2%) produced from acetone-δ-β-naphthylthiosemicarbazone by the reaction $2CMe_2{:}N{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_{10}H_7 = CMe_2{:}N{\cdot}N{:}CMe_2 + C_{10}H_7{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_{10}H_7$, the hydrazinedithiocarbo-β-naphthylamide then giving di-β-naphthylimino-tetrahydrothiodiazole, $\begin{vmatrix} NH{\cdot}C{:}N{\cdot}C_{10}H_7 \\ NH{\cdot}C{:}N{\cdot}C_{10}H_7 \end{vmatrix} > S$, and hydrogen sulphide (compare Busch and Schmidt, *Ber.*, 1913, **46**, 2241, on the corresponding phenyl derivatives; also Pulvermacher, *Ber.*, 1894, **27**, 616). The toluene solution on cooling in ice deposited a substance which, after repeated recrystallisation from alcohol, benzene, and finally from alcohol to remove a little insoluble matter, gave yellow plates (yield, 60%) of *acetone-δ-β-naphthylthiosemicarbazone*, m. p. 150—151°; from benzene it separated apparently amorphous, m. p. 137—138° (Found: N, 16·4. $C_{14}H_{15}N_3S$ requires N, 16·3%). The substance was easily soluble in hot alcohol and hot benzene. Hydrolysis with acid gave acetone, hydrazine hydrochloride, a small amount of an unidentified hydrochloride which softened at 175° and decomposed at 190°, and also a substance insoluble in water and alcohol. The last substance separated from alcohol–pyridine as a white, apparently amorphous powder, which began to decompose at about 220° and finally melted at 252°; it became slightly pink on standing (Found: N, 13·7. $C_{22}H_{18}N_4S_2$ requires N, 13·9%). It is believed to be *hydrazinedithiocarbo-β-naphthylamide*, formed by decomposition of δ-β-naphthylthiosemicarbazide hydrochloride: $2(NH_2{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_{10}H_7,HCl) =$

$$C_{10}H_7{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_{10}H_7 + N_2H_4,2HCl.$$

With n-*heptylamine* (21½ hours). The toluene solution on evaporation left a viscid oil which crystallised on cooling. On dissolving this in hot absolute alcohol and cooling the solution in ice, *acetone-δ-heptylthiosemicarbazone* separated, and recrystallisation from light petroleum gave silvery, glistening plates (yield, 65%), m. p. 75° (Found: N, 18·4. $C_{11}H_{23}N_3S$ requires N, 18·3%). The substance was easily soluble in benzene, ether, and carbon tetrachloride, and moderately or slightly soluble in other organic solvents. The solution obtained by hydrolysis (1 g.; 20 c.c. of acid; 10 minutes) contained acetone, and on cooling, *δ-heptylthiosemicarbazide hydrochloride* separated. This, on recrystallisation from light petroleum containing a little alcohol, formed silvery, glistening leaves, m. p. 135—136°, which were easily soluble in hot water, very soluble in alcohol, and insoluble in other common solvents (Found: N, 18·5. $C_8H_{19}N_3S,HCl$ requires N, 18·6%). The *benzylidene* derivative formed matted needles, m. p. 73°, from light petroleum (Found:

N, 15·3. $C_{15}H_{23}N_3S$ requires N, 15·2%). *δ-Heptylthiosemicarbazide*, which formed silky, glistening, acicular plates, m. p. 54—55°, was prepared by boiling the hydrochloride with sodium carbonate in aqueous-alcoholic solution; the solution was filtered from the excess of sodium carbonate and allowed to evaporate spontaneously in a vacuum; extraction of the residue with hot light petroleum and recrystallisation from the same solvent gave the desired product (Found: N, 22·3. $C_8H_{19}N_3S$ requires N, 22·2%).

In conclusion, we desire to thank the Governors of this College for Research Assistantships which have enabled two of us (W. B. and R. B.) to take part in this investigation. We wish also to thank the Carnegie Trust for the Universities of Scotland for a research grant which has partly defrayed the cost of this work.

THE ROYAL TECHNICAL COLLEGE,
GLASGOW. [*Received, August 12th*, 1927.]

CCCXXXVIII.—*The Atomic Weight of Antimony from Different Sources.*

By KOLAR RAMAKRISHNAIYER KRISHNASWAMI.

THREE determinations of the atomic weight of antimony have been made during the last seven years. Willard and McAlpine (*J. Amer. Chem. Soc.*, 1921, **43**, 797) obtained the value 121·773, Weatherill (*ibid.*, 1924, **46**, 2437) 121·748, and Hönigschmid, Linhard, and Zintl (*Z. anorg. Chem.*, 1924, **136**, 257) 121·76. These figures are in good agreement, but in each case the antimony used was obtained from Kahlbaum. Muzaffar (*J. Amer. Chem. Soc.*, 1923, **45**, 2009) has, however, published results for antimony from Brazil and other sources for which he obtained values varying from 121·444 to 122·374.

In order to see if similar variations were to be found with antimony from a different part of the world, determinations have been made with four ores of Indian and Burmese origin, whilst for comparison parallel determinations have been conducted with a sample of Kahlbaum's antimony. The results agree very closely with those of the three observers mentioned above, and the variation for different ores is within the limit of experimental error.

EXPERIMENTAL.

A few trials were made of Muzaffar's method, but in spite of its apparent simplicity certain disadvantages became evident in practice, and it was abandoned. These attempts will be referred to

later. The method of Willard and McAlpine was then adopted in its entirety and found very satisfactory: Antimony tribromide is prepared in an atmosphere of nitrogen and distilled in a vacuum into a bulb which is sealed, weighed, and finally broken under a solution of tartaric acid; the quantity of bromine is then estimated by conversion into silver bromide, the amount of silver required being determined nephelometrically or weighed as bromide. Reference is only made to details in procedure when this differs in any way from that given by the above authors. The whole of the apparatus used in the course of the experiments was constructed from Pyrex or the very resistant T-glass of Greiner and Friedrichs.

Preparation of Materials.—The water, bromine, potassium bromide, sodium chloride, nitric acid, tartaric acid, and sodium and potassium cyanides required in this research were purified by the methods given by Willard and McAlpine. Silver was prepared from silver nitrate according to the procedure of Richards and Wells (*J. Amer. Chem. Soc.*, 1905, **27**, 459), but in most of the experiments Johnson and Matthey's " chemically pure " silver was used after being washed with absolute alcohol and ether and fused on a lime support, for the two samples were found to give almost identical results.

Hydrogen was generated by electrolysis of a 15% solution of sulphuric acid between platinum electrodes, and purified by passage over heated platinised asbestos and copper gauze, bubbling through a 20% solution of caustic potash containing some dissolved lead oxide, and drying by passage over phosphorus pentoxide (see Noyes, *Bull. Bureau Standards*, IV, 179).

Nitrogen was prepared in an all-glass apparatus by passing a mixture of air and ammonia over heated copper, and purified according to the method of Richards and Krepalka (*J. Amer. Chem. Soc.*, 1920, **42**, 2225).

Balance and Weighing.—A long-beam Oertling balance was employed. Successive weighings of the same object, which were made by substitution, agreed to 0·02 mg. The weights were carefully calibrated, and counterpoises were used whenever necessary. Calcium chloride was kept in the balance case and 50% humidity was assumed when calculating the vacuum correction.

Preparation of Antimony.—Five specimens of antimony were prepared from the following sources: (1) Kahlbaum's purest antimony trioxide, (2) stibnite from the Mysore State, (3) cervantite from the same area, (4) stibnite from the Amherst District in Burma, and (5) stibnite from the Southern Shan States.

The method of preparation of the metal was the same in all the cases. About 500 g. of the finely powdered material were digested

with hot concentrated hydrochloric acid in successive portions until extraction was practically complete. The excess of acid was distilled off and the antimony trichloride distilled 4 or 5 times. It boiled regularly at 210—211°/680 mm., and was always obtained as a clear, pale yellow liquid solidifying to an ivory-white solid. The further steps were according to the method devised by Groschuff (*Z. anorg. Chem.*, 1918, **103**, 168): The trichloride is treated with chlorine and hydrogen chloride to give chloroantimonic acid, $SbCl_5,HCl,\frac{1}{2}H_2O$; this is dissolved in a little water, and large dilution with water then precipitates antimonic acid, which is washed, evaporated to dryness with nitric acid to expel the last traces of chlorine, and ignited. The oxide thus obtained is reduced with sodium cyanide in a porcelain beaker in a muffle furnace at about 650°. The buttons of metal obtained are cleaned as recommended by Muzaffar, powdered in an agate mortar, dried in a current of hydrogen at 400°, and sealed in the containing tube.

Preparation of Antimony Bromide.—Antimony bromide was prepared exactly according to Willard and McAlpine's instructions, the only modification being the use of a mercury-vapour pump for the complete evacuation of the apparatus.

Purity of the Silver.—As a check on the purity of the silver, the ratio AgCl : Ag was determined by following exactly the procedure of Richards and Wells (*loc. cit.*). This work, and all subsequent operations in which silver salts were involved, was done in a special laboratory illuminated by ruby light. Table I shows the results of several determinations.

TABLE I.

Ratio AgCl : Ag.

Wt. of Ag, g.	Wt. of AgCl, g.	100 × AgCl/Ag.	Wt. of Ag, g.	Wt. of AgCl, g.	100 × AgCl/Ag.
7·49956	9·96437	132·866	7·57600	10·06474	132·850
7·41387	9·85066	132·867	7·74410	10·32871	132·862
7·59879	10·09663	132·870	7·48068	9·93930	132·866

The first two experiments were made with silver from silver nitrate, and the remainder with Johnson and Matthey's pure silver, which is evidently of a remarkable degree of purity for a commercial article. The mean value obtained by Richards and Wells was 132·864, and thus the agreement is as close as can be expected.

Weighing and Analysis of Antimony Bromide.—In this part of the work, also, the general method adopted was the one used both by Willard and McAlpine and by Hönigschmid. After being cleaned and dried as recommended by Baxter (*Proc. Amer. Acad. Arts Sci.*, 1924—25, **60**, 228), the bulb containing the antimony bromide was suspended from the balance by means of a platinum wire and

weighed in air and under water. The platinum wire also was weighed in air and in water with the same portion of it immersed as when the bulb was weighed under water. The bulb was then broken with a Pyrex rod under a solution of tartaric acid (250 c.c. of 4—5% solution) in a thick-bottomed, tall beaker. Solution was complete in about 10 hours.

In Expts. Nos. 1—6, the solution was passed through a Gooch crucible to collect the glass. Subsequently, a silica crucible with a porous sintered bottom was used and proved much more satisfactory. In both cases, the glass was ignited to a dull red heat before weighing. Its density was determined and found to be 2·56 g. per c.c. (T-glass).

The analysis of the antimony bromide was effected by determination of the ratio $SbBr_3 : 3AgBr$, and in two cases of the ratio $SbBr_3 : 3Ag$ in addition. For the latter purpose a nephelometer of the Kober type with a Klett top-reader was used.

The gravimetric determination was at first (Expts. 1—6) carried out exactly in accordance with the description given by the authors already mentioned. A Gooch crucible was used, and the solution was refiltered through a small filter-paper to secure any particles of asbestos. As the volume of the solution was about 700 c.c., this was a tedious operation. A great improvement was effected by the use of a Jena-glass crucible with a sintered bottom. In these experiments, the silver bromide was dried for 14—18 hours at 180°, and the moisture content determined by fusing the bulk of the precipitate in a porcelain crucible. Subsequently, the drying was conducted at 300° for 12—18 hours, as recommended by Hönigschmid, and the loss on fusion of the bromide was then found to be negligible, so that it was not determined in every case. The bromide was, however, always fused and its appearance after fusion noted; it was found that when dark spots or a discoloration appeared (due to traces of silver nitrate) a low value for the atomic weight was usually obtained. Such experiments are distinguished by an asterisk in the following table, and are not included in calculating the means. In all other cases, the fused silver bromide was quite clear.

Table II gives the results of the determinations. For calculating the atomic weight, the values Ag = 107·880, Br = 79·920 have been adopted.

In Expts. 7 and 8, the ratio $SbBr_3 : 3Ag$ was determined by the nephelometer before filtering the silver bromide. The values 121·751 and 121·735 were found for the atomic weight, the agreement with the gravimetric value being fair. It was not, however, considered necessary to determine this ratio in every case, as it is sufficient for

the present purpose to compare the relative values for the different samples of antimony, the absolute value of the atomic weight being of secondary importance.

The mean results show an extreme variation of 0·010 in the atomic weights; this is considerably less than the variation among individual experiments and may reasonably be ascribed to experimental error. The difference between these results and those of Muzaffar is considerable, this author having found a variation of 0·93 unit in the atomic weight of different samples of antimony. His individual results are not very concordant, the ratio 3Sb : $KBrO_3$ ranging from 2·1802 to 2·1875 in the case of one sample, corresponding with 0·41 unit in the atomic weight, whilst the preliminary determination of the ratio $3As_4O_6$: $4KBrO_3$ gave results fluctuating

over a range of 0·4%, showing that one of these materials was not very pure, or that the end-point of the reaction was not definite.

An attempt was made to investigate the bromate method as conducted by Muzaffar, but a difficulty was experienced in dissolving the pure antimony in concentrated sulphuric acid except by very prolonged boiling. On cooling, the mass became semi-solid, and although solution could be effected by the addition of a little water, too much water produced a precipitate and transference was troublesome. As Muzaffar gives no details of manipulation, it was considered preferable to make use of a method which had been fully described and experiments by the bromate method were not continued.

Summary.

The atomic weight of antimony has been determined in five samples, one from Kahlbaum and the others from India and Burma. Willard and McAlpine's method was used, and the results ranged from 121·744 to 121·754. These are in good agreement with the best previous determinations; there is no indication that the variation is due to a change in atomic weight, and in any case such variation does not exceed 0·01 unit for the samples examined.

In conclusion, I wish to express my gratitude to Professor H. E. Watson for his valuable suggestions during the course of this work, and to the Directors of Geology of the Governments of India and of Mysore for their kindness in supplying the necessary ores of antimony.

CCCXXXIX.—*Studies of Dynamic Isomerism. Part XXIV. Neutral-salt Action in Mutarotation.*

By THOMAS MARTIN LOWRY and GILBERT FREEMAN SMITH.

Neutral Salt Action in Catalysis by Acids.

THE idea of " neutral salt action " in catalysis by acids arose in the first instance from the observation of Arrhenius (*Z. physikal. Chem.*, 1889, **4**, 226) that the rate of inversion of sucrose by weak acids was augmented by the addition of neutral salts of strong acids, such as potassium chloride, which, at a concentration of $N/8$, increases the catalytic activity of $N/40$-acetic acid by 12·6%. Since neutral salts are not themselves catalysts for the inversion of sucrose, this effect was attributed by Arrhenius to the indirect action of the salt in *increasing* the ionising power of the medium and therefore the ionisation of the weak acid; a similar increase of

the catalytic activity of hydroxyl ions by neutral salts has been postulated by Senter (J., 1907, **91**, 460), and by Osaka (*Z. physikal. Chem.*, 1900, **35**, 661). On the other hand, it has been suggested that neutral salts with a common ion may act by *decreasing* the ionisation of the acid, the undissociated molecules of which are assumed to be catalytically active, as well as the hydrogen ions derived from them. Thus, whereas Arrhenius supposed that only the hydrogen ions act as catalysts, Snethlage (*Z. Elektrochem.*, 1912, **18**, 539; compare Goldschmidt, *Z. physikal. Chem.*, 1912, **81**, 30, and McBain, J., 1914, **105**, 1517) attributed a part of the catalytic activity of the acid to the undissociated molecules, the activity of the molecules and ions being in the ratio $k_m : k_h = 0{\cdot}06 : 1$ for picric acid, but about 2 : 1 for hydrochloric acid. On the other hand, Lapworth (J., 1908, **93**, 2163, 2187) and Dawson (J., 1911, **99**, 1; 1914, **105**, 1093), from a study of the influence of water in diminishing the catalytic activity of acids in alcoholic solutions, concluded that catalysis by acids, so far as it depends on the action of ions, is due to the presence of a mere trace of *free* hydrogen ions, the effect of the *hydrated* hydrogen ions (which are mainly responsible for the conductivity of the acid) being relatively unimportant. This conclusion is directly opposite to that of Kendall (*Proc. Nat. Acad. Sci.*, 1921, **7**, 56), who supposes that the hydrolysis of methyl acetate may be catalysed by compounds of anhydrous hydrogen ions with all the other components of the solution; but it was not intended to exclude catalysis by undissociated molecules of the acid, which was widely advocated by Dawson (J., 1915, **107**, 1426) as the "Dual Theory of Acid Catalysis." More recently, Dawson, who gave for the ratio k_m/k_h values ranging from 1·77 for hydrochloric acid to 0·0034 for acetic acid, has included the anion (but not the metallic kation) of the neutral salt as an independent catalyst, the acceleration produced by these anions being formulated as an inherent property of the ion, comparable with the independent catalytic activity of the hydrogen and hydroxyl ions.

The most important feature of Dawson's work is his repudiation of Arrhenius's hypothesis that the catalytic activity of the ions of a neutral salt is a secondary effect, which is produced only indirectly by stimulating the catalytic activity of some other ion. Each active component is therefore represented by an independent term in his equations. Moreover, Dawson found that he could make use of the *concentrations* of the various components, without attempting to convert them into *activities*. Finally, Dawson's results have attracted widespread attention by reason of their precise quantitative character, which can be illustrated by quoting the catalytic coefficients ($\times 10^6$) deduced from a study of the

velocity of iodination of acetone in presence of sodium acetate and acetic acid, *viz.*,

$$OH' = 10^7;\ H' = 442;\ Ac' = 4{\cdot}5;\ HAc = 1{\cdot}5.$$

The authors of the present paper desire to put on record the fact that, whilst the theory set out in Part XXV (following paper) is a logical development of views advanced in previous papers of this series, the experiments now described were suggested directly by analogy with Dawson's observations on acetone. The analogies that have been detected afford confirmation of the view (which is still based on theory rather than on direct experiment) that the iodination of the ketone and the changes of rotatory power of the sugar are both dependent on a prototropic change, in marked contrast, for instance, to the isomeric change of *N*-chloroacetanilide, which has been shown to depend on a process of reversible chlorination (*Rep. Brit. Assoc.*, 1910, 85).

Neutral-salt Action in Mutarotation.

The influence of neutral salts on the mutarotation of the reducing sugars has received but little attention, perhaps because the changes of rotatory power proceed so rapidly, even in pure water, that a relatively small acceleration makes the velocities too great for accurate measurement. Ample evidence is available, however, to show that, whilst bases and acids (and even water) are powerful catalysts, no marked acceleration is produced by neutral salts of the type of sodium and potassium chlorides (Lowry, J., 1903, **83**, 1317; Worley, *J. Physical Chem.*, 1927, **31**, 882). Kuhn and Jacob (*Z. physikal. Chem.*, 1924, **113**, 389) have indeed plotted a curve showing the influence of sodium chloride on the velocity of mutarotation of glucose at 25° over a range of acidity and alkalinity from p_H 1 to 7·7. The influence of this salt is shown to be almost negligible throughout, although definite catalytic effects were attributed to the anions of the weak acids which were present in certain buffer solutions.

The experiments that have just been cited leave the impression that neutral salts in general exert only a negligible effect on mutarotation, and that the velocity of mutarotation is determined mainly, even if not quite exclusively, by the acidity or alkalinity of the solution, as represented by its "hydrogen-ion concentration." This view is expressed in a precise mathematical form in Hudson's well-known equation (*J. Amer. Chem. Soc.*, 1907, **29**, 1571), in which the velocity of mutarotation of glucose at 25° is given by

$$k^* = 0{\cdot}0096 + 0{\cdot}258[\overset{+}{H}] + 9750[\bar{O}H].$$

* Calculated by the use of logarithms to the base 10.

This equation represents the observed velocities of mutarotation as depending on the sum of two variable terms, representing respectively the catalytic activity of *hydrogen ions* and of *hydroxyl ions*, together with a constant term which can be attributed to the action of *neutral water*. It has been adopted (with slightly different constants) by Kuhn and Jacob (*loc. cit.*), who write

$$k = 0{\cdot}0104 + 0{\cdot}334[\overset{+}{\mathrm{H}}] + 9345[\bar{\mathrm{O}}\mathrm{H}],$$

and has been generally accepted as an adequate expression of all the relevant facts. This is made even more striking if the velocity of mutarotation is plotted against the p_{H} values of the solution, in the form of a " catalytic catenary " (Nelson and Beegle, *J. Amer. Chem. Soc.*, 1919, **41**, 559; Kuhn and Jacob, *loc. cit.*; Euler, *Z. anorg. Chem.*, 1925, **146**, 45; 1926, **152**, 113). The resulting curve falls to a shallow minimum at p_{H} 5, and rises steeply on each side in order to show the rapid increase of velocity which is observed in acid or alkaline solutions for which $p_{\mathrm{H}}<2$ or >8, *i.e.*, at concentrations of acid or alkali greater than $N/100$ or $N/1{,}000{,}000$, respectively. The purpose of the present paper is to prove by direct experiment that the algebraic and the geometric methods of representation are alike inadequate, unless the catalytic activity of at least three other possible components of the solution is also taken into account.

Experimental.

(a) *Materials.*—The glucose included a sample recently used in establishing a standard value for the velocity coefficient of the pure sugar (Richards, Faulkner, and Lowry, this vol., p. 113), together with a similar sample which had been purified and tested in the same way. The sodium acetate was thrice recrystallised from distilled water. Acetic acid was distilled from 2% chromic anhydride (Orton and Bradfield, J., 1924, **125**, 960), and on redistillation the fraction of b. p. 116—118° was collected; after freezing, it melted at 16·2°, and therefore contained about 0·2% of water. Hydrochloric acid (approximately $0{\cdot}2N$) was standardised by estimating the chlorine gravimetrically, and was diluted to the required strength with conductivity water. The pyridine had been purified by Dr. I. J. Faulkner for experiments on mutarotation (J., 1925, **127**, 2883). The phenol was colourless and melted at 40°. Sodium carbonate and bicarbonate of " A. R." quality were used without further purification.

(b) *Polarimetric and Electrometric Measurements.*—The velocities of mutarotation were determined in solutions containing 2 g. of glucose in 20 c.c. of the solution at 20°; the velocity coefficients

(k_c) are for time in minutes and for natural logarithms. After mutarotation was complete the p_H values of the solutions were determined by standard methods. When a hydrogen electrode was used, the gas was passed through alkaline permanganate and saturated mercuric chloride solutions, then over electrically-heated palladinised copper, through water, and finally through a solution identical with that under investigation before entering the electrode vessel; the values of the *E.M.F.* recorded for two electrodes in no case differed by more than 1 millivolt. These p_H values were checked by measurements with the quinhydrone electrode, or, when the concentration of electrolytes exceeded 0·1*M*, with the hydroquinhydrone electrode (Biilmann, *Trans. Faraday Soc.*, 1924, **19**, 676). The bicarbonate and carbonate solutions (p_H 7—9) were examined by Dr. W. S. Hughes with a glass electrode, which had been standardised against a phosphate buffer (p_H 6·80) and a borate buffer (p_H 9·24, as determined by means of a hydrogen electrode).

Determination of the Catalytic Catenary for Glucose at 20°.

Since the data of Kuhn and Jacob related to 25°, a fresh catalytic catenary was plotted for 20°, for comparison with the data of Euler (*Z. anorg. Chem.*, 1926, **152**, 113). This was done (as in the experiments of the earlier workers) by using dilute hydrochloric acid and sodium bicarbonate or carbonate to produce the desired degrees of acidity or alkalinity. The electrometric and polarimetric data are set out in Table I, and the velocity coefficients from Table I have been plotted in Fig. 1 against the p_H values of the solutions.

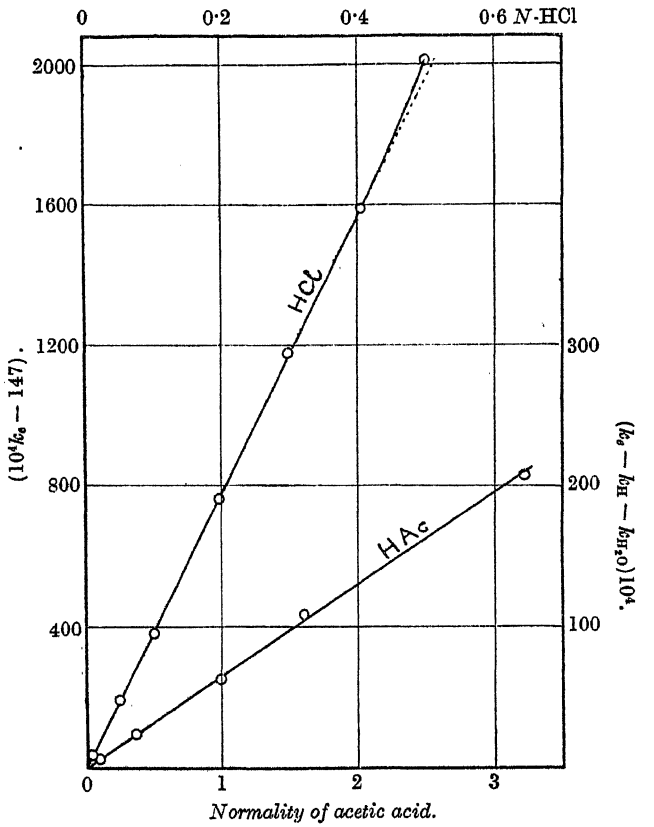
The velocities measured by Euler at 20°, and by Kuhn and Jacob at 25°, have also been included in the figure, the latter being divided

FIG. 1.



Velocity of mutarotation of glucose at 20° in acid and alkaline solutions: (a) *the hollow circles are for solutions made acid with hydrochloric acid or alkaline with sodium carbonate or bicarbonate. The crosses* (+) *on a dotted curve represent Euler's data for* 20°. *The diagonal crosses* (×) *represent Kuhn and Jacob's data for* 25° *reduced to* 20° *by dividing the velocity coefficients by* 1·65 ; (b) *the black circles are for solutions containing* (i) *various proportions of acetic acid* (*L.H.*), (ii) N/10-*acetic acid with various proportions of sodium acetate* (*R.H.*).

by 1·65 to allow for the difference of 5° in temperature (Hudson and Dale, *J. Amer. Chem. Soc.*, 1917, **39**, 320).

(a) *Acid solutions.* The velocity coefficients and hydrogen-ion concentrations were measured in 10% solutions of glucose in aqueous hydrochloric acid over a range from 0·0001 to 0·5*N*-acid. The p_H values, which were determined with a hydrogen electrode and checked in some cases with a hydroquinhydrone electrode, agree closely in this part of the catenary with those given by the

FIG. 2.

Velocity of mutarotation of glucose at 20° in presence of hydrochloric and acetic acids.

earlier workers; but these electrometric data do not give a very satisfactory constant for the catalytic coefficient of the ion. On the other hand, Fig. 2, in which the increment produced by the acid in the velocity coefficient of the sugar is plotted against the volumetric concentration of the acid, shows a linear relation between these two quantities which persists up to about 0·4*N*, but is then followed by a definite upward curvature. The values of the ratio

$(k_e - 0{\cdot}0147)/c$, which are given in the last column of Table I, show a small progressive increase with increasing concentration, from 0·38 at 0·05N to 0·40 at 0·5N. This increase can be explained quite readily by accepting Snethlage's view that the catalytic coefficient of the undissociated molecules of hydrochloric acid is greater than that of the hydrogen ions derived from them. Since the degree of dissociation of hydrochloric acid in water is about 83% at $N/2$ and 93% at $N/20$, a rough extrapolation to zero concentration would give a limiting value of 0·36 for the catalytic coefficient of the hydrogen ion at 20°. This agrees closely with the coefficient given by Hudson, which is about 0·36, when reduced to base e and divided by 1·65 to correct for the difference of 5° in temperature. A much rougher estimate shows that, since the catalytic coefficient of the acid is increased in the ratio of 19 : 20 when the ionisation is decreased from 93 to 83%, that of the undissociated molecules of the acid must be about half as great again (1·53 : 1) as that of the hydrogen ions derived from them, in close agreement with the ratio 1·55 : 1 deduced by Dawson in 1915.

(b) *Alkaline solutions.* On the alkaline side, the quinhydrone electrode is no longer trustworthy, and the hydrogen electrode is subject to error as a result of the displacement of carbon dioxide from the solutions by hydrogen. We have therefore based our calculations on a series of determinations by Dr. W. S. Hughes, in which a glass electrode was used. The alkaline arm of our catenary is therefore notably different from that of the catenaries plotted by Kuhn and Jacob, and by Euler, which are practically coincident when allowance is made for the different temperatures at which their measurements were made. We believe, however, that the velocities now recorded for the mutarotation of glucose in alkaline solutions ($p_H > 7$) are free from a source of error that was previously present, and are therefore more trustworthy than those published hitherto. Whilst, however, it is possible to deduce a satisfactory value for the catalytic activity of the *hydrogen ion* from measurements of the velocity of change in a dilute solution of a strong acid, this cannot be done in the same simple way in the case of the *hydroxyl ion* of an alkali because (i) the concentrations of alkali that are required to produce a given velocity are about 30,000 times smaller than in the case of an acid, and (ii) a very dilute solution of a free alkali inevitably becomes carbonated, and to an unknown extent, by the carbon dioxide of the atmosphere. The required degree of alkalinity can therefore only be maintained by using a "buffer solution"; and, as Kuhn and Jacob have shown, the anion of the buffer solution may have a catalytic activity which is comparable in magnitude with that of the trace of hydroxyl

ions which the solution contains. Since precisely the same considerations must apply to a carbonate or bicarbonate as to a phosphate or citrate, it is clear that solutions that have been made alkaline with sodium carbonate or bicarbonate cannot be used to give an exact value for the catalytic activity of the hydroxyl ion, unless a correction is made for the catalytic activity of the carbonate and bicarbonate ions, of which the concentrations are uncertain and the specific catalytic activities unknown. We therefore merely put on record the fact that the catalytic coefficient of the hydroxyl ion is probably less than $k_e = 20{,}000$, since this number includes the catalytic activity of the bicarbonate ions as well as of the hydroxyl ions; but we are not yet prepared to put forward a more definite value.

(c) *Neutral solutions.* The concentrations of the hydrogen and hydroxyl ions at the isoelectric point are so small that their effect on the velocity of mutarotation of the sugar (as calculated from the effects produced by higher concentrations of acid or alkali) is only of the order of 1×10^{-5}, and is therefore quite inappreciable. This is true, not only at the isoelectric point, but over a considerable range on either side, so that the central part of the catalytic catenary is almost horizontal over the range p_H 3—7. The actual velocity of mutarotation at the isoelectric point, however, so far from being inappreciable, is only a little less than it is in neutral water, where the influence of the ions should be about 100 times greater than at the isoelectric point. Thus Hudson's equation gives a velocity coefficient $k = 0{\cdot}0106$ for glucose in neutral water at 25°, falling to a minimum value of $k = 0{\cdot}0097$ at the isoelectric point; the velocity at the isoelectric point is therefore 91·5% of that in neutral water. In the same way, the minimum velocity, $k = 0{\cdot}01041$, calculated from the equation of Kuhn and Jacob is 92% of the velocity, $k = 0{\cdot}01133$, in neutral water. These authors therefore concur in postulating a diminution of about 8% in the velocity of mutarotation of glucose in feebly acid solutions. On the other hand, this effect was not observed by Andrews and Worley (*J. Physical Chem.*, 1927, **31**, 882). In the present series of experiments, our own measurements have given a velocity coefficient $k_e = 0{\cdot}0147$ at p_H 3·23 and 3·42, and $k_e = 0{\cdot}0150$ at p_H 6·18, as contrasted with the standard value $k_e = 0{\cdot}0146$ in neutral water at 20°. These measurements therefore afford no experimental confirmation for the very plausible theoretical view that the velocity coefficient in feebly acid solutions should be rather less than in pure water; and it is noteworthy that Euler also does not record any value less than 0·0146 for the velocity coefficient of glucose at 20°, although his measurements at 5·2° show a well-marked minimum.

Determination of the Catalytic Coefficient of an Undissociated Acid.

The catalytic coefficient of the undissociated molecules of a strong acid is difficult to detect, because this component only becomes important at high concentrations, when the velocity of mutarotation is too great for accurate measurement. We can, therefore, only put on record a general statement to the effect that the catalytic coefficient of the undissociated molecules of hydrochloric acid is apparently about 1·5 times as great as that of its ions. In the case of a weak acid, such as acetic acid, however, a fairly accurate value for the catalytic coefficient of the undissociated acid can be deduced from the measured velocities of mutarotation of glucose in solutions of the acid. The data for 10% solutions of glucose in acetic acid over the range 0·1—3·22N are set out in Table II and plotted in Fig. 2.

TABLE II.

0·100	2·78	0·0158	0·0152	0·0006	—

In Fig. 2 the velocity coefficients have been diminished by an amount equal to the value of the coefficient in dilute hydrochloric acid of equal electrometric activity, and the differences have been plotted against the normality of the acetic acid. The relation between these two quantities is linear over the whole range of concentrations. This difference is a measure of the catalytic activity of the acid, after allowing for the catalytic activity of the hydrogen ions and of the water in the solution. Since the acid is ionised only to a very small extent (about 1%) even in the most dilute solutions, the constant ratio shown in the last column of Table II gives the catalytic coefficient of the undissociated acid, $k_e = 0{\cdot}0065[\mathrm{HAc}]$.

Determination of the Catalytic Coefficients of Anions and Kations.

Although the equations of Hudson and of Kuhn and Jacob contain a "neutral water" term (which is not present in Dawson's equation), there is nothing in their equations to correspond with Dawson's "anion" term. This omission is all the more remarkable in view of the observations made by Kuhn and Jacob on the catalytic activity of buffer solutions. A most important feature

of the present experiments, therefore, was an attempt to discover the existence of an "anion" term in mutarotation, and to determine its magnitude in some particular case. It was already clear from earlier observations that the ions of sodium and potassium chlorides had no marked catalytic properties; but we anticipated on theoretical grounds that the anion of a weak acid might possess appreciable catalytic activity. A difficulty immediately arises, however, from the fact that the salts of a weak acid are hydrolysed to an extent which increases as the dissociation constant of the acid diminishes; moreover, the catalytic activity of the hydroxyl ions resulting from this hydrolysis is so enormous that it would entirely mask any small catalytic activity due to the anion of the acid, unless the latter were present at relatively enormous concentrations. For this reason we adopted the device of adding to the neutral salt (*N*-sodium acetate solution) a quantity of the free acid (*N*/10-acetic acid) sufficient to make the reaction of the solution definitely *acid* instead of *alkaline*. The ideal condition would, of course, be to work at the isoelectric point, where the velocity of mutarotation (in the absence of some catalytically active ion other than hydrogen and hydroxyl) would be, if anything, rather less than in pure water.

(a) *Catalytic coefficient of the acetate ion.* Our first experiment showed that a solution of glucose in *N*-sodium acetate gave a velocity coefficient, $k_e = 0{\cdot}0982$ at 20°, which was nearly *seven* times as great as in neutral water ($k_e = 0{\cdot}0146$ at 20°). In this case an acceleration was inevitable in view of the alkaline character of the salt; but this explanation was no longer possible in a second experiment in which the velocity coefficient for 0·961*N*-sodium acetate, *in a solution acidified with* N/10-*acetic acid* to p_H 5·54, was found to be $k_e = 0{\cdot}0822$, or about *six* times as great as in water. In this experiment, if hydrogen and hydroxyl ions and neutral water had been the only catalysts in the solution, the velocity coefficient would have been $k_e = 0{\cdot}0147$; and a correction for the catalytic activity of the undissociated molecules of acetic acid would have increased this only to $k_e = 0{\cdot}0153$. This number is rather less than one-fifth of the velocity coefficient actually observed, and, since the sodium ion is known to be inactive, the other four-fifths of the observed velocity must have been due to the *acetate ion*, which was thus shown to be an active catalyst for the mutarotation of the sugar.

Table III gives the velocity coefficients and p_H values for a series of solutions containing *N*/10-acetic acid, with various proportions of sodium acetate. The velocity coefficients of these solutions are plotted against the p_H values in the form of a catalytic catenary

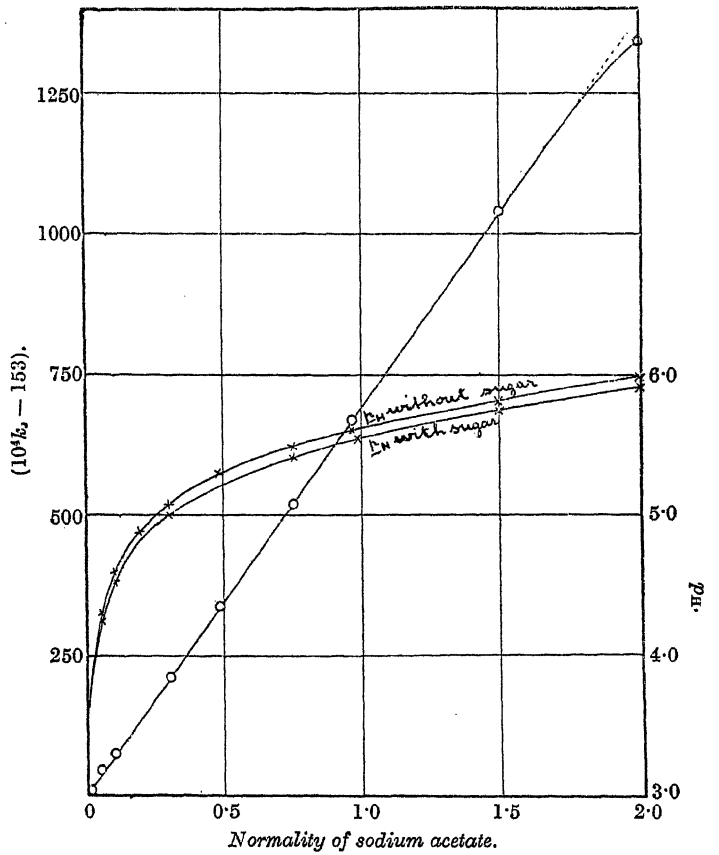
in Fig. 1, whilst in Fig. 3 the p_H values are plotted against the concentrations of sodium acetate.



The p_H values plotted in the upper curve of Fig. 3 *for solutions which did not contain any sugar* agree closely with those given by Dawson, but these values were lowered when determined in presence of 10% of glucose by an amount which varied from 0·02 to 0·06 as the concentration of the sodium acetate increased from 0·0096 to 0·3N, and then remained almost constant up to 2N.

The solutions now under consideration were too near to the isoelectric point to exhibit any marked catalysis by hydrogen or hydroxyl ions, but they all contained, in addition to the acetate ion, the catalytically active molecules of water (which would give a partial velocity coefficient of 0·0147) as well as active molecules of N/10-acetic acid (which would give a partial velocity coefficient of 0·0006). Fig. 3 shows that, when the difference between the observed velocity coefficients and a constant partial velocity coefficient of 0·0153 is plotted against the volumetric composition of the sodium acetate, these two quantities are proportional to one another over the range from 0·0096N to 1·5N. The ratio $(k_e - 0{\cdot}0153)/c$, which is given in the last column of Table III, tends to increase in the most dilute solutions; but, over the range from 0·3N to 2·0N, it gives an average value for the catalytic coefficient of the acetate ion, $k_e = 0{\cdot}069$. In Dawson's experiments on the iodination of acetone, the catalytic coefficient of the acetate ion was about 3 times as great as that of the undissociated molecule of acetic acid, but the ratio of the two coefficients, when deduced from a study of their influence on the mutarotation of glucose, is rather greater than 10 to 1.

(b) *Catalytic coefficient of the ammonium ion.* Theoretical reasons led us to suppose that catalytic activity need not be confined to the *anion* of a salt, but that a *kation* might possess similar catalytic powers, provided that it could be classed as a proton donator. We therefore determined the velocity of mutarotation of glucose

in a *N*-solution of ammonium chloride, and found that, although the hydrogen-ion concentration of the solution (p_H 4·7) coincided almost exactly with the isoelectric point, the velocity coefficient, $k_e = 0{\cdot}0159$ at 20°, was actually 8% greater than in neutral water. The catalytic coefficient of the ammonium ion as deduced from

FIG. 3.

Velocity of mutarotation and p_H *values for solutions of glucose in* N/10*-acetic acid with various concentrations of sodium acetate.*

this experiment is approximately 0·0012. This is about one-fifth as great as the coefficient for undissociated acetic acid, but sixty times smaller than that of the acetate ion.

Catalytic Coefficients of Neutral Salts.

A comparison of the "acetate" catenary of Fig. 1 with the "carbonate" catenaries previously deduced from the behaviour of

carbonate and bicarbonate solutions is very instructive, since it shows the relatively small part that is played by the feeble acidity or alkalinity (p_H 2 to 8) of a buffer solution in determining the velocity of mutarotation of the sugar, and the enormous influence of the neutral or saline components of the solution. In order, however, to dissipate finally the idea that the velocity of mutarotation is determined predominantly by the acidity or alkalinity of the solution, or by its hydrogen-ion concentration, a number of measurements were made with aqueous solutions of glucose containing a salt of a weak acid and a weak base, under conditions which ensured that the hydrogen-ion concentrations were either approximately equal to that of neutral water or intermediate between that of neutral water and the isoelectric point. Since the velocity coefficients calculated from the equations of Hudson or of Kuhn and Jacob are substantially constant from p_H 3 to p_H 7, any solution in this range might be expected, on the basis of these equations, to give a velocity coefficient equal to, or slightly less than, that observed in neutral water; on the other hand, if our theoretical views were well-founded, it appeared likely that *a neutral solution containing the neutral salt of a weak acid and base* would change much faster than a neutral solution in pure water, or than a neutral solution containing only a neutral salt of a strong acid and base.

(a) *Ammonium acetate.* This prediction was tested by measuring the velocity of mutarotation of glucose in presence of *N*-sodium acetate and *N*-ammonium chloride. Since sodium chloride produces no important changes of velocity, this solution was equivalent to one containing *N*-ammonium acetate. As we anticipated, the sugar in this *neutral* solution changed even more rapidly than in a solution containing only *N*-sodium acetate, which has a strongly *alkaline* reaction, or in a solution of ammonium chloride, which is definitely *acid* in its reaction. The velocity coefficient, $k_e = 0{\cdot}106$ at p_H 6·66, was found to be *more than seven times* as great as in neutral water. It is also about 25% greater than the value, $0{\cdot}0147 + 0{\cdot}0012 + 0{\cdot}069 = 0{\cdot}085$, calculated by adding together the catalytic coefficients of neutral water and of the ammonium and acetate ions. This acceleration, which can be attributed to the " hydrolysis " of the salt to free ammonia and free acetic acid, was in accord with the expectations which we had formed in view of the increase in the amphoteric properties of the solution, which would result from the simultaneous presence of the weak acid and the weak base. The approximate value of the catalytic coefficient of the salt in its various forms is 0·091.

(b) *Pyridine and phenol.* The neutral-salt effect described in the preceding paragraph (which is of a totally different character

from that postulated by Arrhenius, since the increment of velocity produced by the neutral salt was 626% instead of only 12·6%) would obviously become negligible if the acid and base were so weak as no longer to exhibit any appreciable acid or basic properties; it is also known to be negligible when the acid and base are both strong. The effect must therefore rise to a maximum at some intermediate value of the dissociation constants. For this reason, the experiment was repeated, but with phenol and pyridine as the acid and base in place of acetic acid and ammonia. The relevant dissociation constants are set out below, whilst the velocity coefficients and p_H values are included in Table IV.

Acid dissociation constant, K_a.		Basic dissociation constant, K_b.	
Phenol :	$1{\cdot}1 \times 10^{-10}$ at 18° or 25°	Pyridine :	$1{\cdot}6 \times 10^{-9}$ at 18° $2{\cdot}3 \times 10^{-9}$ at 25°
Acetic acid :	$1{\cdot}8 \times 10^{-5}$ at 18° or 25°	Ammonia :	$1{\cdot}75 \times 10^{-5}$ at 18° $1{\cdot}8 \times 10^{-5}$ at 25°

TABLE IV.

Mutarotation of glucose in presence of a weak acid and base.

Solvent.	p_H.	Velocity coefficient at 20°.
N-Sodium acetate	—	0·0982
N-Ammonium chloride	4·7	0·0159
N-Sodium acetate + *N*-Ammonium chloride	6·66	0·106
0·5*N*-Phenol	5·8	0·0146
0·1*N*-Phenol	6·21	0·0147
0·1*N*-Pyridine + 0·1*N*-Phenol	7·48	0·0447

Since phenol is not sufficiently soluble to give a *N*-solution, the acid and base were used at *N*/10-concentrations, and gave a velocity coefficient, $k_e = 0{\cdot}0447$ at 20° for p_H 7·48. The velocity coefficient was therefore 3 times as great as in water, although the p_H was changed by less than 0·5 unit from that of neutral water. If the slight alkalinity of the solution had been produced by a trace of sodium bicarbonate, the velocity coefficient would have been about 0·0175, or about 40% of that actually observed; the other 60% must therefore be due to the *N*/10-pyridinium phenoxide. The catalytic coefficient of the pyridinium salt as deduced from these data is roughly 0·272. It is noteworthy that the catalytic coefficient of the pyridinium salt in *N*/10-solution is about 3 times as great as that of ammonium acetate in *N*-solution, and is very nearly as large as that of the hydrogen ion, although it is still not so great as that of the undissociated molecules of a strong acid.

Summary.

(*a*) Although the mutarotation of glucose is catalysed by acids and bases, as well as by water, it is not affected appreciably by neutral salts of the type of sodium chloride.

(*b*) Definite catalytic activity has been detected, however, in (i) the undissociated molecules of a strong or weak acid, (ii) the anion of a weak acid, and (iii) the kation of a weak nitrogenous base.

(*c*) The catalytic coefficients of these components are

$$[HCl] \text{ about } 0{\cdot}5; \quad [\overset{+}{N}H_4] = 0{\cdot}0012;$$

$$[HAc] = 0{\cdot}0065; \quad [\bar{A}c] = 0{\cdot}069.$$

UNIVERSITY CHEMICAL LABORATORY,
CAMBRIDGE.

[*Received, July 28th*, 1927.]

CCCXL.—*Studies of Dynamic Isomerism. Part XXV. The Mechanism of Catalysis by Acids and Bases.*

By THOMAS MARTIN LOWRY.

Catalysis of Mutarotation by Acids and Bases.

THE fact that mutarotation, like so many other chemical changes, is not a spontaneous process, but depends on the presence of a catalyst (Lowry, J., 1899, **75**, 211), compels us to seek an explanation of the part played by the catalyst in effecting the change, and in particular to discover a reason for the unique efficiency of water as a solvent for the mutarotation of the sugars, and for the still more remarkable catalytic activity of acids and bases. The earliest suggestion (*ibid.*, p. 219) postulated that mutarotation could be initiated by any oxygenated solvent, since the changes of rotatory power in these solvents were usually very rapid when compared with the slow changes observed in hydrocarbons and in analogous solvents such as chloroform. This view became untenable, however, when it was found that the mutarotation of nitrocamphor could be "arrested" by adding a trace of carbonyl chloride to *ether*, in order to eliminate basic impurities (Lowry and Magson, J., 1908, **93**, 119). It was then pointed out that catalytic solvents all appeared to be of the type HX, and that solvents from which a hydrogen atom cannot be eliminated easily are not able to initiate isomeric change, although (as in the case of ether) they may contain oxygen, and may even possess ionising properties (*ibid.*, p. 132). Subsequent investigations (Lowry and Richards, J., 1925, **127**, 1385; Lowry and Faulkner, *ibid.*, p. 1883) showed that, although dry pyridine had been repeatedly cited as an effective catalyst for the mutarotation of glucose (Behrend and Roth, *Annalen*, 1904, **331**, 361), pyridine and cresol are alike impotent *in the absence of water*, but that when mixed with one another they develop a catalytic activity which is

far greater than that of water itself. The view was therefore advanced that the prototropic changes which give rise to the mutarotation of the sugars can only take place in an amphoteric solvent, *i.e.*, in a solvent which can both accept a proton from the sugar and give a proton back again to it or to its ion.

An entirely different method of approach to the problem is found in the theory put forward by Euler (Euler and Hedelius, *Biochem. Z.*, 1920, **170**, 150; Euler, Myrbäck, and Rudberg, *Arkiv. Kemi Min. Geol.*, 1923, **8**, No. 281) in order to provide a quantitative basis for determining the influence of acids and alkalis on the mutarotation of glucose. Euler supposes (i) that the velocity of mutarotation of glucose is proportional to the volume concentration of its *ions*, and (ii) that these ions are produced by the formation of *salts* of the sugar, on the one hand with alkalis, and on the other with acids. According to this theory, the velocity of mutarotation of the sugar in a solution of given acidity or alkalinity could be calculated from its acid and basic dissociation constants, K_a and K_b, together with the reaction velocities, r_a and r_b, of the anion and kation of the sugar salts; but in practice the calculation can only be carried out in the converse direction, since only one of the four fundamental constants has been measured by an independent method. This one independent constant is the acid dissociation constant of glucose in water at 18°, which was determined electrometrically by Michaelis and Rona (*Biochem. Z.*, 1913, **49**, 232) from the change of "hydrogen-ion concentration" on adding the sugar to a dilute alkali. Euler and Hedelius (*loc. cit.*) measured the velocity of mutarotation of glucose in buffer solutions containing sodium citrate and hydrochloric acid of $N/10$ and $N/100$ concentration, and deduced (by extrapolation to zero concentration of buffer solution) the value $k^* = 0{\cdot}0066$ for the minimum velocity at 20°, and $p_H = 3{\cdot}6$ for the hydrogen-ion concentration at this point of maximum stability of the sugar; they then used the value, $K_a = 6{\cdot}6 \times 10^{-13}$, given by Michaelis for the *acid dissociation constant* of the sugar at 18°, in order to calculate an approximate value, $K_b = 10^{-19}$, for the *basic dissociation constant*, on the assumption that the point of maximum stability is identical with the isoelectric point and that the hydrogen-ion concentration at the isoelectric point is given by the equation $[H^+] = \sqrt{K_a K_w / K_b}$, where K_w is the dissociation constant of water. In two subsequent papers (*Z. anorg. Chem.*, 1925, **146**, 45; 1926, **152**, 113), Euler used his own measurements of the acid dissociation constant of water at 5·2° in order to deduce values for the concentration of the sugar ions and for their reaction velocities at this temperature, which he

* The velocity coefficient calculated from logarithms to the base 10.

supposed to be equal to one another, since he obtained symmetrical catenary curves on plotting the velocity of mutarotation at 5·2° and at 20° against the p_H of the solution. In this way he deduced for the four essential constants at 5·2° the values $K_a = 1 \times 10^{-13}$; $K_b = 2 \times 10^{-18}$; and $r_a = r_b = 38$, the half-change period being therefore 0·45 sec. *for the ion of either sign.*

Euler's ionic theory of mutarotation was at once adopted by Kuhn and Jacob (*Z. physikal. Chem.*, 1924, **113**, 389) as the basis for their numerical calculations. These authors made a new series of measurements of the velocity of mutarotation of glucose at 25° in solutions of different degrees of acidity and alkalinity, and showed that it could be expressed by an equation which differed only slightly from that of Hudson. Since this equation contains a term which does not depend on the acidity or alkalinity of the solution, they concluded that the *neutral molecules* of glucose, as well as the kations and anions derived from them, undergo isomeric change. Moreover, since the two arms of their catenary curve were not symmetrical, they concluded that the reaction velocity of the anions and kations are not equal (as Euler supposed) but that the reaction velocity of the anions is 2·1 times as great as that of the kations. They therefore assigned to the reaction velocities at 25° of the neutral molecules of the sugar and of the kations and anions derived from them the values $r_u = 0{\cdot}0104$, $r_b = 54{\cdot}4$, and $r_a = 113{\cdot}2$. The dissociation constants of the sugar at this temperature were given as $K_a = 10{\cdot}5 \times 10^{-13}$ and $K_b = 7{\cdot}8 \times 10^{-17}$.

In his later papers, Euler also adopted the view that mutarotation is not due exclusively to the anion and kation of the sugar, but he suggested that the constant term in Hudson's equation need not necessarily represent the isomeric change of the undissociated molecules of the sugar, since it could also be attributed to a "zwitterion" (or bipolar molecule, compare J., 1925, **127**, 1371) carrying both a positive and a negative charge, or to "some form of glucose which is present at a concentration proportional to that of the uncharged molecules."

It will be seen that, whilst the simple ionic theory of mutarotation can be used to calculate hypothetical values for the ionisation of the sugar, and for the reaction velocities of its ions, it does not provide any numerical data which can be checked by independent experiments. It is, moreover, definitely incompatible with our more recent observations on mutarotation in non-aqueous solutions, and must be rejected for the following reasons:

(i) If the sugar is capable of being ionised by mere dissolution in water, according to the scheme $HS \rightleftharpoons H^{\cdot} + S'$, it must obviously be ionised even more readily to form an ionised pyridinium salt accord-

ing to the scheme $C_5H_5N + HS \rightleftharpoons C_5H_5NH^{\cdot} + S'$, when dissolved in anhydrous pyridine.* If then the ion S′ has a definite reaction velocity, as Euler supposes, this ion must at once undergo isomeric change and give rise to a very rapid mutarotation, since the half-life period of the ion (according to Euler's calculation) is less than a second. In reality, however, nothing of the sort happens, since the mutarotation of tetramethyl glucose in pyridine can be stopped completely over a period of 2 or 3 hours by very moderate purification and drying (Lowry and Richards, *loc. cit.*, p. 1398).

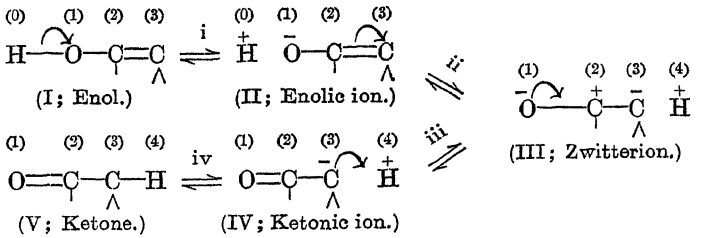
(ii) Conversely, if the sugar is capable of being ionised, either by removal of hydroxyl or by addition of hydrogen, according to the scheme $HOS \rightleftharpoons HO' + S^{\cdot}$ or $S + H^{\cdot} \rightleftharpoons HS^{\cdot}$, it seems certain that this ionisation must be promoted by dissolving the sugar in an acidic solvent, such as cresol, which would form an ionised salt according to the scheme $C_7H_7{\cdot}OH + HOS \rightleftharpoons C_7H_7{\cdot}O' + S^{\cdot} + H_2O$, or $C_7H_7{\cdot}OH + S \rightleftharpoons C_7H_7O' + HS^{\cdot}$. The ionic theory then indicates once more that this ionisation must be followed by a rapid isomeric change, and consequent mutarotation, in accordance with the ordinary laws of mass action and reaction velocity. Actually, however, the velocity of mutarotation of tetramethyl glucose in cresol is almost inappreciable, since it is at least forty times less than in pure water.

(iii) Finally, if the simple ionic theory were correct, mutarotation must inevitably occur *in any ionising solvent*, whereas experience has shown that it is only in the case of media which possess definite amphoteric properties that we can assert with any degree of confidence that the pure solvent is a complete catalyst for mutarotation. Thus, even in the case of methyl alcohol, which is quite a good ionising solvent, the very low velocity coefficient observed by Faulkner and Lowry (J., 1926, 1938) has been reduced about 8-fold in the recent experiments of Worley and Andrews (*J. Physical Chem.*, 1927, **31**, 742), so that the residual velocity of change is now altogether insignificant.

On all these grounds the simple ionic theory of catalysis is seen to be untenable in the light of experiments on mutarotation in non-aqueous solutions.

An Electrolytic Theory of Catalysis.

A mechanism of catalysed mutarotation, which is in harmony with the observations cited above (and which actually led to the experiments by which most of the relevant facts were discovered)



* It is assumed that the pyridine has not been dried so perfectly as to inhibit completely the formation of a salt, as in Baker's experiments on dry ammonia and hydrogen chloride.

was described in 1925 (J., 127, 1371). This mechanism depends on an initial *addition and subtraction of a proton* by a medium possessing both acid and basic properties, giving rise to the formation of a bipolar molecule or "zwitterion"; the rupture of a bond (by the conversion of the covalency into an electrovalency) then produces just those electric charges which are needed to neutralise the charges already present in the bipolar molecule, and thus gives rise immediately to the intermediate aldehydic form of the sugar. Only two additional points are needed in order to make this mechanism cover also Dawson's recent experiments on the iodination of acetone in presence of acids and their salts, as well as the new observations on mutarotation which are described in Part XXIV (preceding paper). These additional points are (i) a clear recognition of the fact that prototropic change involves *a flow of electrons through the molecule*, in addition to the transfer of a proton to and from the medium, and (ii) an extended conception of the meaning of the terms acid and base, to include all those ions and molecules which are able to give or to receive a proton. The isomeric change is then seen to depend on a process which is closely analogous to an electrolysis of the prototropic compound between positive and negative poles provided by the basic and acid components of the medium.

(a) *Electron-migration as a Condition of Isomeric Change.*—It is not generally realised that the process of isomeric change in unsaturated compounds involves a flow of electrons through the molecule, as well as the migration of a radical. It is, however, obvious that, if the *radical* migrates in the form of an *ion*, it must deliver up an electric charge at its new point of attachment, whilst leaving behind a charge of opposite sign at the point of departure; the elimination of these electric charges is therefore an essential feature of the isomeric change. It is then easy to show that the rearrangement of bonds (described by Jacobsen as "desmotropy"), which accompanies isomeric change in unsaturated and conjugated systems, actually consists in a transfer of valency electrons from atom to atom, and that this transfer produces a flow of electrons of precisely the kind that is required to neutralise the charges set up by the migration of the ion.

Since the iodination of acetone, which has formed the basis of Dawson's recent experiments on catalysis, depends on the enolisation of the ketone (Lapworth, J., 1904, 85, 30), it will be convenient to select this type of isomeric change as an illustration of the general proposition set out above. We will therefore suppose that an enol is to be changed into a ketone by an ionic mechanism of the same general character as that postulated by Euler and by Kuhn and Jacob for an action catalysed by bases. The four consecutive

stages (i)—(iv) of such a process may be illustrated by a scheme of the same general character as that already used to represent the mutarotation of a sugar (J., 1925, **127**, 1384), but dissected into a series of steps as follows :

(i) *Ionisation of the enolic compound.* In this process, the pair of shared electrons which constitutes the hydrogen–oxygen bond in (I) is transferred *in toto* to the oxygen atom in (II); the oxygen atom (1) thus acquires an electron whilst the hydrogen atom (0) loses one.

(ii) *Isomeric change of the enolic ion.* In passing from (II) to (III), the pair of shared electrons which represents the second link of the 2 : 3-double bond is transferred *in toto* to the carbon atom (3), which thus acquires an electron, whilst the carbon atom (2) loses one.

(iii) *Formation of the ketonic ion.* In passing from (III) to (IV), a lone pair of electrons on the oxygen atom (1) is shared with the carbon atom (2) in order to form the second link of the ketonic double bond; in this process the oxygen atom (1) loses an electron and the carbon atom (2) gains one.

(iv) *Formation of the ketone.* Finally, in passing from (IV) to (V), a proton is fixed in the position (4) by sharing a lone pair of electrons belonging to the carbon atom (3); in this case the hydrogen atom (4) gains an electron and the carbon atom (3) loses one.

Each stage in the process is therefore accompanied by the transfer of an electron from left to right, and these four transfers are equivalent to moving a single electron *through the organic compound* from (0) to (4). They thus provide the necessary electrical compensation for the migration of the proton *through the medium* from (0) to (4).

(b) *Characteristics of the Electrolytic Theory of Catalysis.*—(i) The chief novelty of the electrolytic theory consists in the suggestion that isomeric change in the molecule or the ion is effected *by a displacement of valency electrons* between the two alternative points of attachment of the proton, which may be described as the "terminals" of the labile system. Since, however, it has already been pointed out (*Nature*, 1925, **115**, 376) that a mechanism for effecting this flow of electrons is present in all conjugated compounds, it is not

necessary to elaborate this point in connexion with the simpler case of keto–enolic change.

(ii) When compared with the simple ionic theory described above, the electrolytic theory is seen to depend on a *ternary reaction* between the sugar and the acid and basic components of the solvent, whereas Euler postulated a *binary reaction* between the sugar and a catalyst, which may be either acid or basic, but not both. It is, of course, possible that, if the sugar were ionised, say by the removal of a proton with the help of an alkaline catalyst, the resulting anion might be discharged by a proton coming into contact with the opposite " terminal " of the sugar, instead of with the "terminal" from which the proton had been originally removed, thus giving rise to an isomeric form of the sugar; but no provision is made in Euler's theory for any independent supply of protons for this purpose, apart from those which were derived in the first instance from the sugar by ionisation. The electrolytic theory, on the other hand, definitely requires that the medium, instead of being merely an ionising solvent, must be one which can act both as a " proton source " and as a " proton sink."

(iii) A third feature of the electrolytic theory is to be found in the suggestion that the easiest way of effecting isomeric change is to bring the organic compound into a circuit in which it is in contact *simultaneously* with a proton acceptor and a proton donator. It has already been suggested (J., 1925, **127**, 1383, footnote) that the changes in question " may occur simultaneously in the same electric circuit, as in Armstrong's theory of chemical change "; but this tentative suggestion is now advocated as affording for the first time an adequate explanation of the impotence of acids and bases to produce mutarotation when acting alone, and of their wonderful efficiency when acting together. The obvious alternative is to suppose that the acid and basic components of the medium may act on the sugar *consecutively* instead of simultaneously. Thus the action might be supposed to depend on *two consecutive bimolecular actions*, in which the acid and basic components act independently on the sugar (i) to produce a sugar ion by the addition (or removal) of a proton, and (ii) to discharge this ion through the body of the sugar by the removal (or addition) of a proton at the opposite " terminal " of the labile system. The initial stage in this action is, however, an endothermic process, in which the molecules of the sugar are converted into ions of such an unstable character that the dissociation constants are said to be of the order of 10^{-13} and 10^{-19}. The exact amount of energy required to produce these ions is unknown; but it is obvious that, if we can regard the entrance and the exit of the proton as simultaneous, no energy at all is needed beyond the small

amount that is required to cover the difference in energy content of the two isomerides, and perhaps to overcome the "frictional" resistance to the migration of an electron through the sugar. The ternary reaction therefore exhibits, in a characteristic form, the essential feature of a catalysed reaction, since, by making use of a "coupled reaction" in place of two consecutive reactions, it avoids the necessity for lifting the molecule to the high energy level represented by its extremely unstable ions.

Acidity and Basicity as Factors in Catalysis.

In order that the electrolytic theory of catalysis may cover Dawson's experiments, as well as the new results set out in the preceding paper, it is necessary to abandon the narrow definition which measures acidity in terms of hydrogen-ion concentration and basicity in terms of hydroxyl-ion concentration, and to make use of definitions and constants which are not limited to the special case of aqueous solutions. Thus, when water is the solvent, the basicity of a solution can be expressed in terms of its alkalinity, as measured by the concentration of hydroxyl ions in the liquid; but this is no longer true of solutions of nitrogenous bases in non-aqueous solvents, many of which do not contain any oxygen at all. We have, therefore, adopted the more modern view, which regards acidity as a characteristic property of all those hydrogen compounds which can give up a proton to some other molecule or ion, whilst basicity is the more general and passive property of being able to accept a proton from an acid.

(a) *Acid catalysts.* If this conception is adopted we must include as *acids* all those ions or molecules which can give a proton to acetone or to a sugar. Of these acidic catalysts, we may exclude from our consideration the *free hydrogen ion*, $H^{\cdot}$, which is probably non-existent in solution, since its formation can only take place by an endothermic action involving the absorption of about 260,000 calories; it can, however, be replaced (perhaps quantitatively) by the *oxonium ion*, $OH_3^{\cdot}$, which is probably the principal form in which "hydrogen ions" exist in the solution, although the presence of $OH_4^{\cdot\cdot}$ is not excluded. The *undissociated acid*, HX, must also be classed with the oxonium ion as a proton donator, and may therefore be an active catalyst, apart altogether from any pre-existent ionisation, since there is nothing to prevent the molecule of acid from giving a proton directly to the acetone or to the sugar, instead of passing it on (as an oxonium ion) through the agency of a molecule of water; it is also clear that the undissociated molecule of a strong acid is necessarily a more powerful proton donator than the molecule of a weak acid, and must therefore be a much more powerful catalyst,

as Snethlage and others have found to be the case. *Neutral water* also must be classed as a proton donator, quite independently of its pre-existent ionisation, since here again there is no reason why one molecule of water should be compelled to make use of a second molecule of water as an agent for transferring a proton to the ketone or to the sugar.* According to our theory, however, these proton donators can only act in conjunction with a proton acceptor, which in dilute aqueous solutions will usually be a molecule of the solvent.

(b) *Basic catalysts.* Amongst the bases or proton acceptors it is usual to reckon only the *hydroxyl ion* as having any catalytic activity, but for the present purpose the molecule of *neutral water* must also be included as a basic catalyst, in view of the readiness with which it can combine with a proton from the acetone or from the sugar to form an oxonium ion. More novelty is to be found in the perfectly logical conclusion of Brönsted (*Rec. trav. chim.*, 1923, **42**, 718) that *the anion of an acid* is also a base or proton acceptor, in view of the fact that it can combine with a proton to form a molecule of the undissociated acid. The fact that *the basicity of the anion is inversely proportional to the acidity of the acid* provides an obvious explanation of the fact that the chloride ion has no marked catalytic activity, such as is possessed by the acetate ion in virtue of the weakness of the acid from which it is derived. It is of interest to notice that, whilst ammonia is a *base* in virtue of its ability to accept a proton from an acid, the resulting ammonium ion is an *acid* (just like an oxonium ion) in virtue of its ability to give up a proton, *e.g.*, when the ammonium salt is dissociated into the free acid and base, $NH_4Cl \rightleftharpoons NH_3 + HCl$. In the case of ammonium acetate or pyridinium phenoxide, there is a similar reversal of function on the two sides of the equation:

$$\underset{\text{acid}}{CH_3\cdot CO\cdot OH} + \underset{\text{base}}{NH_3} \rightleftharpoons \underset{\text{base}}{CH_3\cdot CO\cdot \bar{O}} \underset{\text{acid}}{\overset{+}{N}H_4}$$

$$\underset{\text{acid}}{C_6H_5\cdot OH} + \underset{\text{base}}{NC_5H_5} \rightleftharpoons \underset{\text{base}}{C_6H_5\cdot \bar{O}} \underset{\text{acid}}{\overset{+}{N}HC_5H_5}$$

On the other hand, a metallic ion, which can neither give nor accept a proton, possesses no acid or basic properties of any kind, and cannot act as a catalyst for mutarotation.

Applications of the Electrolytic Theory of Catalysis.

(a) *The Dual and Quadruple Theories of Acid Catalysis.*—The "dual theory" of acid catalysis met with a good deal of passive resistance merely because it was not easy to see how an acid could

* The ionisation of water cannot give rise to a free proton, and must therefore be written as $2H_2O \rightleftharpoons OH_3^{\cdot} + OH'$, instead of $H_2O \rightleftharpoons H^{\cdot} + OH'$.

act as a catalyst apart from its acidity, *i.e.*, its ability to liberate hydrogen ions. This difficulty no longer exists, however, if we admit that HX and OH_3^+ can both act as proton donators, and so contribute to the catalytic activity of the system, although only the ion is able to contribute directly to its electrical conductivity. Dawson's "quadruple theory" of catalysis presents even greater difficulties, since no hint is given to suggest why the *anions* of a salt should be catalytically active, but not the *kations*. The distinction thus made between anions and kations has, however, been shown to be fictitious, in that it only applies to metallic kations, which cannot take any part in a catalysis which depends on giving or receiving a proton; on the other hand, our own experiments have shown that the ammonium and pyridinium ions, which can give but not receive a proton, both act as catalysts for the mutarotation of a sugar in aqueous solutions. It is also clear that the catalytic activity of an anion depends on the weakness of the acid from which it is derived, and should therefore disappear, as experiment has proved (*e.g.*, in the case of the chlorides), when the anion is derived from a strong mineral acid. If, then, we admit that the kations of a weak base and the anions of a weak acid possess similar catalytic functions to the hydrogen and hydroxyl ions, since they must also be classed as acids and bases in terms of the modern definitions, all the coefficients in Dawson's equation for the catalysis of acetone are then seen to refer to molecules or ions which possess acid or basic functions, thus:

$$v = k_{H}[H^+] + k_a[A^-] + k_{OH}[OH^-] + k_m[HA].$$

On the other hand, those molecules and ions which cannot act as acids or bases are omitted from the equation, since they are not able to influence the course of the change.

(b) *Catalysis by Neutral Water.*—A similar difficulty to that encountered in connexion with the dual theory of acid catalysis is presented by the constant term in Hudson's equation for the velocity of mutarotation of glucose, which we may write as:

$$k_1 + k_2 = 0{\cdot}258[\overset{+}{H}] + 9750[\overset{-}{O}H] + 0{\cdot}0096.$$

The constant term, which accounts for practically the whole of the velocity at the isoelectric point, and for 92% of the velocity in neutral water, was regarded by Kuhn and Jacob as a measure of the velocity of isomeric change in *neutral molecules of sugar*, and by Euler as representing the *isomeric change of a "zwitterion"* derived from the sugar; but it can be explained much more naturally by regarding it as a measure of the catalytic activity of *neutral molecules of water*. It was, however, very difficult to see how water could

act as a catalyst, in a process that is catalysed specifically by acids and alkalis, except by dissociation into hydrogen and hydroxyl ions, the activity of which was already allowed for in the equation. On the other hand, since the electrolytic theory of catalysis postulates that prototropic change depends on the combined action of an acid and a base, we may regard the first two terms in the above equation as representing the combined action of (i) a hydrogen (or oxonium) ion acting as a proton donator at one "terminal" of the sugar, with water as proton acceptor at the other, and (ii) a hydroxyl ion acting as proton acceptor at one "terminal" point with water as proton donator at the other. There is then still room for a "neutral water" term to represent (iii) the action of a molecule of water acting as a proton donator (with formation of a hydroxyl ion) at one terminal, with another molecule of water acting as a proton acceptor (with formation of an oxonium ion) at the other terminal. This neutral-water term, which is independent of the acidity and alkalinity of the solution, does not appear in Dawson's equations, perhaps because the enolisation of acetone is too difficult a process to be effected to any appreciable extent by the combined action of two molecules of water and requires the intervention of at least one component with stronger acid or basic properties. Since, however, components of both types are necessary for the effective catalysis of a prototropic change, all the other terms in his equation must be regarded as representing the combined action of the ions or molecules of the catalyst *with neutral molecules of water*, which would be present in an enormous excess in the dilute aqueous solutions with which he worked.

(c) *Hydrolysis.*—Since the analogy between hydrolysis and prototropic change provided the experimental data from which the mechanism now under discussion was first deduced (J., 1925, **127**, 1379), it is inevitable that the electrolytic theory of mutarotation should be supplemented by an electrolytic theory of hydrolysis. Thus, when regarded from the point of view which is set out above, the rupture of the ester bond in hydrolysis and its formation in esterification are seen to involve a transfer of valency electrons, which is equivalent to the passage of an electric current; the process therefore again resembles an electrolysis of the organic compound between positive and negative poles provided by the acid and basic components of the solution. Whilst, however, any molecule or ion which is capable of accepting a proton from an organic compound can play the part of the base in promoting prototropic change, this is no longer true of hydrolysis, where the *hydroxyl ion* and the *neutral molecule of water* are the only catalysts which are able to provide the necessary atoms of oxygen and hydrogen. We can

therefore foresee that the acetate ion, which has such a marked effect on the mutarotation of glucose, can exert no *direct* action in promoting hydrolysis. Any effects which it can produce must then result from an indirect process of activating either the pre-existing hydroxyl ions or the ester, or (in some more vague way) the medium in which hydrolysis is proceeding. These effects may be purely apocryphal, although they have been used freely to support the view that catalysis by acids depends exclusively on the concentration of pre-existing hydrogen ions. It is, however, noteworthy that, whilst other workers have suspected that the undissociated acid as well as its ions can act as a catalyst in hydrolytic processes such as the inversion of cane sugar, the inherent activity of the anion of a weak acid was only demonstrated when catalysis was studied by a process depending on prototropic change, and not on hydrolysis. Whilst, therefore, it is quite possible that a physico-chemical analysis may disclose some influence of the anion on esterification or hydrolysis, it appears probable that this indirect effect will be very much smaller than the direct effects which have been observed in the iodination of acetone and in the mutarotation of glucose.

Summary.

(*a*) The catalysis by acids and bases of prototropic change and of hydrolysis is interpreted in terms of an electrolytic theory, according to which a flow of valency electrons through the molecule is produced by bringing a proton donator and a proton acceptor, or a hydroxyl donator, into contact with the two terminals of the labile complex.

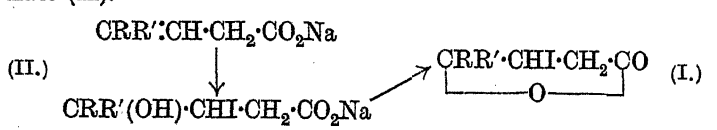
(*b*) An explanation is given of the parts played in the catalysis of isomeric change by (i) neutral water, (ii) the molecules of a strong acid, (iii) the anions of a weak acid, and (iv) the kations of a weak base. The ineffectiveness of metallic kations in isomeric change and of the anions of an acid in hydrolysis are also accounted for.

UNIVERSITY CHEMICAL LABORATORY,
CAMBRIDGE. [*Received, July 28th,* 1927.]

CCCXLI.—*The Quantitative Estimation of Mixtures of Isomeric Unsaturated Compounds. Part II. Iodometric Methods.*

By REGINALD PATRICK LINSTEAD and CECIL JOHN MAY.

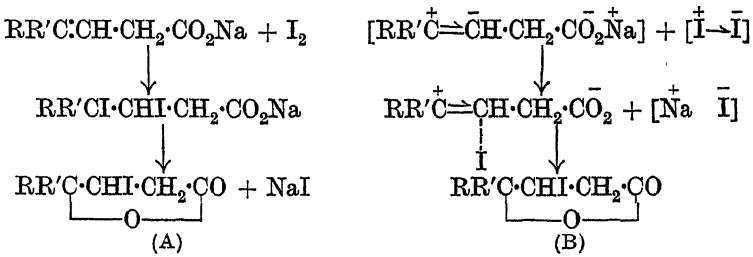
RAPID and quantitative addition of halogens to unsaturated substances is known to be prevented if the double bond is in the $\alpha\beta$-position with respect to a negative group. In the case of iodine



this prevention has been observed with a variety of compounds and is responsible for the low " iodine numbers " sometimes obtained.

For mixtures of isomerides of the type $CHRR_1{\cdot}CH{:}CHX$ ($\alpha\beta$) + $CRR_1{:}CH{\cdot}CH_2X$ ($\beta\gamma$), where X is CO_2H, CO_2R, COR, or other negative group, the velocity of addition of halogen depends on the proportion of the isomerides present, and a bromine addition method for the analysis of such mixtures, based on this principle, has been described (this vol., p. 355). The present communication deals with the application of iodometric methods for the same purpose.

I. *Acids.*



Iodine may be added to unsaturated acids in the form of the chloride (Hübl, Wijs), the bromide (Hanus), or as hypoiodous acid (Margosches, Bougault). In the present work these methods were tested by means of mixtures of two representative unsaturated acids, Δ^1-*cyclo*hexenylacetic acid ($\beta\gamma$) and *cyclo*hexylideneacetic acid ($\alpha\beta$). The $\alpha\beta$-acid showed a much lower reactivity in every case, but the methods did not yield uniformly satisfactory results. Under the conditions of Hübl and of Wijs the end-point in the back titrations was not clearly marked. The use of nascent hypoiodous acid from iodine, moist ether, and mercuric oxide (Bougault) was unsatisfactory for quantitative measurements. The method of Margosches and his collaborators (*Ber.*, 1924, **57**, 996) was of value when a high velocity of reaction was required (see p. 2569). In general, the sodium salt method of Bougault was most satisfactory (*Compt. rend.*, 1904, **139**, 864; *Ann. Chim. Phys.*, 1908, **14**, 145).

Bougault observed that when iodine in aqueous potassium iodide was added to unsaturated acids in sodium bicarbonate solution, $\alpha\beta$-acids were apparently unchanged whilst $\beta\gamma$-acids reacted to give as final products β-iodo-γ-lactones (I). Ponzio and Gastaldi (*Gazzetta*, 1912, **42**, ii, 92) suggested that $\alpha\beta$-acids react extremely slowly under these conditions, and their view has now been confirmed. The difference between the reactivities of the isomerides, however, is large and hence the reaction, as suggested by Bougault, is of value for analytical purposes. According to Bougault the reaction of the $\beta\gamma$-acids takes place by the addition of nascent hypoiodous acid; which must involve the formation of the intermediate (II).

Whilst the present work is not claimed to represent a full study of this reaction, the mechanism suggested above cannot be passed

without comment. In the first place addition of this type would involve an exceptionally high velocity coefficient for the reaction, account being taken of the facts that the formation of lactone is often extremely fast and the concentration of hypoiodous acid in the presence of the excess of sodium bicarbonate is very small (compare Francis, *J. Amer. Chem. Soc.*, 1925, 47, 2340). Again, the sodium salt of a γ-hydroxy-acid such as (II) should show no tendency to lactonise in alkaline solution. We suggest that the mechanism of the reaction is represented either by (A) or by (B), which is a modification of (A) based on the views of Francis (*loc. cit.*) on bromine addition, the first stage being the addition of positive iodine to the negative β-carbon of the ionised salt.*

The velocity of addition *inter alia* would be inversely proportional to the concentration of the salt of the di-iodo-acid (or its ionic equivalent) and would therefore be greatest when this was most rapidly removed as the insoluble lactone. The lack of reactivity of the αβ-acids can thus be attributed in part to the instability of the α-iodo-β-lactones which would be formed as final products. Recent investigations have shown that the presence of two β-substituents has a stabilising influence on the β-lactone ring and facilitates its formation, as anticipated by the Thorpe–Ingold modification of the Baeyer theory (private communication from Mr. S. F. Biggs). It is therefore to be expected that addition of iodine to αβ-acids may be appreciable in the case of ββ-disubstituted acids. We find that with a large excess of iodine under the conditions of Bougault, *cyclo*hexylideneacetic acid gives 32% addition in 24 hours, while with equivalent amounts of reagents the reaction occurs to the extent of some 1% per hour.

The method described by Bougault (*loc. cit.*), which depends on the actual isolation and weighing of unchanged acid (αβ) and of iodo-lactone, gives only approximately correct figures, as it is not possible to obtain complete reaction of the βγ-acid without some conversion of the αβ. In addition, β-iodo-lactones are unsatisfactory substances for quantitative estimation owing to the ease with

* We are indebted to Professor R. Robinson, F.R.S., for this suggestion.

which the iodine atom is displaced by hydroxyl. The following methods of analysis give satisfactory results.

(1) *When the pure isomeric acids are available.* The reaction of iodine with the mixed sodium salts is carried out as described in the experimental portion of this paper. The use of the concentrations suggested by Bougault leads to irregular results and in general the presence of an excess of iodine is detrimental. The most satisfactory results are obtained by using equivalent quantities of $N/20$-iodine and $N/15$-acid (against alkali). A curve connecting composition and percentage addition of iodine is constructed as described in Part I and the compositions of unknown mixtures are found by reference to it. This method is more convenient than that involving bromine addition and the absence of substitution reactions renders it more accurate. The experimental error does not exceed 1%.

(2) *When the isomeric acids cannot be isolated in the pure state.* With certain acids (see *e.g.*, Kon and May, this vol., p. 1549) it is either impossible to obtain definite evidence of homogeneity or else no methods are available for the complete separation of the isomerides, and the interpolation method can no longer be used. In these circumstances the separation method of Bougault has been applied to obtain the value for the position of equilibrium in the *cyclo*heptylideneacetic acids (Kon and May, *loc. cit.*), and the figure so obtained remains to be checked by the more accurate method now available. Attempts were also made to isolate pure di*iso*butylacrylic acid from mixtures by this method, but very little was obtained owing to the velocity of reaction of the αβ-acid with iodine. It has now been found possible to apply a correction for this source of error, which prevents the direct determination of the iodine taken up by the βγ-acid. The extrapolation method described below takes advantage of the *relatively* small reaction of an αβ-acid in mixtures containing its isomeride.

If iodine absorption is plotted against time for a pure βγ-acid, the curve will be that of an ordinary bimolecular reaction, ultimately becoming asymptotic to the line of 100% addition. The curve for the αβ-isomeride will follow the same general course, but over the period during which βγ-addition goes to completion it will approximate to a straight line. For a mixture of the two acids, the curve will resemble that for the pure βγ-acid, but instead of becoming asymptotic to a line parallel to the time axis it will continue along a line representing the αβ-addition after all the βγ-acid has reacted. If, therefore, this rectilinear portion of the curve is continued back to meet the axis, the point of intersection will represent the addition due to the βγ-acid alone. Or, if a_1 and a_2 are the addition values after times t_1 and t_2, then βγ-addition $= a_1 - t_1 (a_2 - a_1)/(t_2 - t_1)$.

It is, of course, only a first approximation to assume that the rate of $\alpha\beta$-addition remains constant during the progress of the $\beta\gamma$-reaction: actually it progressively decreases. The error involved, however, is not large if the conditions of experiment are carefully controlled. To test the accuracy of results so obtained, a series of titrations was carried out with mixtures of Δ^1-*cyclo*hexenyl- and *cyclo*hexylidene-acetic acids of known composition; the curves are shown in Fig. 2.

The strengths of the solutions and the details of the titrations are similar to those described in the experimental portion of this paper for the interpolation method (p. 2573). For a given mixture, four or five determinations of iodine addition must be made at accurately known intervals of time. The following additional features require attention.

(i) In general, the time for complete reaction lies between 2 and 3 hours, provided that the amount of $\beta\gamma$-acid is not above 50% and that the theoretical amount of iodine for 100% addition has been added. Sometimes, however, strict adherence to these conditions makes it necessary to extend the titrations for an inconveniently long time. The period may be shortened by employing an excess of iodine, but this device leads to the occurrence of side reactions. The necessary increase in reaction velocity may be brought about by applying the method of Margosches (*loc. cit.*), which eliminates potassium iodide by using alcoholic solutions of iodine. The retarding influence of potassium iodide on the reaction velocity is clearly shown by the following figures for the reaction with hydrosorbic acid ($CH_3{\cdot}CH_2{\cdot}CH{:}CH{\cdot}CH_2{\cdot}CO_2H$): Solutions of 0·0696 g. (0·61 $\times$ 10^{-3} g.-mol.) of the unsaturated acid in 10 c.c. of saturated bicarbonate solution and of 0·1580 g. (0·613 $\times$ 10^{-3} g.-mol.) of iodine in 25 c.c. of 50% ethyl alcohol were added in the order named to 10 c.c. of water containing a definite quantity of potassium iodide. The % reactions were:

KI (g.-mol. $\times$ 10^{-3}) ...	0	0·157	0·314	0·470	0·784	0·941	1·157
% Addition in 10 mins.	54·4	48·2	43·2	40·6	36·2	34·0	32·8

The occurrence of side reactions is not eliminated by this modification, for the curve for the pure $\beta\gamma$-acid shows a noticeable rise above 100% absorption. This does not appear to affect the results appreciably and it would seem that the effects of the side reaction are eliminated by the process of extrapolation employed.

(ii) While it is necessary to use sufficient iodine to ensure the virtual completion *of the* $\beta\gamma$*-reaction* within a reasonable time, any considerable excess over this amount is to be avoided; the amount of iodine used may therefore be reduced below the theoretical quantity for complete reaction of both acids, provided that an

excess of 10—20% above that required for complete $\beta\gamma$-addition is used. The requisite amount can be determined by carrying out a rough preliminary examination of the mixture.

(iii) The most satisfactory method of conducting the experiments is to mix the acid and iodine solutions in bulk and to remove aliquot portions for titration at definite times. This can, however, only be done when the lactone formed is soluble in the particular solution employed. Otherwise there is a tendency for the precipitated lactone to carry down iodine, and it becomes necessary to prepare a number of separate solutions, similar in all respects, each one being titrated as a whole. Iodine occluded in this way does not harm the accuracy of each individual titration, as the lactone is dissolved by the chloroform which is first added.

The application of this method to the determination of the tautomeric equilibria in the dipropyl- and di*iso*butyl-acrylic acids is described on p. 2575.

II. *Neutral Substances.*

The substances examined were ketones and esters, but the methods employed should be applicable to nitriles, substituted esters such as cyano-esters, and probably to olefines containing a phenyl substituent. These compounds were known to add on halogens much more readily than the corresponding acids and it was therefore necessary to find considerably milder reaction conditions. In the first place, the use of bromine in an inert solvent was tried at lower concentrations than those used for the acids (Part I, *loc. cit.*). This work was carried out on the isomeric ketones (III) and (IV) and it was only under extremely mild conditions that the addition to the $\beta\gamma$-ketone (III) was sufficiently slow to be measured. The reference figures for the pure ketones being known, the equilibrium between them was studied:

(III.) $CHMe{:}CEt{\cdot}CH_2{\cdot}COMe \rightleftharpoons CH_2Me{\cdot}CEt{:}CH{\cdot}COMe$ (IV.)

It has been shown (Kon and Linstead, J., 1925, **127**, 815) that this interconversion occurs in cold sodium ethoxide solution, the extent of the change in 28 hours being 15% $\beta\gamma \longrightarrow \alpha\beta$ and 35% $\alpha\beta \longrightarrow \beta\gamma$. It is now found, by the bromine method of analysis, that equilibrium is attained in about 30 hours and is approximately 14% $\alpha\beta$-ketone $\rightleftharpoons$ 86% $\beta\gamma$-ketone. The experimental error, however, is high, at least 2%, and a redetermination by the more accurate iodine chloride method given below has not yet been possible owing to lack of material.

Use of Iodine Chloride.—The well-known Hübl method for the determination of iodine numbers may be modified to give satisfactory results. It has been applied in a number of cases, but only three,

namely, ethyl styrylacetate ($CHPh{:}CH{\cdot}CH_2{\cdot}CO_2Et$), ethyl *cyclo*hexylideneacetate, and ethyl Δ^1-*cyclo*hexenylacetate, will be described. As in the Hübl method, the unsaturated substance or mixture of substances is allowed to react with iodine chloride prepared from mercuric chloride and iodine in alcoholic solution. The concentrations of the reagents are, however, lower than those under Hübl's conditions and the substances are brought together in equivalent amounts. When the pure isomerides are available, an addition curve is constructed in the usual way and the composition of an unknown mixture is determined by reference to it. The experimental procedure for this method is given on p. 2578. In cases where the pure isomerides are not available the extrapolation method already described should be of value; we have, however, not yet tested it.

No evidence of the movement of the double bond in ethyl styrylacetate could be obtained by comparing its iodine figures before and after treatment with sodium ethoxide (compare Linstead and Williams, J., 1926, 2735), for the action of this agent led to partial hydrolysis and partial polymerisation.

Unlike ethyl styrylacetate, ethyl Δ^1-*cyclo*hexenylacetate shows no tendency to condense in the $\alpha\beta$-phase under the conditions of the Michael reaction and therefore it was not expected that sodium ethoxide would cause any tautomeric change in this ester. At 60°, however, the isomeric esters were readily interconvertible and analyses by the iodine chloride method indicated that an equilibrium was reached in the neighbourhood of 10% $\alpha\beta$-ester $\rightleftharpoons$ 90% $\beta\gamma$-ester; the equilibrium mixture derived from the $\alpha\beta$-ester was carefully hydrolysed and substantially pure $\beta\gamma$-acid obtained. The equilibrium figure is close to that (12% $\alpha\beta \rightleftharpoons$ 88% $\beta\gamma$) found for the corresponding acids in caustic alkali solution (Linstead, this vol., p. 2579). It would appear probable that the esters of mono-olefinic acids undergo a reaction analogous to the Fittig change. This does not seem to have been observed previously, although many examples of changes in unsaturated esters containing a second negative group have been recorded (compare Thorpe, J., 1905, **87**, 1670; Vorländer, *Annalen*, 1906, **345**, 244; Farmer, J., 1923, **123**, 3324). This branch of the work is being further investigated.

The iodine chloride addition method has now been used in a study of the pulegone $\rightleftharpoons$ *iso*pulegone change and is being used in that of other tautomeric ketones.

EXPERIMENTAL.

Materials.—The Δ^1-*cyclo*hexenyl- and *cyclo*hexylidene-acetic acids satisfied the usual criteria of purity. The $\beta\beta$-dipropylacrylic acid,

$\beta\beta$-di*iso*butylacrylic acid, and their isomerides were the original materials prepared by Kon and May (*loc. cit.*). The isomeric ethylhexen-β-ones (III and IV) were prepared by Kon and Linstead's method (*loc. cit.*) and had the following properties: $\beta\gamma$-Ketone, b. p. 70°/20 mm.; semicarbazone, m. p. 141° after one crystallisation. $\alpha\beta$-Ketone, b. p. 71°/18 mm.; semicarbazone, m. p. 156° without crystallisation. Ethyl styrylacetate, prepared by esterification of the pure acid, had b. p. 162°/24 mm. This ester underwent slow fission to benzaldehyde on standing and was redistilled immediately before use. Ethyl *cyclo*hexylideneacetate, prepared from the pure acid through the acid chloride (b. p. 104°/11 mm.), had b. p. 111°/16 mm. Ethyl Δ^1-*cyclo*hexenylacetate, made from the pure solid acid through the acid chloride (b. p. 86°/13 mm.), had b. p. 95°/14 mm. The iodine used was of analytical purity.

Reaction of the Isomeric cyclo*Hexenylacetic Acids with Iodine.*—(1) *Qualitative.* Excess of iodine in aqueous potassium iodide was added to a solution of the $\beta\gamma$-acid in aqueous sodium bicarbonate. A resinous oil was formed almost immediately, and after 5 minutes this was extracted with ether; the extract was washed with solutions of sodium thiosulphate and sodium carbonate and dried. The ether was removed cautiously, the last traces in a good vacuum; the residue slowly solidified. Subsequent preparations were readily induced to crystallise by seeding. The crude product was pressed on a porous tile and then boiled in ether with the addition of animal charcoal. The purified lactone, obtained by filtration and evaporation, was recrystallised from light petroleum, the *γ-lactone* of 1-*iodo*-2-*hydroxy*cyclo*hexylacetic acid*, $C_6H_9I<\overset{CH_2}{O}>CO$, separating in white prisms, m. p. 58° (Found: C, 36·0; H, 4·3; I, 46·3. $C_8H_{11}O_2I$ requires C, 36·1; H, 4·2; I, 47·7%). It is soluble in organic solvents except cold light petroleum, insoluble in water and in alkali carbonate solutions, but soluble in caustic alkalis. The crude material has a strong characteristic smell, which is diminished by purification. Hot petroleum solutions develop a characteristic pink colour which is not due to the liberation of iodine. The liquefied lactone decomposes vigorously at 80—100° with the formation of free iodine.

When treated with iodine under similar conditions, the isomeric $\alpha\beta$-acid slowly formed an insoluble resin, which had a strong smell quite different from that of the preceding lactone and could not be obtained in a pure condition. The rate of reaction of the $\alpha\beta$-acid under these conditions was determined in the following experiments.

i. 0·4986 G. of the acid in 25 c.c. of saturated aqueous sodium

bicarbonate was treated with 25 c.c. of iodine solution of Bougault's concentration (25 g. I_2, 40 g. KI, water to 125 c.c.). % Addition found: (in 2 hrs. 10 mins.) 7; (in 24 hrs.) 30, 34.

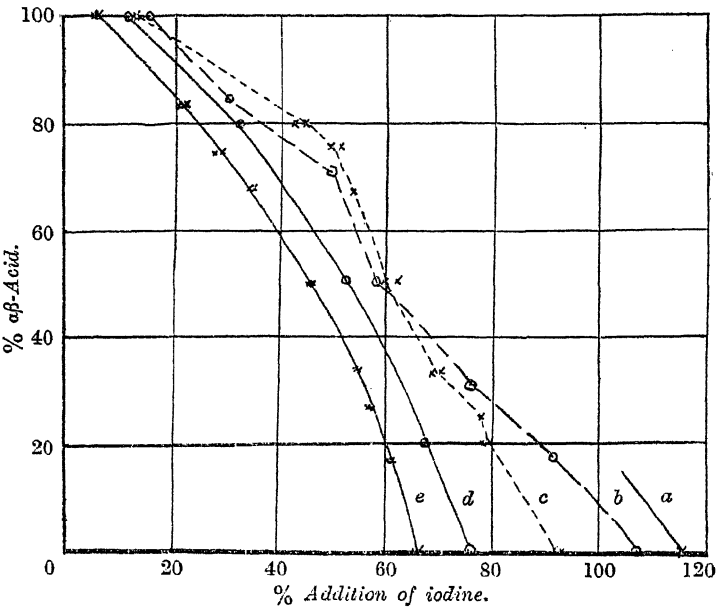
ii. $0{\cdot}7140 \times 10^{-3}$ G.-mol. of the acid in 10 c.c. of the bicarbonate solution was treated with $0{\cdot}6435 \times 10^{-3}$ g.-mol. of iodine in potassium iodide solution. % Addition found: (in 1 hr.) 1; (in 2 hrs.) 1·9; (in 2 hrs. 30 mins.) 2·7.

(2) *Quantitative.* When mixtures of the acids were treated under the analytical conditions described below, the product was a mixture of the 1-iodo-γ-lactone and the unchanged $\alpha\beta$-acid. The following experiments indicate the degree of completion of the separation. The mixed acids in known proportion (1—2 g.) were dissolved in some 15 c.c. of saturated sodium bicarbonate solution, and iodine (3 g.-atoms to 1 of acid) was added in potassium iodide solution of Bougault's concentration. After 1—2 hours, 4 c.c. of saturated sodium carbonate solution were added and the lactone was isolated in the manner already described. The $\alpha\beta$-acid was separated from the carbonate solution in the usual way and weighed. The weight of $\beta\gamma$-acid present in the mixture was calculated from the weight of crude lactone.

Mixture 1. Found: $\alpha\beta$-acid, 81·8; $\beta\gamma$, 19·6% (= 101·4%). Actual $\alpha\beta$-acid, 85%.

Mixture 2. Found: $\alpha\beta$-acid, 48·5; $\beta\gamma$, 47·7% (= 96·2%) Actual $\alpha\beta$-acid, 52·6%.

Mixture 3. Found: $\alpha\beta$-acid, 80·7; $\beta\gamma$, 24·3% (= 105%). Actual $\alpha\beta$-acid, 76·3%.



Titration Methods of Analysis.—(1) *By interpolation.* To find the most satisfactory conditions of reaction, various concentrations of the reagents were tried. The results are shown in Fig. 1. Curves *a*, *b*, and *c* were obtained on using 500, 250, and 100% excess of iodine respectively, and curves *d* and *e* on using the reagents in exactly equivalent proportion. The high addition values in series *a* and *b* are due to side reactions still under investigation. Some reaction of the iodine with traces of carbonate present certainly occurs. Curve *e* is the standard reference curve, obtained by using 0·033 g.-mol. of each reagent per litre.

In carrying out a determination, the acid (1/60th g.-mol.) is dissolved in a little saturated sodium bicarbonate solution without heating, and the mixture is then made up to 250 c.c. with the bicarbonate solution. To 10 c.c. of the solution, contained in a stoppered bottle, the theoretical quantity (about 28 c.c.) of approximately $N/20$-iodine (in potassium iodide solution) is added, and the reaction is allowed to proceed for 10 minutes in the dark; 10 c.c. of chloroform and about 200 c.c. of water are then added, the solution

is acidified with hydrochloric acid, and the unchanged iodine immediately titrated with $N/20$-sodium thiosulphate.*

The time of reaction can be altered to bring out the difference in reactivity of any pair of isomerides, provided that the time taken in analyses of unknown mixtures of the isomerides is the same as that taken in the analyses from which the reference curve is constructed. Exact thermostatic control of temperature is unnecessary, but large temperature changes obviously introduce a source of error and are to be avoided.

FIG. 1.

By plotting % addition of iodine against composition a smooth curve is obtained (curve *e*, Fig. 1) which can be used for the analysis of unknown mixtures of these acids.

(2) *By extrapolation.* The titrations were carried out as in the preceding method.

* The acidification is desirable, as traces of carbonate present in the bicarbonate react with hypoiodous acid as follows (Bougault, *Compt. rend.*, 1917, **164**, 949):

$$I_2 + H_2O \rightleftharpoons HIO + HI;\quad 2HIO + Na_2CO_3 \longrightarrow NaIO;$$
$$4NaIO + Na_2S_2O_3 + H_2O \longrightarrow 2NaHSO_4 + 4NaI.$$

The last reaction proceeds concurrently with the ordinary titration reaction and requires only 1/8th of the normal amount of thiosulphate per g.-mol. of free iodine. In the early work described above, this precaution was omitted and there is therefore a slight absolute error.

TABLE I.

% Addition	66·4, 65·5, 65·5			

TABLE II.

Test Mixtures of Δ^1-*cyclo*Hexenyl- and *cyclo*Hexylidene-acetic Acids (see Fig. 2).

Mixture.	Acid in 10 c.c. (g.-mol. × 10^3).	Iodine added (g.-mol. × 10^3).	Iodine solution.	% $\beta\gamma$-Acid. Actual.*	Found.
A	0·7140	0·6435	25 c.c. aq.	0	−0·1
B	0·5897	0·6451	,,	8·7	9·4
C	0·5508	0·6470	,,	23·7	24·7
D	0·7012	0·6451	,,	40·1	40·5
E	0·7226	0·7280	,,	60·9	61·3
F	0·4936	0·5170	15 c.c. alc.	81·4	82·5
G	0·7106	0·8413	32·5 c.c. alc.	100	103

* These points are shown in Fig. 2, marked ⊙, where the ordinates represent % $\beta\gamma$-acid for this purpose.

The iodine solutions in aqueous potassium iodide were similar to those used in the previous method. The solution in alcohol which was used in all the determinations described in this paper had the composition: iodine 6·35 g., 95% ethyl alcohol 600 c.c., water to 1 litre.

The accuracy of the method will not, in most cases, exceed ± 5%, as we consider the *cyclo*hexenylacetic acids to be an exceptionally favourable pair. The method, however, is the only one capable of giving trustworthy results for acids which cannot be completely separated from their isomerides. As such it has been applied in the two cases studied by Kon and May (*loc. cit.*).

Equilibrations.—1. *Dipropyl-acids.* $\beta\beta$-Dipropylacrylic acid and its $\Delta^{\beta\gamma}$-isomeride were heated with aqueous potash under the following conditions:

a.	$\beta\gamma$-Acid	heated	with	excess	60%	potash	for	24 hours.
b.	$\beta\gamma$- ,,	,,	,,	,,	60%	,,	24	,,
			then	with	20%	,,	24	,,
c.	$\alpha\beta$- ,,	,,	,,	,,	60%	,,	48	,,
d.	$\alpha\beta$- ,,	,,	,,	,,	20%	,,	48	,,

The results of iodine absorption by the products (Table III) show that equilibration is slow in 60% potash, probably owing to the sparing solubility of the potassium salts of the acids at this

concentration. The effect on the result of an increase in iodine concentration is shown by the two analyses (cA and cB) of the product in experiment c.

FIG. 2.

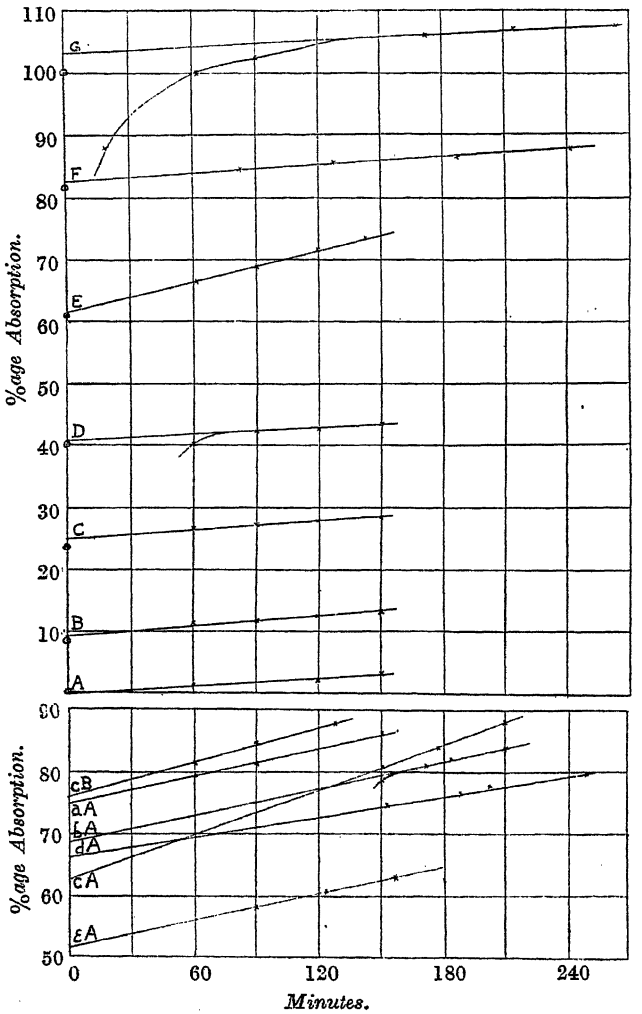

FIG. 3.

2. *Diisobutyl-acids.*—Only one accurate determination has been carried out, on a mixture of ββ-di*iso*butylacrylic acid and its $\Delta^{\beta\gamma}$-isomeride which was heated with 60% potash for 24 hours. The result obtained (51·5% of βγ-acid) by the iodine absorption method

agrees with that to be expected from the physical properties of the mixture (Kon and May, *loc. cit.*).

Addition of Bromine to the Isomeric Ethylhexenones.—The reaction with bromine was studied by the method given in Part I (this vol., p. 355). The reaction of the αβ-ketone with an equimolecular quantity of bromine was approximately bimolecular; the mean velocity coefficients obtained under various conditions are in Table IV, where *c* is the concentration (g.-mol. per l.) of each reagent.

TABLE IV.

Solvent.	*c*.	Temp.	Mean *k*.
CCl_4	1/60	25°	0·0141±0·0059
CS_2	,,	,,	0·0151±0·0094
$CHCl_3$	,,	,,	0·0024±0·0008
$CHCl_3$	,,	0	0·195 ±0·035
CCl_4	1/120	25	0·0052±0·0004

The order for the rates of reaction in the various solvents at 25° is the same as that found by Herz and Mylius for cinnamic acid (*Ber.*, 1906, **39**, 3817), namely, $CS_2 > CCl_4 > CHCl_3$. Under all the above conditions the βγ-ketone reacted completely (within the limits of experimental error).

Experiments at 25° with concentrations of the reagents each 1/300 g.-mol. per litre of carbon tetrachloride (a bromine solution at this dilution retained its strength during the necessary interval of time) showed that the βγ-ketone reacted completely in 6—7 minutes, whereas the reaction of the αβ-ketone was quite slow. The addition figures over a 2-minute interval were determined and compared with those obtained for the equilibrated ketones (prepared in the usual way from the parent ketones by the action of cold sodium ethoxide solution). The figures given in Table V are subject to considerable experimental error owing to the small differences measured.

TABLE V.

Ketone.	Treatment.	Mean % addition of bromine in 2 mins.
$\alpha\beta$	Pure.	37·9 ± 0·6
$\alpha\beta$	NaOEt, 24 hrs.	83·3
$\alpha\beta$	NaOEt, 48 hrs.	89·3
$\beta\gamma$	NaOEt, 48 hrs.	89·2
$\beta\gamma$	Pure.	97·3 ± 1·9

By interpolation the equilibrium is found to be approximately 14% $\alpha\beta$-ketone $\rightleftharpoons$ 86% $\beta\gamma$-ketone. In confirmation, the semicarbazone of the equilibrium mixture was prepared and was found to be mainly that of the $\beta\gamma$-ketone.

Use of Iodine Chloride.—The two standard solutions required in this method contain respectively 3·384 g. of iodine and 5·076 g. of mercuric chloride per 100 c.c. of 95% ethyl alcohol. These solutions are mixed in equal parts 24 hours before use; the mixture does not retain its strength. 10 C.c. are approximately equivalent to 1/1500 g.-mol. of a mono-olefinic substance.

An analysis is carried out by weighing out 1/300 g.-mol. of the unsaturated substance into a graduated flask and dissolving it in 50 c.c. of pure carbon tetrachloride. 10 C.c. of this solution are pipetted into a stoppered bottle. The iodine chloride solution prepared as described above is standardised against $N/20$-sodium thiosulphate and the exact theoretical amount is run into the solution of the unsaturated substance from a burette.* The reaction is allowed to proceed in the dark. At the end of a convenient time, determined by preliminary experiments, the mixture is treated with some 30 c.c. of 10% potassium iodide solution and 300 c.c. of water, and the unchanged iodine chloride is determined by back titration. The isomeric ethyl *cyclo*hexenylacetates showed the expected large difference in reaction; the figures for these esters and for ethyl styrylacetate under these conditions are in Table VI.

TABLE VI.

		Time (mins.).		
		10.	20.	60.
% Addition to ethyl	*cyclo*hexylideneacetate ($\alpha\beta$)	0·2	2·2	4·2
	Δ^1-*cyclo*hexenylacetate ($\beta\gamma$)	56·0, 56·1	62·0	69·8
	styrylacetate ($\beta\gamma$)	34·2	46·4	62·7, 61·8

* If M is the mol. wt. in g. of the substance, t is the titre of 10 c.c. of iodine chloride solution, and F the factor of the thiosulphate (1 c.c. = F g. of iodine), then the volume of iodine chloride solution (J) required by 10 c.c. of a solution containing x g. per 50 c.c. is given by (i) $J = 507{\cdot}6x/MtF$, and the % of unchanged substance at the end of the reaction period by (ii) $1000T/tJ$, where T is the back titre. Expression (i) allows for small discrepancies in weighing the unsaturated material; x/M should equal 1/300 to the nearest milligram.

There was no back reaction with the αβ-ester after titration, but a slow liberation of iodine occurred in the case of the two βγ-esters.

Artificial mixtures of known amounts of the two *cyclo*hexenylacetates reacted as follows in 1 hour :

% αβ-Ester.....	100	75·1	50·2	33·5	25·1	0
% Addition ...	4·2±0·5	23·5±0·05	43·3±0·05	54·5±0·3	59·7	69·8

The smooth composition–addition curve given by these figures was then used to determine the compositions of equilibrated mixtures of the esters. The pure esters were refluxed at 60° with an equimolecular amount of alcoholic sodium ethoxide for 43 hours. The product was in each case poured into water and extracted with ether. After drying and removal of the ether the residue was fractionated. Some 15—20% of liquid was isolated (b. p. 134°/12 mm., probably β-ethoxy-ester), but the bulk of the material was recovered as unsaturated ester, which had the following properties :

Parent ester.	B. p. of product.	% Addition of iodine chloride in 60 mins.	% αβ-Ester (calc.).
αβ	94—102°/12 mm.	68·4 ± 0·1	6
βγ	102—107°/17 mm.	63·8 ± 0·05	16

The equilibrium appears to be of the order of 10% αβ-ester $\rightleftharpoons$ 90% βγ-ester.

The equilibrated ester from the αβ-ester was hydrolysed under conditions precluding isomeric change in the acids, namely, at room temperature with 10% alcoholic-aqueous sodium hydroxide for 4 days. The acid isolated in the usual way was found to consist of Δ^1-*cyclo*hexenylacetic acid [plates, m. p. (crude) 33—34°], contaminated with an oily mixture which deposited more βγ-acid but no αβ-acid on standing.

The authors wish to express their thanks to Professor J. F. Thorpe, F.R.S., and Dr. G. A. R. Kon for their interest in this work.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,

CCCXLII.—*The Chemistry of the Three-carbon System. Part XIV. The Effect of Conditions on Isomeric Change in Unsaturated Acids.*

By REGINALD PATRICK LINSTEAD.

IN previous papers of this series the terms "mobility" and "position of equilibrium" were used somewhat freely, but their expression in quantitative terms was not possible. The position

of equilibrium was assumed to be constant for a definite pair of isomerides, and subsequent experimental evidence has supported this view (Linstead, this vol., p. 362; Johnson and Kon, J., 1926, 2748). The work of the latter on the β-alkylcinnamic acids, however, was based on a salt-separation method, whilst that of the present author on the *cyclo*hexane acids was limited in scope. Further work has now been carried out on this important point and on the quantitative expression of mobility. The technique of the equilibration experiments has been improved and the convenient iodine method of analysis (Linstead and May, preceding paper) has been used in place of the bromine method.

The value now found for the equilibrium is 88·2% Δ^1-*cyclo*hexenylacetic acid ($\beta\gamma$) $\rightleftharpoons$ 11·8% *cyclo*hexylideneacetic acid ($\alpha\beta$), which confirms that ($88 \rightleftharpoons 12$) previously reported. The probable accuracy of both analytical methods is shown by the agreement between the results. In addition, it has now been found that this position of equilibrium is, within the limits of experimental error, independent of temperature, concentration of the unsaturated acid and of the catalytic alkali, the nature of the alkali, and the presence of alcohol. It may therefore be regarded with some certainty as a structural constant. The independence of the equilibrium point of temperature indicates that the reaction between the acids, whilst requiring considerable energy for its inception, takes place with scarcely any heat change. In view of the work of Derick (*J. Amer. Chem. Soc.*, 1910, **32**, 1333), it is of interest to note that the ionisation constants of the two acids are very similar, 0·00260 for the $\alpha\beta$- and 0·00249 for the $\beta\gamma$-acid (Zelinski and Izgaryschev, *J. Russ. Phys. Chem. Soc.*, 1908, **40**, 1379).

The *mobility* of systems such as these, tautomeric in the presence of a powerful catalyst, can only be expressed rationally in terms of the velocity of the interconversion reaction. As previously pointed out (this vol., p. 368), a definite set of conditions has to be standardised before the mobilities of different series can be compared. From a survey of the results so far obtained, the following have been selected as the most convenient conditions : The equilibration is carried out at 100°, the unsaturated acid being treated with 25% aqueous potassium hydroxide (ten times the quantity required for exact neutralisation).* The velocity coefficient of interconversion is given by $k_1 + k_2 = \log_e\{\xi/(\xi - x)\}/t$ (this vol., p. 367). It is proposed to take the expression $100\ (k_1 + k_2)$, when t is expressed

* If 0·01 g.-mol. of unsaturated acid is used, this quantity is 18·12 c.c. of a solution containing 25 g. of potassium hydroxide in 100 g. of solution (30·96 g. in 100 c.c.), $d_4^{15°}$ 1·239. Solutions between 24 and 26%, if used in equivalent amounts, may be taken as satisfactory.

in hours and ξ and x in g. of potassium salt per c.c. of water, as a convenient numerical figure for the *degree of mobility* of the system. For the acids here dealt with, this figure becomes $10{\cdot}0 \pm 1{\cdot}3$ units (see p. 2584). Previous work was not carried out under these standard conditions, but various acids, including the simplest straight-chain olefinic acids, are now being examined with a view to obtain definite values for their mobility and position of equilibrium.

EXPERIMENTAL.

Equilibration.—Δ^1-*cyclo*Hexenylacetic acid and *cyclo*hexylideneacetic acid were prepared and purified by the standard methods. The acid under investigation (1·40 g.; 0·01 g.-mol.) was sealed up in a thick-walled tube of resistance glass with the appropriate amount of alkali. The concentrations and the excess of the alkali solutions were varied to suit the particular conditions required. The concentrations, allowing for neutralisation, of the potassium salt of the acid and the excess alkali in the various solutions are given in Table I.

TABLE I.

Concentrations of Reactants.

	Amount present (g.).			Concentration (g./c.c.).	
Sol.	K salt.	KOH.	Water.	K salt.	KOH.
A	1·78	5·04	15·74	0·114	0·321
B	,,	,,	17·53	0·102	0·287
C	,,	0·56	3·29	0·541	0·170
D	,,	,,	22·63	0·079	0·025
E	,,	,,	13·93	0·128	0·041

Solutions A and B are approximately "standard," the theoretical concentrations conforming with the conditions given on p. 2580 being 0·105 g. K salt and 0·297 g. KOH per c.c.

The reaction tube was heated at the desired temperature in a bath of boiling liquid (chloroform, 61·2°; trichloroethylene, 87°; water, 100°; saturated solution of potassium nitrate, 115°). At the end of the required interval of time the product was freed from a trace of lactone in the usual way and the acid was dried, carefully freed from solvent, and weighed. The loss was of the order of 5%.

Examination of the Mixed Acids.—In the earlier work little or no addition of water to the double bond occurred when the unsaturated acids were boiled with 60% alkali. The absence of such addition products was shown in the present work by the normal iodine addition values of all the products and by the fact that no hydroxy-acid could be isolated by Fittig's method (separation by steam

distillation), although in control experiments a quantity of 2% could readily be isolated under the conditions used.

The mixed unsaturated acids were then examined by the iodine addition method (First method, Linstead and May, *loc. cit.*) and the proportion of the isomerides was determined by reference to the standard curves.

Tabulation and Examination of Results.

I. *Point of Equilibrium.*—

TABLE II.

Concentrations of Reagents—A (Table I).

Expt.	Initial material.	Temp.	Time (hrs.).	Product. % Addition of iodine.	Product. % αβ-Acid.
1	αβ-Acid	100°	21	61·8; 62·8; 62·8; 63·0	12·0 ± 1·0
2	,,	,,	23	63·8; 62·8; 63·2; 62·5	10·8 ± 1·0
3	,,	,,	49	63·7; 62·7; 62·7	10·8 ± 1·1
4	,,	B. p.	7·5	62·6	12·2
5	βγ-Acid	100	8·8	62·6; 62·5; 61·0	13·3 ± 1·7
6	,,	,,	24	62·9	11·0
7	,,	115	17·5	63·2	10·5

The effect of less vigorous conditions was most conveniently tested by starting with the equilibrium mixture. A quantity of this (addition value, 62·6%; αβ-acid content, 12·2%) was prepared from the αβ-acid and treated under the following conditions:

(8) Concentrations, A; temperature, 61°; time, 24 hrs. The product had addition value, 62·5%; αβ-acid content, 12·3%.

(9) 1·40 G. of the equilibrium mixture were treated with 18·62 c.c. of 24·4% KOH solution (B) and an additional 18·62 c.c. of ethyl alcohol were added. Temperature, 100°; time, 24 hrs. The product had addition value, 63·1%; αβ-acid content, 10·5%.

(10) 1·40 G. of the equilibrium mixture were treated with ten times the amount required for neutralisation of a 25% solution of sodium hydroxide. The product had addition value, 61·3%; αβ-acid content, 15·0%.

The mean of these results corresponds to an αβ-acid content at equilibrium of 11·8% ± 1·1%. The corresponding mean value for the equilibrium in boiling 40, 50, and 60% potassium hydroxide solutions is 12% ± 0·8% (Linstead, *loc. cit.*). The equilibrium is therefore constant over a wide range of conditions.

II. *Effect of Temperature on Mobility.*—These experiments were carried out with the "standard" solutions, namely, at concentrations (A). In experiments 18 and 22 the slightly weaker solution (B) was used. The initial material was αβ-acid throughout, except in experiment 28 where βγ-acid was used.

* From melting point and crystalline form.

The results indicate that there is no interconversion at 61° and that at the higher temperatures the reaction follows fairly closely a reversible unimolecular course. The figures for the velocity coefficient calculated from the equation (p. 2580) are in Table IV.

TABLE IV.

Initial concentration, $\alpha\beta$-K salt 0·114 g./c.c. (except in Expts. 18 and 22); equilibrium concentration of $\beta\gamma$-K salt (ξ) 0·1006 g./c.c.; x = change in concentration of $\alpha\beta$-K salt; t in hours.

	Time.	% $\beta\gamma$-Acid.	x.	$\xi - x$.	$(k_1 + k_2)$.

					Mean 0·272 ± 0·051

The reaction velocity is approximately doubled for a 10° rise above 100°, and the low value at 87° is to be expected from the zero reaction at 61°. From the figures found for the reaction at 100°, the degree of mobility of the series is 10·0 ± 1·3. An inspection of the above figures and others previously obtained indicates that for rapid determinations of the degree of mobility of a series it is best to carry out three or four estimations of the amount of interconversion over periods ranging from ¼ to ½ the time required for complete equilibration. On this basis the mobility in the present series would be 9·3 ± 0·8.

III. *Effect of Concentration on Mobility.*—The velocity of the reaction diminishes with dilution and is particularly sensitive to decrease in alkali concentration. The mathematical relationship between these factors has not been obtained, but several points of interest arise from the results given below.

TABLE V.

Initial material, αβ-acid; temperature, 100°.

			Product.		
Expt.	Conc. (see Table I).	Time (hrs.).	% Yield.	% Addition of iodine.	% αβ-Acid.
29	D	21·0	90	21·8; 21·1; 22·0; 19·4	84·4 ± 1·1
30	D	47·5	94	20·2; 18·4	86·7 ± 1·2
31	C	21·0	54	48·1; 48·7; 45·9; 45·6	43·8 ± 2·3
32	E	6·0	94	10·8; 11·8	95·3 ± 0·4
33	E	17·0	97	13·3; 11·9; 15·5	93·1 ± 1·1
34	E	24·0	89	18·2; 15·6; 16·0	89·8 ± 1·2
35	E	41·5	97	20·9; 20·1; 20·9	84·9 ± 0·5

Experiments 29 and 30 show that the αβ-acid is essentially unchanged by 5% alkali just below its boiling point even over long periods of time. In experiment 31, the concentration of potassium salt is very high (five times that under the standard conditions), and the catalyst concentration is about half its standard value. As a result the reaction velocity decreases considerably, there being only 56% change instead of complete equilibration in 21 hours. In the last four experiments (Series E) the concentration of the potassium salt is approximately standard, while that of the catalyst is much lower. The velocity coefficients compare as follows:

	Conc. of K salt.	Conc. of KOH.	Mean $(k_1 + k_2)$.
Standard (Series A)	0·114	0·321	0·100
Series E	0·128	0·041	0·0048

The effect of catalyst concentration is clearly marked. General theoretical considerations indicate that the catalytic agent is the hydroxyl ion and are supported by the fact that sodium hydroxide does not affect the equilibrium attained in potash solution. An obvious analogy exists between this effect and that of the hydrogen

ion in hydrolyses, when the velocity of reaction is proportional to the concentration of the catalyst.

The Hydrolysis of Esters of Mobile Acids.

The results obtained are of value in that they indicate the conditions under which the ester of a comparatively unstable, unsaturated acid can be hydrolysed with alkali without movement of the double bond. The alcohol liberated from the ester does not affect the equilibrium (Experiment 9) and the following results show that, if anything, it has a slight *retarding* influence on the velocity of interconversion.

Concentrations, (A); solvent, 70% water + 30% ethyl alcohol; temperature, 100°.

		Product.	
Time (hrs.).	% Yield.	% Addition of iodine.	% $\alpha\beta$-Acid.
6	96	37·8; 36·4	61·1 ± 1·2
25	94	58·5; 59·3; 57·9; 58·5	21·8 ± 0·9

It may therefore be predicted that in this series hydrolysis of either ester with cold aqueous or alcoholic alkali of any strength will yield the corresponding acid in a state of purity. Hydrolysis with boiling solutions of 10% alkali for periods of 8 hours or so will yield substantially pure products. The latter conditions should prove more convenient than those used at present, which involve 50% alkali and often lead to considerable fission.

The author wishes to thank Professor J. F. Thorpe, C.B.E., F.R.S., and Dr. G. A. R. Kon for their kind interest in this work, and the Royal Society for a grant which has largely defrayed its cost.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,
LONDON, S.W. 7. [*Received, July 23rd,* 1927.]

CCCXLIII.—*The Chemistry of the Three-carbon System. Part XV. Pulegone and* iso*Pulegone.*

By WILFRED EYNON HUGH, GEORGE ARMAND ROBERT KON, and REGINALD PATRICK LINSTEAD.

THE experiments described in Part X of this series (J., 1926, 3101) made it clear that pulegone (I) and *iso*pulegone (II) were related in the same way as the ketones studied by Kon and Linstead (J., 1925, 127, 815), and that they exhibited what was described as retarded mobility; thus they are quite distinct, but the formation from pulegone of *iso*pulegoneoxime in the presence of alkali (Wallach,

Annalen, 1909, **365**, 240), and of methyl*iso*pulegone by the action of sodium and methyl iodide, on the one hand, and the conversion of *iso*pulegone into pulegone by baryta (Tiemann and Schmidt, *Ber.*, 1897, **30**, 22), on the other, point to the establishment of an equilibrium.

$$CMe_2{:}C\langle \begin{matrix} CO-CH_2 \\ CH_2{\cdot}CH_2 \end{matrix} \rangle CHMe \qquad CH_2{:}CMe{\cdot}CH\langle \begin{matrix} CO-CH_2 \\ CH_2{\cdot}CH_2 \end{matrix} \rangle CHMe$$

(I.) (II.)

Owing to their accessibility, these ketones form a convenient material for the study of tautomerism, but whilst pulegone is well known and readily characterised, the data on *iso*pulegone (especially on its physical properties) are scanty and, in part, conflicting. As a preliminary step, therefore, it appeared necessary to establish definitely the properties of pure *iso*pulegone and to evolve a method of estimating it in mixtures with pulegone.

Probably the simplest method of obtaining *iso*pulegone consists in the preparation of its oxime from pulegone (Wallach, *loc. cit.*), but all our attempts to hydrolyse this oxime led to mixtures containing a high proportion of pulegone and some methyl*cyclo*hexanone.

The ketone is, however, readily obtained by the oxidation of *iso*pulegol (Tiemann and Schmidt, *Ber.*, 1896, **29**, 917), although special precautions are necessary to obtain a pure product (see Experimental). The ketone consists of a mixture of the active and the inactive compound, but in our experiments the latter was only obtained in very small quantities. The optical activity of the active ketone is higher than that previously found.

The method of Harries and Roeder (*Ber.*, 1899, **32**, 3357) is untrustworthy and gives rise to mixtures from which a pure ketone is isolated only with great difficulty; this is *dextrorotatory* and identical with that obtained from *iso*pulegol, as might have been anticipated from the work of Wallach (*loc. cit.*). The lævorotation of the crude ketone is due to the presence of other compounds. The lævorotatory ketone prepared by Grignard (*Compt. rend.*, 1926, **182**, 422) by this method cannot have been *iso*pulegone owing to its totally different physical properties ($d_4^{14°}$ 0·9097, n_D 1·46335); on one occasion we obtained a ketone of very similar properties which consisted mainly of menthone, evidently formed by the reduction of pulegone hydrobromide.

No *iso*pulegone could be found in the three samples of oil of pennyroyal examined. Fractions with properties agreeing with those recorded by Grignard have in every case been isolated, but these consisted mainly of menthone which had already been found

in the oil by Tétry (*Bull. Soc. chim.*, 1902, **27**, 186), a fact which had apparently escaped Grignard's notice. This ketone occurs in a strongly dextrorotatory fraction of the oil, but is, curiously enough, inactive when isolated by means of its semicarbazone. The physical properties of Grignard's natural *iso*pulegone, although almost identical with those of the ketone he prepared by Harries and Roeder's method, differ considerably from those of pure *iso*pulegone; and it appears certain that his material consisted, like ours, of a mixture of pulegone and menthone. It is unfortunate that this material was used by Kon and Nutland (Part X, *loc. cit.*) before its true nature was realised, although the poor yield of methyl*iso*pulegone obtained from "natural *iso*pulegone" was noted at the time. The formation of the methylation product was evidently due to the pulegone still left in the mixture; the methylation has since been repeated with a genuine sample of *iso*pulegone and found to give the same lævorotatory product.

The proportion of pulegone and *iso*pulegone in mixtures of the two ketones can be roughly estimated from the physical properties of the mixture (see Experimental), but a more accurate method has been worked out, based on the different rates of reaction with iodine chloride and similar to that employed by Linstead and May (this vol., p. 2565). This method incidentally provided a ready means of differentiating between *iso*pulegone and mixtures like "natural *iso*pulegone" containing saturated compounds, and supplied the final proof that *iso*pulegone did not occur in the oils examined.

The equilibrium between pulegone and *iso*pulegone was studied in the presence of a variety of reagents with reference both to the rate of equilibration and to the proportion of the constituents in the final product. The results show that the final equilibrium point is so close to pure pulegone that no difference between the latter and the equilibrium mixture can be detected even by the iodometric method employed. The system is evidently very mobile, because in the presence of small quantities of sodium ethoxide (1/50 mol.) the rate of equilibration is already too rapid for exact measurement. With baryta (1/50 mol.) the reaction is complete in 2 hours, but with sodium carbonate it requires several days; piperidine also produces a small change in 24 hours. Cold aqueous sulphuric acid produces little change, but hot acids have a marked effect; this could not be studied quantitatively owing to the ready fission of both pulegone and *iso*pulegone under these conditions, but it is apparent from the fact that, if comparatively large quantities of *iso*pulegonesemicarbazone are hydrolysed by digestion with oxalic acid in a current of steam, the resulting ketone contains up to 50% of pulegone, whereas small quantities can be hydrolysed without

much conversion taking place. The most noteworthy points are the very rapid equilibration in the presence of sodium ethoxide, and the coincidence of the final equilibrium point with pure pulegone, within the limits of experimental error. From these results it is clear that Grignard's figure for the equilibrium between the two ketones (*loc. cit.*) is erroneous; and the great sensitiveness of *iso*pulegone makes its occurrence in essential oils extremely improbable.

EXPERIMENTAL.

Preparation of iso*Pulegone.*—Commercial *iso*pulegol ($\alpha_D^{20°}$ — 1·22°), obtained from Messrs. Boake, Roberts & Co., of Stratford, was oxidised exactly as described by Tiemann and Schmidt (*loc. cit.*), and the resulting oil treated with semicarbazide acetate; the semicarbazone was purified by thorough grinding with light petroleum, followed by repeated grinding with cold ether; the ethereal extract gave on evaporation a solid (E), whilst a large proportion remained undissolved (R).

The solid (E) was freed from adhering oil by means of light petroleum, and a portion was recrystallised from methyl alcohol. The various crops obtained were somewhat indefinite and melted at 157—158°. They were combined and hydrolysed by means of oxalic acid; the ketone had b. p. 94—96°/13 mm., $d_4^{18·3°}$ 0·92540, $n_D^{18·3°}$ 1·47241, α_D + 34·3° (c = 9·1408 in ethyl alcohol),* and evidently contained some pulegone. Another sample obtained in a similar way was treated with aluminium amalgam (Harries and Roeder, *loc. cit.*) before the final distillation; the greater portion had b. p. 100—102°/20 mm., $d_4^{22·0°}$ 0·91759, $n_D^{22·0°}$ 1·46519, $[R_L]_D$ 45·85, α_D + 38·0° (c = 6·6708 in methyl alcohol). The optical activity of the ketone so obtained depends on the number of times the semicarbazone is extracted with ether, the first extract containing the most active material, which is, however, more liable to be impure. Subsequent extracts usually give a semicarbazone which, after several crystallisations from methyl alcohol, forms long, silky needles, m. p. 175—176°.

The residue (R) on crystallisation from methyl alcohol separated in silky needles, m. p. 176—177°, although a small amount representing the least soluble portion formed transparent prisms, m. p. 180°, doubtless belonging to the inactive ketone (compare Wallach, *loc. cit.*); mixtures of the two melted at about 178°. The ketone regenerated from the pure material, m. p. 176—177°, and treated with aluminium amalgam had b. p. 105—106°/23 mm., $d_4^{25·2°}$ 0·91731, $n_D^{25·2°}$ 1·46589, α_D + 23·8° (c = 6·6676 in methyl alcohol), and gave an oxime, m. p. 134° after one crystallisation from methyl

* All the rotations recorded in this paper were measured in a 2-dcm. tube.

alcohol. Another sample similarly obtained from the less soluble portions of (E) had $d_4^{22\cdot5°}$ 0·91994, n_D 1·46689, α_D + 26·6°. When a large quantity of semicarbazone (*e.g.*, 100 g.) was hydrolysed all at once, the product contained as much as 60% of pulegone ($d_4^{18\cdot9°}$ 0·93161, n_D 1·47917); the aluminium-amalgam process of purification is not altogether satisfactory in this case because an appreciable quantity of pulegone is reduced to menthone; but the amount of menthone formed is negligible if the crude *iso*pulegone contains but small quantities of pulegone. For this reason it is necessary to hydrolyse *iso*pulegonesemicarbazone in small portions (about 20 g.). A separate experiment showed that *iso*pulegone was unaffected by treatment with aluminium amalgam, the material having the same physical properties and iodine-absorption before and after treatment (see below).

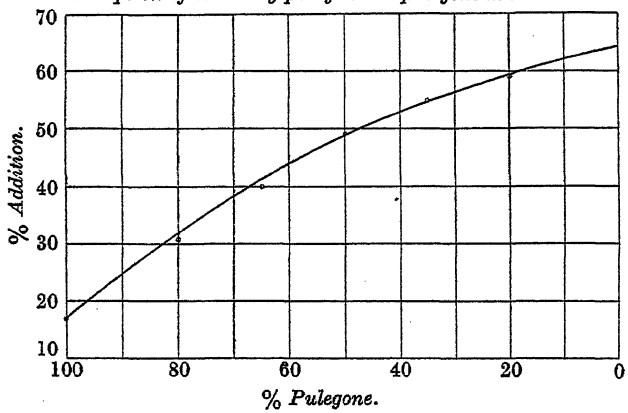
iso*Pulegone from Pulegone Hydrobromide.*—The preparation was carried out as described by Harries and Roeder (*loc. cit.*). The results were extremely variable, pulegone being usually almost the sole product obtained. This is removed in the process of reduction, but the product then contains menthone; thus, on one occasion a ketone regenerated from the crude semicarbazone had b. p. 84°/9 mm., $d_4^{18\cdot0°}$ 0·90846, $n_D^{18\cdot0°}$ 1·45833, α_D − 11·6°, in good agreement with Grignard's figures (*loc. cit.*); it was reconverted into a semicarbazone from which considerable quantities of menthonesemicarbazone were isolated. In most cases a semicarbazone is formed with great difficulty as already observed by Harries and Roeder (*loc. cit.*). Sometimes, however, almost pure *iso*pulegone is formed; *e.g.*, on one occasion a considerable amount of an optically inactive fraction, b. p. 104—105°/18 mm., was obtained; the refractive index approximated to that of *iso*pulegone, although the density was too high (this was always the case). The product was treated with aluminium amalgam and converted into the semicarbazone. The ketone regenerated from it had b. p. 101—102°/17 mm., $d_4^{20\cdot0°}$ 0·920855, $n_D^{20\cdot0°}$ 1·46669, $[R_L]_D$ 45·81, α_D + 24·7° (*c* = 5·5532 in methyl alcohol), agreeing well with the properties of *iso*pulegone prepared from *iso*pulegol ($d_4^{20\cdot4°}$ 0·92177, $n_D^{20\cdot4°}$ 1·46787). The latter are regarded as the physical constants of the *pure* ketone.

When pulegone hydrobromide was allowed to stand for 4 days with a slight excess of piperidine in light petroleum solution, the resulting ketone proved to be pulegone.

Estimation of Pulegone and iso*Pulegone in Mixtures.*

The proportion of the two ketones in a mixture can be roughly estimated by means of the density or the refractive index, an

examination of several synthetic mixtures having shown that these two properties could be satisfactorily expressed by a straight-line relationship. For the accurate analysis of mixtures, however, the iodometric method of Linstead and May (*loc. cit.*) has been adopted.



Preliminary experiments were made to ascertain suitable conditions. An *M*/300-solution of each ketone in chloroform was allowed to stand with the theoretical quantity of iodine solution with the following result:

Time (mins.).	2.	10.	20.	27.	
% Reaction with pulegone	5·2	9·9	15·4	—	(complete in 45 hrs.)
,, ,, *iso*pulegone *	32·1	57·5	—	72·6	

* The sample of *iso*pulegone used in the preliminary work was not quite pure.

FIG. 1.

Absorption of iodine by pulegone–isopulegone mixtures.

A standard time of 10 minutes was therefore adopted. Mixtures of pure pulegone and *iso*pulegone, made by mixing *M*/300-solutions in chloroform, were then titrated, with the following results (mean of 3 concordant determinations in each case):

Mixture (% pulegone)	0	20	35	50	65	80	100
% Addition	64·7	58·5	55·1	48·9	40·1	30·9	16·6

From the above data the reference curve (Fig. 1) was constructed.

Examination of Oil of Pennyroyal.

Spanish Oil.—Two samples of this oil gave practically identical results, of which one is recorded: Light green oil, $d_4^{22\cdot5^\circ}$ 0·9324, $\alpha_D^{22\cdot5^\circ}$ approx. + 22°. 1370 G. distilled under reduced pressure (fractionating column) gave:

<92°/11—12 mm.	92—98°/11 mm.	98—105°/11 mm.	Residue.	Loss.
194 g.	1110 g.	7 g.	30 g.	29 g.

The low fraction was refractionated and another large fraction, b. p. 90—91°/10 mm., was obtained, which was increased by a third fractionation. This fraction had $n_D > 1{\cdot}48$ and was therefore added to the main pulegone fraction, which thus amounted to 1270 g., or 93% of the original oil; it had $d_4^{16{\cdot}6°}$ 0·93869, n_D 1·48820; titrations with iodine gave 12·9% addition (mean of 3), showing that no appreciable amount of *iso*pulegone was present. The low fractions gave on refractionation at 10 mm.: 48—52°, 13 g.; 58—62°, 4 g.; 84—90°, 10 g. The terpene fractions were progressively refractionated under atmospheric pressure, but were not definitely separated; a portion, b. p. 168—174°, had $d_4^{14{\cdot}7°}$ 0·85569, $n_D^{14{\cdot}7°}$ 1·46768, α_D — 23° in alcohol; its odour suggested limonene. These were not further investigated. The fraction 84—90°/10 mm. still contained pulegone and terpenes.

750 C.c. of the pulegone fraction were treated with sodium hydrogen sulphite and alcohol until no further precipitation occurred, and the solid was filtered off and washed with alcohol and ether. The oil recovered from the mother-liquor and washings still contained pulegone and was therefore again treated with bisulphite. The portion which had failed to combine was isolated and distilled, but was found to contain pulegone; it was finally reduced by means of aluminium amalgam in ether, and fractionated at 10 mm.:

	Fraction.	Weight.	$d_4^{18°}$.	n_D.
(1)	<83°	3·8 g.	—	—
(2)	83—83	7·9 g.	0·89522	1·45763
(3)	84—87	5·7 g.	0·90822	1·46250
(4)	87—90	6·5 g.	0·91728	1·46669
(5)	High	2·1 g.	—	1·47014

The two lowest fractions were combined and redistilled under ordinary pressure, a part boiling below 200°, and the rest about 207°. The same semicarbazone was obtained from each in moderate yield and melted at 181—182° after washing with petroleum, extraction with ether, and crystallisation from methyl alcohol; this was identified as menthonesemicarbazone (Found: C, 62·5; H, 10·1. . Calc.: C, 62·6; H, 9·9%). The fraction (4), which corresponds with Grignard's *iso*pulegone fraction, had α_D + 43·16° (c = 5·22 in alcohol), and on treatment with semicarbazide gave a sparingly soluble semicarbazone (fine needles from methyl alcohol, m. p. 184—185°) together with a portion which dissolved in ether, from which it was obtained on evaporation as a brown syrup. The ketone regenerated from this by means of oxalic acid was again treated with semicarbazide and gave a product consisting mainly of menthonesemicarbazone. The presence of *iso*pulegone in fraction (4) could not be demonstrated, although its behaviour

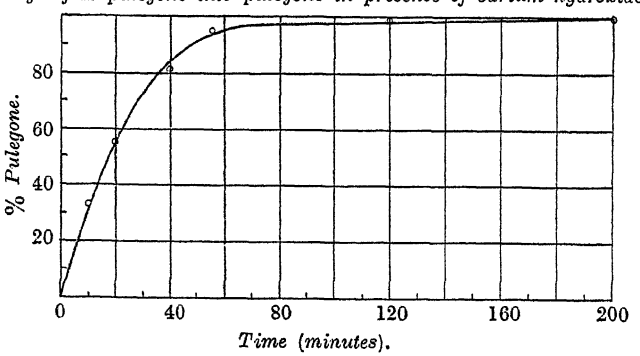
towards iodine suggested the presence of some unsaturated material, corresponding with an *iso*pulegone content of 25%. This unsaturated material, however, appeared to be non-ketonic and accumulated in the light-petroleum washings from the menthonesemicarbazone, from which it could be obtained on evaporation; it appeared to be a mixture of menthol and terpenes and was highly unsaturated (iodine number, Hübl: 154·3).

French Oil.—A sample of French oil was found to have properties closely agreeing with those of the Spanish oils: $d_4^{15\cdot9°}$ 0·93671, n_D 1·48627. On distillation, some 1·5% of terpene fraction was isolated; 93% boiled at 98—103°/16 mm. and had $d_4^{15\cdot5°}$ 0·93525, n_D 1·48724; titrations with iodine gave a mean addition of 16%, showing that no appreciable quantity of *iso*pulegone could be present.

The whole of this fraction (839 g.) was treated with sodium hydrogen sulphite for a fortnight, and the oil which had failed to react was isolated and treated again until no further precipitation occurred. The resulting oil amounted to 59 g. and gave the following result on fractionation at 12 mm.:

Fraction.	Weight (g.).	$d_4^{17\cdot7°}$.	$n_D^{17\cdot7°}$.	α_D (in methyl alcohol).
(1) Below 79°	11·3	0·87113	1·45323	+13°
(2) 79—84	4·3			
(3) 84—88	14·9	0·89360	1·45893	+33·0
(4) 88—92	9·2	0·90617	1·46201	
(5) 92—98	4·8	0·91166	1·46728	+29·7
(6) 98—105	4·5	0·91771	1·47309	
Residue	10·0			

Fraction (1) consisted of a mixture of terpenes, whilst fraction (2) contained some menthone; fraction (3) was almost pure menthone, which was also present in most of the other fractions. It was isolated in the form of its semicarbazone, which, after being washed with petroleum, crystallised from alcohol in fine needles, m. p. 184—185°, unaltered on admixture with a sample prepared from *l*-menthone. The regenerated ketone had b. p. 88°/12 mm., $d_4^{19\cdot0°}$ 0·89774, $n_D^{19\cdot0°}$ 1·45233, $[R_L]_D$ 46·35 (Calc., 46·20), but was *inactive*.* Owing to the small amounts of material available it was impossible to decide as to the nature of the menthone originally present, especially as a solid oxime was not obtained; the rotations of the menthone fractions were diminished somewhat by treatment with sodium ethoxide (compare Read and Robertson, J., 1926, 2209). The petroleum washings from the menthonesemicarbazone were evaporated and gave an oil with a strong mint-like odour; on distillation a fraction, b. p. 92—96°/15 mm., was obtained which



* The hydrolysis of the semicarbazone was carried out with oxalic acid on two separate occasions; the product was inactive in each case.

was probably mainly menthol (Found: C, 76·9; H, 12·3. Calc.: C, 76·9; H, 12·8%), but still contained some unsaturated material; it had α_D + 27·2°, $d_4^{20°}$ 0·89151, n_D 1·45623.

The small fraction (5), which would correspond with Grignard's *iso*pulegone, was specially investigated, but menthone was still the principal constituent, probably accompanied by some pulegone; no trace of *iso*pulegone could be isolated. The slightly high iodine-absorption of the original pulegone fraction is evidently due to the presence of terpenes, which were found to react rapidly with iodine. The terpene fraction obtained in the first fractionation of the oil was feebly lævorotatory (α_D −13·5°), whilst the terpenes isolated from the main fraction were dextrorotatory and had a lower refractive index. The small amounts obtained did not allow of investigation.

FIG. 2.

Change of iso*pulegone into pulegone in presence of barium hydroxide.*

Equilibrium between Pulegone and iso*Pulegone.*—The following procedure was used throughout. The ketone (4 c.c.) was mixed with the catalyst, and the whole made up to 50 c.c. with ethyl alcohol. After standing for the requisite time, the mixture was diluted with water and thoroughly extracted with ether, the extract was washed, dried, and evaporated with the aid of a long column, and the residue was distilled under reduced pressure from a glycerol-bath, the first two drops of distillate being rejected; the remainder was collected (about 3·5 c.c.). The physical properties of the distillate were determined in all cases as an additional check. An *M*/300-solution of the distillate in pure chloroform was then made up and three titrations with iodine were carried out. The catalyst used and its concentration are specified at the head of the corresponding results in the table, and the results with barium hydroxide are illustrated in Fig. 2.

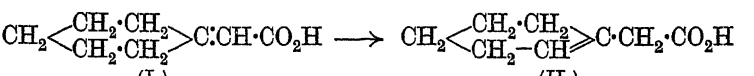
* In this case 25 c.c. of 12% sodium ethoxide solution were used.
† In this case 10 c.c. of 12·5% sulphuric acid solution were used.

The composition of the mixtures can be readily ascertained from the reference curve in Fig. 1.

The authors' thanks are due to the Government Grant Committee of the Royal Society for a grant which has defrayed the cost of this investigation.



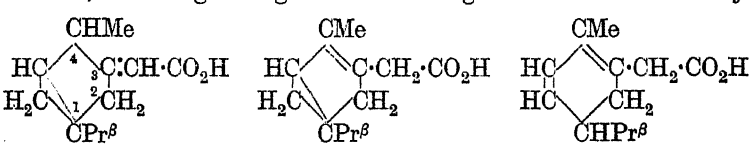
IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,
LONDON, S.W. 7. [*Received, July 22nd*, 1927.]

CCCXLIV.—*The Chemistry of the Three-carbon System. Part XVI. The Effect of some Bridged and Unsaturated Rings on Tautomerism.*

By WILFRED EYNON HUGH and GEORGE ARMAND ROBERT KON.

IN several previous papers of this series (J., 1926, 1792, 2727; 1923, 123, 1361, 2440) it has been suggested that the tendency of the double bond to enter a *cyclo*pentane or *cyclo*hexane ring in a com-

pound such as (I) could be correlated with the internal strain in the ring. Particularly striking examples of this correlation were



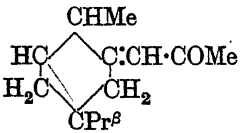
(I.) (II.)

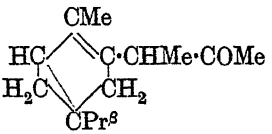
found in ethyl *cyclo*pentylidenemalonate and the *cyclo*hexane compound, the former having the αβ-, and the latter the βγ-unsaturated structure.

In *cyclo*hexane rings which occur in nature the strain is generally relieved either by a double bond (limonene, carvone, piperitone) or by a bridge (thujone, pinene). Such rings, if introduced in place of the simple *cyclo*hexane ring in a compound such as (I), should exhibit less tendency to acquire a double bond and consequently the stability of the βγ-form (II) of the new compounds should be diminished as compared with the acids (I) and (II). The same should be true of compounds in which the *cyclo*pentane or *cyclo*hexane ring already contains a double bond, but the issue here is complicated by the tendency to form a conjugated system with two double bonds in the ring; the βγ-form in these cases should be actually much more stable than in (I) and (II).

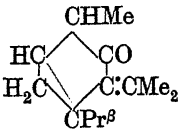
In order to test these conclusions, we selected a number of pairs of unsaturated acids containing suitable bridged rings and derived from the corresponding ketones such as β-thujone, pinocamphone, sabinaketone, nopinone, and fenchocamphorone, whilst a variety of acids derived from *cyclo*hexenones had already been prepared by Wallach and were easily available.

β-Thujone was readily converted into the αβ-unsaturated acid (III), but all attempts to prepare the pure βγ-isomeride (IV) * were fruitless, the bridge being attacked to a greater or less extent by





(III.) (IV.) (V.)



the dehydrating agents employed. The high-melting solid acid so produced evidently contains two double bonds and probably has the structure (V). The αβ-acid, on treatment with alkali, was partly converted into the liquid βγ-isomeride; the equilibrium, estimated by Bougault's method, was 75 : 25 in favour of the βγ-form, as compared with 88 : 12 for the acids (I) and (II) (the method em-

* No attempt has been made to decide between this formula and one with the double bond in the position 2 : 3; the same applies to the compounds (V) and (VII).

ployed gives a *minimum* value for the αβ-acid). The acid (III) can be converted into the corresponding ketone, which, unlike *cyclo*hexenylacetone, has the αβ-structure (VI); it is, however, readily methylated, the new ketone having the βγ-structure (VII). The

(VI.)

(VII.)

(VIII.)

methylated ketone shows an exaltation of the molecular refraction (0·43 unit), which is, however, less than that of the parent ketone (1·08 units). This is doubtless due to the "conjugation" of the double bond with the three-membered ring in the βγ-formula (VII); the low density of the ketone also supports this formula. β-Thujone readily condenses with acetone, but the product is quite different from the ketone (VI), being a solid of the formula (VIII), having evidently been formed in the same way as the condensation product of acetone and *cyclo*pentanone (Wallach, *Annalen*, 1912, **394**, 376).

These reactions suffice to show that the αβ-form is much more favoured in the compounds derived from thujone than in those derived from *cyclo*hexanone. The reaction with acetone can be taken to indicate that the acidity of the ketone group in thujone is less than that of the ketone group in *cyclo*hexanone, the relatively high acidity of which can in turn be correlated with a tendency to enolisation and thus to the production of a double bond in the ring.

The effect of a bridge containing a carbon atom on the stability of compounds derived from pinocamphone could not be studied, because this ketone, like camphor, could not be condensed either with ethyl cyanoacetate or with ethyl bromoacetate, and we have not yet obtained a sufficient quantity of nopinone or fenchocamphorone to serve as a starting point for further work. In the meantime, it appeared of interest to examine the acid (IX) and the ketone (X) derived from 3-methyl*cyclo*hexenone in which one double bond is already present in the ring.

(IX.)

(X.)

The ester of this acid does not undergo the Michael reaction (Dr. E. H. Farmer, private communication), so evidently it does not possess an αβ-phase. It is now found that the acid itself is unaffected by prolonged boiling with alkali and shows no tendency whatever to pass into its αβ-isomeride. All attempts to synthesise

the latter, and to prepare the ketone from the chloride of the acid, failed.

This behaviour of the acid as a static $\beta\gamma$-form, whilst confirming our view on the probable effect of a double bond in the ring on the stability, is in contrast with that of the cyano-esters prepared by Farmer and Ross (J., 1926, 1570). The reason for the difference appears to be that there are two activating groups in the latter, both favouring the $\alpha\beta$-form and competing with the double bond in the ring, a condition enabling tautomeric equilibrium to be established. In the acid now examined, the stability of one form ($\beta\gamma$) is so much greater than that of the other ($\alpha\beta$) that mobility is completely suppressed. Ethyl α-cyano*cyclo*hexylideneacetate exists apparently only in the $\alpha\beta$-form, whereas Farmer's cyano-esters can be isolated in three forms, of which one is the $\beta\gamma$; the existence of this is evidently due to the additional stabilising effect of the double bond already present in the ring on the $\beta\gamma$-phase.

EXPERIMENTAL.

β-*Thujolacetic Acid.*—β-Thujone was isolated from oil of tansy (Semmler, *Ber.*, 1892, **25**, 3343) and had b. p. 81—82°/12 mm., $d_4^{17\cdot7°}$ 0·91773, $n_D^{17\cdot7°}$ 1·45143, $[\alpha]_D^{17\cdot7°}$ + 75·64°. The semicarbazone crystallised from alcohol in needles, m. p. 174°. The ketone did not condense with ethyl bromoacetate in the presence of magnesium, but the reaction proceeded well with zinc, ethyl thujolacetate, b. p. 136—142°/10 mm., being obtained in 54% yield; much of the ketone was recovered. The acid, m. p. 90—91°, was obtained from it on hydrolysis with sodium ethoxide (Wallach, *Annalen*, 1900, **314**, 166.).

β-*Thujylideneacetic Acid* (III).—The hydroxy-acid was boiled with acetic anhydride for 3 hours and the product was diluted with water and distilled in steam for a long time; the *unsaturated acid*, which separated from the distillate as a solid (yield, 64%), crystallised from light petroleum in needles, m. p. 103—104° (Found: C, 74·2; H, 9·2. $C_{12}H_{18}O_2$ requires C, 74·2; H, 9·3%). On oxidation with alkaline potassium permanganate in a current of steam the acid gave oxalic acid and β-thujone (which was identified by its semicarbazone, m. p. 174°), the structure (III) assigned to the acid thus being confirmed. The *acid chloride*, prepared with the aid of thionyl chloride, had b. p. 136—138°/14 mm.; the *ethyl* ester, prepared by pouring the chloride into ethyl alcohol, had b. p. 136—137°/10 mm., $d_4^{17\cdot8°}$ 0·95995, $n_D^{17\cdot8°}$ 1·47800, $[R_L]_D$ 65·61 (calc., 64·40).* The *anilide* crystallised from petroleum (b. p. 60—80°) in prisms, m. p. 118·5°

* This and subsequent values take into account the exaltation due to the three-membered ring.

(Found: C, 79·9; H, 8·5; N, 5·4. $C_{18}H_{23}ON$ requires C, 80·3; H, 8·6; N, 5·2%).

Dehydration of Ethyl Thujolacetate.—The hydroxy-ester was heated with potassium hydrogen sulphate at 160° for 3 hours, and the resulting ester was isolated by means of steam and distilled. The fraction, b. p. 138—148°/14 mm., was hydrolysed with 30% aqueous potassium hydroxide and alcohol, and the acid formed was liberated and isolated by means of ether. This acid was a mixture of a solid (main product) and an oil. The solid *acid* (V) separated from benzene–petroleum in plates, m. p. 169° (Found: C, 74·2; H, 9·3. $C_{12}H_{18}O_2$ requires C, 74·2; H, 9·3%). The oily acid could not be purified and decomposed on distillation, and solid derivatives could not be obtained from it. The same mixture of acids was also produced when the hydroxy-ester was dehydrated with phosphorus oxychloride or pentoxide.

The acid, m. p. 169°, could not be characterised by the formation of derivatives because the acid chloride, although evidently formed, decomposed violently on attempted distillation. The *sodium* salt is characteristic, being sparingly soluble in water and forming fine, silvery plates. The *silver* salt was prepared from it (Found: Ag, 35·9. $C_{12}H_{17}O_2Ag$ requires Ag, 35·9%).

Equilibration Experiments.—β-Thujylideneacetic acid in 1·94 g. lots was heated with 18 c.c. of 25% aqueous potassium hydroxide in sealed tubes at 100° for 24, 32, 40 and 48 hours. The products were worked up under the standard conditions of Linstead and May (this vol., p. 2565) and the iodine values of the equilibrated acids and of the original αβ-acid were then determined as described by them:

Time (hrs.).	0	24	32	40	48
% Absorption	8·4	33·9	52·0	49·6	56·8

The last three values, although not very concordant, suffice to show that equilibration was complete after 32 hours. As the iodine value of the pure βγ-acid was not known, it was necessary to estimate the proportion of the two acids present in the equilibrium mixture by isolating the αβ-acid by Bougault's method (*Ann. Chim. Phys.*, 1908, **14**, 145); this gives the minimum amount of αβ-acid present. For this purpose, 10 g. of pure αβ-acid were heated with potassium hydroxide for 45 hours; the semi-liquid product was isolated as before and treated with iodine under Linstead and May's standard conditions. The excess of iodine was removed with sodium thiosulphate after 10 minutes and the unchanged αβ-acid contained in the aqueous layer was liberated, extracted with ether, and recovered from the extract by evaporation, 2·50 g. being obtained.

This represents a minimum of 25% of αβ-acid in the equilibrium mixture.

The acid (V) was similarly treated with both 25% and 50% potassium hydroxide solution, but in every case it was isolated completely unchanged. The acid was treated with iodine before and after treatment with alkali, and the absorptions were identical within the limits of experimental error (96·1 and 96·3%). The high iodine value and the high melting point (169°) of the acid and its general similarity to dihydro-*m*-tolylacetic acid (see below) point to a formula with two double bonds in the ring. The true βγ-acid (IV) appears to be a liquid.

β-*Thujylideneacetone* (VI).—The chloride of β-thujylideneacetic acid, on treatment with zinc methyl iodide (Blaise and Maire, *Ann. Chim. Phys.*, 1908, **15**, 556), gave a 30% yield of the ketone. The sparingly soluble *semicarbazone* crystallised from methyl alcohol in plates, m. p. 191° (Found : C, 67·2; H, 9·2; N, 17·1. $C_{14}H_{23}ON_3$ requires C, 67·5; H, 9·2; N, 16·9%). The *ketone* regenerated from it had b. p. 120°/10 mm., $d_4^{17\cdot4°}$ 0·93111, $n_D^{17\cdot4°}$ 1·48464, $[R_L]_D$ 59·15 (calc., 58·07), its physical properties agreeing with the αβ-structure (VI). The ketone was readily methylated with sodium and methyl iodide (Kon, J., 1926, 1792), a 30% yield of an oil, b. p. 122—124°/14 mm., being obtained. This was converted into the *semicarbazone*, which crystallised from methyl alcohol in plates, m. p. 194° (Found: C, 68·3; H, 9·6; N, 16·1. $C_{15}H_{25}ON_3$ requires C, 68·4; H, 9·6; N, 16·0%), and was less soluble than the semicarbazone of the parent ketone; a mixture of the two melted at about 176°. The *ketone* (VII) regenerated from the semicarbazone had b. p. 122°/14 mm., $d_4^{17\cdot8°}$ 0·91690, $n_D^{17\cdot8°}$ 1·47339, $[R_L]_D$ 63·12 (calc., 62·69).

Condensation of β-*Thujone with Acetone*.—Dry sodium methoxide, prepared from 12 g. of sodium by Komppa's method (*Annalen*, 1909, **368**, 137), was cooled in ice, an ice-cold mixture of β-thujone and acetone (½ g.-mol. of each) added, and the whole kept in the ice-chest for 4 days. Water and dilute sulphuric acid were then added and the mixture was distilled in steam for a short time. From the residue in the flask a considerable quantity of solid, accompanied by an oil, separated on cooling. The solid consisted of 2-iso*propylidene*-β-*thujone* (VIII) and crystallised from methyl alcohol in needles, m. p. 78·5° (Found : C, 81·2; H, 10·2; *M*, cryoscopic in benzene, 194·6, 186·3. $C_{13}H_{20}O$ requires C, 81·3; H, 10·4%; *M*, 192). Further small quantities of the ketone could be isolated from the oily by-product in the form of its sparingly soluble *semicarbazone*, which crystallised from methyl alcohol in leaflets, m. p. 208° (Found : C, 67·3; H, 9·2; N, 17·0. $C_{14}H_{23}ON_3$ requires C, 67·5; H, 9·2;

N, 16·9%). The ketone, on oxidation with ozone, gave acetone and a substance (giving a purple colour with ferric chloride), which was not further investigated.

Pinocamphone.—This ketone was obtained from oil of hyssop by fractionation under reduced pressure; the fraction, b. p. 84—86°/11 mm., had $d_4^{16\cdot5^\circ}$ 0·95676, $n_D^{16\cdot5^\circ}$ 1·47522, $[R_L]_D$ 44·74, and gave a semicarbazone, m. p. 228°. All attempts to condense the ketone with ethyl bromoacetate, ethyl malonate, ethyl acetoacetate, and ethyl cyanoacetate were fruitless.

*Dihydro-*m*-tolylacetic Acid* (IX).—This acid was prepared from 3-methyl*cyclo*hexenone as described by Wallach (*Annalen*, 1902, **323**, 138). The pure acid was treated with potassium hydroxide as described on p. 2598, but was recovered completely unchanged. Specimens of the acid before and after treatment with alkali were treated with iodine, but no difference in iodine absorption could be detected (95·6% in both cases).

Attempts to prepare the corresponding ketone (X) by the Blaise–Maire reaction failed because the chloride of the acid, like that of the acid (V), could not be distilled. The crude acid chloride did not give a satisfactory product.

Attempts were also made to obtain the ketone by condensing 3-methyl*cyclo*hexenone with acetone, but a pure substance could not be isolated from the complex mixture formed.

The authors' thanks are due to the Government Grant Committee of the Royal Society for a grant which has defrayed the cost of the investigation.

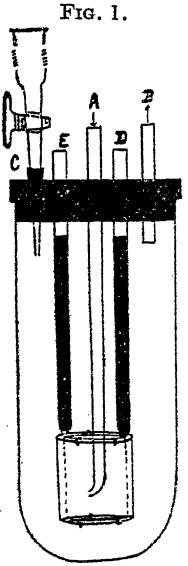
CCCXLV.—*The Constitution of Colloidal Platinum.*

By STUART W. PENNYCUICK.

THE source of the charge on colloidal metal particles, as prepared by the Bredig sparking method, has been a debatable question for many years. The older ideas, that the electrical method was one purely of dispersion and that the charge was frictional, have been shown to be insufficient and incorrect. At present two opposing views stand out. Both agree that the charge is ionic, and also that the method of preparation consists essentially in a mechanical dispersion to a vapour of perhaps atomic dimensions, with a subsequent condensation to form the colloid particles. They differ, however, as to the source of charge. One holds that the charge is

due to the combination of the condensed particles with certain foreign ions present in the medium. The other claims that the mechanical dispersion is always accompanied by the oxidation of the metal, and that in the subsequent condensation the fine particles of metallic oxide combine or react with the water to form a complex kation (in the case of copper or silver), or a complex anion (in the case of gold) (see Wo. Pauli, *Trans. Faraday Soc.*, 1921, **16**, 14; Fuchs and Pauli, *Koll.-Chem. Beih.*, 1925, **21**, 195; Paine, *ibid.*, 1912, **4**, 24; Rebière, *Compt. rend.*, 1912, **154**, 1540; Beans and Eastlack, *J. Amer. Chem. Soc.*, 1915, **37**, 2667).

The former explanation is the one more generally accepted, but it is shown in this paper that in the case of colloidal platinum, at least, although it may be difficult to fix the structure of the complex platinum anion, nevertheless the latter explanation appears to be the correct one. It will be shown that colloidal platinum solutions can be prepared of such strengths that their high conductivities cannot possibly be due to the impurities present, and further that all such solutions are definitely acid.



The Preparation of the Platinum Sols.—It is well known that platinum sols can be prepared in the total absence of added stabilisers, and accordingly those used throughout this work were prepared by sparking pure platinum electrodes in conductivity water and in the absence of carbon dioxide. The conductivity-water still was after the design of Bourdillon (J., 1913, **103**, 791), and the water used had a specific conductivity of 0·2—0·4 gemmho at 18°. The sparking apparatus was the same as that described by Pennycuick (*Australian J. Exp. Biology*, 1927, **4**, 99). Briefly, it consisted of a short-necked 500 c.c. borosilicate flask, through the cork of which two platinum electrodes passed to a small ebonite frame above. One electrode was firmly fixed whilst the other had a small range of vertical freedom. This freedom was used to close the spark gap, and a spiral spring on the movable electrode threw the gap open to any prearranged extent. The cork also carried an inlet and an outlet tube, so that during the preparation carbon dioxide-free air could be slowly bubbled through the sol. These tubes also served for the introduction of the conductivity water and for the removal of the prepared sol. All the connexions through the cork were air-tight, and the method of preparation therefore precluded the accidental introduction of any impurities.

It was essential to make certain that the only foreign matter present was that which was initially in the conductivity water, and this was kept strictly in mind. The air used was in every case freed from carbon dioxide. The conductivity water under air pressure was siphoned into the sparking vessel until a sample

from the latter showed a specific conductivity of less than 0·4 gemmho. About 450 c.c. of platinum sol were prepared at each operation, and during the sparking the sample was kept very close to 0° by the use of a freezing mixture. A direct current of about 5—6 amps. was used at 220 volts, and the time of sparking (excluding stoppages) was approximately 18—20 minutes per 450 c.c. of water.

The Conductivity Cell.—The conductivity cell was very similar in design to that used by Beans and Eastlack (*loc. cit.*). It was of borosilicate glass and had a total capacity of 120 c.c. The cell constant was 0·0107. The cell mouth was fairly wide (38 mm. diameter) and ground, and was closed with an ebonite stopper surrounded with an air-tight rubber band. The stopper carried 5 tubes (see Fig. 1)—the two electrode tubes D and E, an inlet and an outlet tube for air-stirring, A and B, and a spare tube for the introduction of any solution. All tubes were firmly fixed, and when in use the cell was air-tight. (I am indebted to Mr. J. S. Walker, B.Sc., for this cell, which proved very satisfactory.) All conductivities were measured in an electrically controlled thermostat at 25°.

FIG. 1.

The Specific Conductivity of the Platinum Sols.—Particular care was taken to keep the platinum sols pure. After preparation they were siphoned under air pressure, into thoroughly cleaned borosilicate flasks, always in the absence of carbon dioxide. They were kept for several days in order to allow the layer particles to precipitate, and the overlying sol was then siphoned into stock flasks and kept at the required temperature until wanted, the necessary quantity then being siphoned into the conductivity cell. The many samples examined are believed to be quite free from contaminations, including atmospheric carbon dioxide.

The first interesting point noticed was that the sols which had been prepared and stored at 0°, when put in the bath and allowed to come to 25°, showed a steady increase in conductivity over several days. Examples of such changes (at 25° and at 30°) are set out in Table I A.

TABLE I A.

Time interval (hrs.)	0	½	2	4	8	16	24	36	∝
κ (gemmhos) (at 25°)	5·65	6·10	6·58	7·05	7·97	9·23	9·91	10·42	14·3
κ (gemmhos) (at 30°)	5·68	6·96	8·20	9·02	10·00	11·17	11·69	12·01	14·6

An attempt was made to determine whether these changes followed any known velocity law, and, if possible, to obtain the temperature coefficient of the action; but although all solutions showed the same general changes, different samples of the same solution gave curves which did not correspond. (This is yet another example of the difficulty of reproducing exactly the same conditions in two samples of a colloidal solution.) All that could be concluded was that the change was always very rapid initially and then progressively slowed down.

The figures in Table I A, and in fact all similar figures, indicated that the specific conductivities of the platinum sols were approaching some limiting equilibrium value. Accordingly the solutions were boiled for 3 minutes and the conductivities redetermined, and it was thus found that equilibria were practically reached at 14·3 and 14·6 gemmhos in the above cases. It was observed that these values with the boiled solutions were not set up at once, but that the conductivities again changed with time. With these sols, however, the conductivities decreased, but the change was far less than before. Further investigation of the boiled and stable sols then revealed that, after any temperature changes, there was a lag in the equilibrium as indicated by conductivity measurements; a hot sample cooled to 25° always showed a steady fall in conductivity, whilst a cold sample warmed to 25° showed a corresponding rise, such changes being measurable over several days. These conclusions have an important bearing on the later work in this paper. The abnormally large lag shown by the unboiled solutions which had been made and kept at 0° (see Table I A) seems to indicate that these solutions have never reached their equilibrium; and this is supported by the fact that the unboiled platinum sols kept and *measured* at 0°, did not reach a maximum conductivity value even after 2 months.

Beans and Eastlack (*loc. cit.*), starting with conductivity water of 0·8 gemmho, prepared platinum sols of $\kappa = 3{\cdot}5$—$4{\cdot}3$ gemmhos. Further, they showed that the specific conductivity due to the charged platinum particles, calculated from their number, their charge, and their mobility, was of the order 0·0001 gemmho, and therefore negligible. They concluded that the "mechanical dispersion of the metal was followed by the formation of a colloidal complex between the dispersed metal and certain ions present in the medium." The present work goes considerably further, for, by starting with conductivity water of a maximum conductivity of 0·4 gemmho, and taking special precautions to exclude contaminations, platinum sols were readily prepared with specific conductivities which rose to 14·6 gemmhos. Further, as there was

no reason to believe that this was a limiting value, stronger sols were prepared by prolonged sparking which gave specific conductivities (after boiling) as high as 16·8 gemmhos. Higher values could probably have been obtained but prolonged sparking caused abnormal platinum wastage. Higher values were actually obtained by the prolonged boiling of a platinum sol, and also of course by evaporation; *e.g.*, an unboiled sample of $\kappa = 6{\cdot}21$ was boiled in a Pyrex flask in contact with carbon dioxide-free air; after 5 minutes' boiling it rose to 12·76 and after 25 minutes to 21·46 (all readings being taken at 25°). Conductivity water, when treated in the same flask in the same way, showed a change of κ from 0·4 to 0·89 gemmho. Similar platinum sols, when boiled in a large platinum dish for 2 minutes and for 15 minutes, showed $\kappa = 15{\cdot}35$ and 41·2, respectively; evaporation probably accounted for the latter high value. The highest conductivity obtained for a platinum sol by boiling in a platinum dish was 66·1 gemmhos. It was found that these high values very slowly decreased when the sol was kept at 25° for several days, but the fact that such values are actually obtained is very interesting. It is quite impossible, in view of the experimental precautions, to imagine that these conductivities can be due to the impurities present. The alternative, and the only reasonable explanation, seems to be that an electrolyte is formed during the sparking process.

Now it is well known that colloidal platinum particles carry a negative charge; and as a working hypothesis, the author suggests, in conformity with the theory of Pauli (see Pauli and Perlak, *loc. cit.*), that during the disintegration process some of the platinum is oxidised, and that during the subsequent condensation some platinum particles and some oxidised platinum particles coalesce; the oxidised platinum, however, in contact with water acts as an electrolyte (probably H_4PtO_4), with the result that the growing platinum particles form a complex anion, or ionic micelle of structure $[Pt_x(PtO_4)_y]^n$, which is in equilibrium with an equivalent amount of hydrogen ions. The high conductivities obtainable indicate that at least a small proportion of the hydrogen ions are "free," *i.e.*, that some of the complex is wholly ionised; whilst the lag in the equilibrium which is always shown when the sol suffers a temperature change, indicates that some of the hydrogen ions are held at the surface or in a surface double layer, and that rearrangements are slow and probably complex. These slow rearrangements are probably related to the slow equilibria changes in colloid systems observed by Du Noüy ("Surface Equilibria of Organic and Biological Colloids," 1926, p. 155).

It now remains to be shown that the complex anions and the

corresponding hydrogen ions are actually present. With regard to the former, all that can be said at present is that it has been abundantly proved that the platinum particles in the absence of foreign electrolytes are negatively charged, but the exact constitution of the micelle is so far unknown. With regard to the hydrogen ions, however, definite evidence will now be produced which clearly indicates the existence in the pure platinum sol of "free" hydrogen ions and also of slowly removable hydrogen ions, the latter being probably on the micelle surface or in the double layer.

The Titration of Platinum Sols.—Having obtained platinum sols of remarkably high specific conductivities, and believing that the charged platinum anions contributed only a negligible fraction thereof, it was considered that any real existence of hydrogen ions would be revealed by the titration of the sol with a base. For this purpose, the cell already described was utilised; 60 c.c. of the platinum sol were carefully introduced into the cell, and put into the bath at 25° until equilibrium was attained, or until the conductivity showed a negligibly small change over a period of 1 hour. A 3 c.c. burette, containing the titrating base and with a soda-lime tube on the upper end, was introduced into the opening C. A piece of rubber tubing on the lower end of the burette ensured an air-tight connexion; air was bubbled through a wash-bottle in the bath, containing a corresponding sample of the sol, and then through A into the cell for the purpose of efficient stirring and mixing. The exit tube B was connected to a water trap. Titrations were carried out initially with sodium or potassium hydroxide. These bases were prepared with conductivity water, diluted to exactly 0·001*N*, and stored in waxed bottles. They were introduced into the pipette without coming in contact with the air.

Now, if practically the whole of the conductivity of the platinum sol be due to the hydrogen ions, then from the known mobility of the hydrogen ion at 25° one may calculate at once its concentration. Writing the equivalent conductivity as equal to the sum of the ionic conductivities, we have

$$\Lambda_v = \Lambda_{H^+} + \Lambda_{Pt\ complex^-};$$

and neglecting the last term,

$$\Lambda_v = \Lambda_{H^+} = 349{\cdot}5,$$

whence $\kappa v = 349{\cdot}5$, where κ is the specific conductivity, and v is the volume in c.c. containing 1 g.-equiv. of hydrogen ions. We have then $v = 349{\cdot}5/\kappa$, and therefore $1000/v$, or the normality in the usual units, is given by $\kappa/0{\cdot}3495 = \kappa$ in gemmhos/349,500. (The ionic mobilities in this paper are calculated from those at 18°

by the use of the corresponding temperature coefficients; see H. S. Taylor, "A Treatise on Physical Chemistry," 1924, p. 540.)

Every platinum sol titrated showed with all bases used a minimum in the titration curve, indicating very clearly the presence of an acid or of titratable hydrogen ions—acids and salts showed no such minima. Further, with sodium and potassium hydroxides, all the platinum sols of various strengths showed a very good agreement between the hydrogen-ion concentration as calculated above from direct conductivity and that obtained from the minimum on the titration curve. Several normal cases are set out in Table I B. The differences in the minima shown by the two hydroxides are negligible.

TABLE I B.

	1.	2.	3.	4.	5.	6.	7.
κ (gemmhos)	6·57	7·00	12·76	15·03	15·35	21·46	41·2
(A) Normality of H^+ (calculated from κ) $\times 10^6$ ...	19	20	36	43	44	61	120
(B) Normality of H^+ (by titration) $\times 10^6$.	17	16	37	44	45	65	140

The normality marked (A) is calculated from κ (gemmhos)/349,500; that marked (B) is the normality of the solution with regard to total alkali hydroxide at the minimum on the titration curve. The figures in cols. 1 and 2 are for two unboiled samples. As such samples are not in equilibrium they were titrated fairly rapidly and the titration minima are approximate only. The figures in cols. 3, 4, and 5 are for samples which were brought to equilibrium by boiling for 2—5 minutes. Cols. 6 and 7 relate to samples boiled in Pyrex for 25 minutes, and in an open platinum dish for 15 minutes, respectively. They titrate fairly well.

From the agreement between the figures in Table I B, three conclusions may be drawn: (*a*) Colloidal platinum sols are definitely acid; (*b*) practically the whole of their conductivities can be attributed to the hydrogen ions present (the complex anion having negligible mobility); and (*c*) platinum sols behave as strong acids, for only strong acids show the correct conductivity minima when titrated with alkali hydroxides (see Eastman, *J. Amer. Chem. Soc.*, 1925, **47**, 332). A more detailed consideration, however, indicates that whilst the first of these conclusions is undoubtedly correct, the second and third cannot both be true. Table II shows the figures obtained on titrating platinum sols with each alkali, and also those obtained by titrating hydrochloric acid with potassium hydroxide. The latter figures allow a comparison to be made between the platinum sol and a strong acid, and they serve also to show that certain irregularities in the platinum sol titration curves

are not inherently due to the abnormally small concentrations with which we are here dealing (*q. v.*).

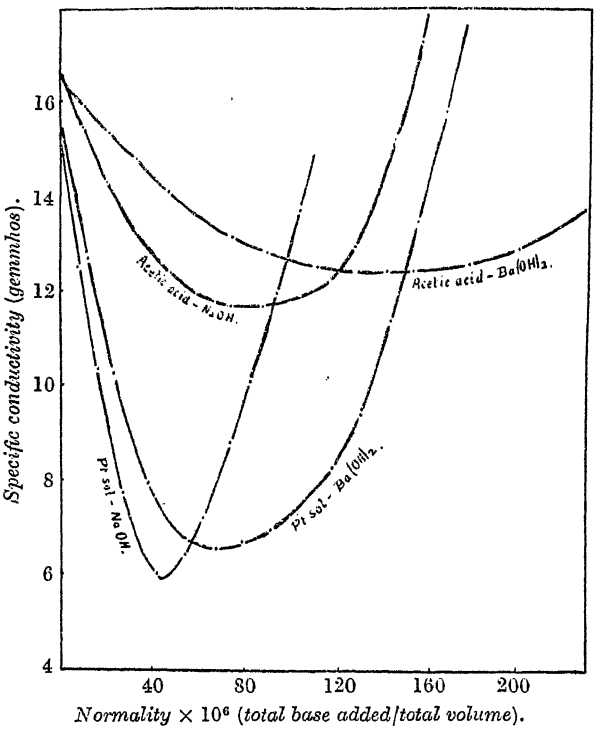
The normality refers to that of the solution in respect to total sodium or potassium ions present, and is the quotient Total base added/Total volume of solution.

The corresponding curves are shown in Fig. 2. The KOH–Pt sol curve is omitted, because it is of exactly the same form as the NaOH–Pt sol curve; in fact, the differences between the two curves agree remarkably well with the calculated differences between the mobilities of the potassium and sodium ions. This is also the case with the corresponding hydrochloric acid–strong base curves. Accordingly only the two curves shown in Fig. 2 need be discussed.

The initial specific conductivity of the platinum sol was 15·03 gemmhos, which, on the assumption that the hydrogen ion is practically the sole contributor to the conductivity, represents a hydrogen-ion concentration of 43×10^{-6}. The minimum on the curve appears to lie between 42×10^{-6} and 44×10^{-6}. At this minimum, the corresponding specific conductivity of the solution is 6 gemmhos; but if the platinum sol is behaving as a strong acid, then the minimum point on the curve will indicate that the whole of the hydrogen ions have been replaced by sodium ions, and the specific conductivity of 43×10^{-6} equivs. of sodium ion is only 2·27 gemmhos. The broken-line curve, ABCD on the figure, is that calculated from the mobilities of hydrogen, sodium, and hydroxyl ions on the foregoing assumptions. Although the curves are similar in shape and situation, the divergence is pronounced. In order to see whether titrations at such low concentrations were trustworthy, hydrochloric acid of approximately the same normality (*viz.*, $44{\cdot}6 \times 10^{-6}$) was titrated with various bases, and the HCl–NaOH curve also appears in Fig. 2. Other and weaker hydrochloric acid solutions were similarly titrated, and in every case the theoretical

and experimental end-points showed remarkably good agreement. In the curve illustrated, the end point corresponds to a concentration 45×10^{-6}, and the broken-line curve is the corresponding theoretical curve calculated from mobilities. The close approximation of the turning points in these two curves (Found: $\kappa = 7{\cdot}18$. Calc.: $\kappa = 6{\cdot}81$) shows that such titrations are quite trustworthy; and

FIG. 2.



the divergence of the two curves after the turning point is doubtless due to the mutual repression of ionisation of the sodium chloride and hydroxide present.

Returning then to the platinum sol titration curve, the difference between the specific conductivities at the experimental minimum (6 gemmhos) and at the theoretical minimum (2·27 gemmhos) needs

explanation. It appears either that some of the conductivity of the sol is contributed by other than the hydrogen ions, or that the colloidal platinum does not function as a strong acid. If either of these suggestions be true, then the agreement between the concentrations set out in Table I B would appear to be largely fortuitous This may actually be the case, for although a wide range of platinum sols was taken, the titrating bases were chemically similar. Accordingly, the titrations were repeated with calcium and barium

FIG. 3.

hydroxides, both prepared with the usual precautions and diluted with conductivity water to 0·001*N*. The two curves differed only slightly, and the difference could be directly ascribed to the difference in the mobilities of the barium and the calcium ions. Accordingly, Table III and Fig. 3 contain the details for only one of these bases. As a titration curve for a weak acid is also necessary for comparison, Table III and Fig. 3 contain the details of the titration of acetic acid of comparable conductivity (0·000141*N*) with sodium and calcium hydroxides.

TABLE III.

143	11·43	111·8	12·23	153·4	12·50
155	13·58	127·2	13·00	176·3	12·64
167	15·80	145·4	15·19	198·3	12·97
189	20·72	157·2	17·28	229·0	13·90
				242·9	14·50
				257·7	15·29

Now strong acids, such as hydrochloric acid, when titrated at this high dilution with sodium and barium hydroxides, show the same correct turning points and strictly comparable curves. The differences again are entirely due to the differences in the mobilities of the sodium and barium ions, and accordingly the HCl–$Ba(OH)_2$ figures are not quoted. On the other hand, weak acids such as acetic, when titrated with these two alkalis, show quite different curves, and give no indication of the *true* end point. It is of interest, however, that at these high dilutions these curves show remarkably good agreement with the theoretical titration results deduced by Eastman (*loc. cit.*). With the platinum sols, whilst the curves of sodium and potassium hydroxides are comparable, and those of barium and calcium hydroxides are also comparable, Table III and Fig. 3 show that the sodium and barium hydroxide curves differ radically, the minima appearing at $44 \times 10^{-6}N$ and $68 \times 10^{-6}N$, respectively. It is therefore evident that platinum sols are not strictly comparable with strong acids. On the other hand, they seem to be far stronger acids than acetic; in fact, their behaviour indicates that they approximate more closely to strong than to weak acids. The author believes that they are really unique, and that they cannot strictly be compared either with strong or with weak acids. This belief is based, not only upon the above facts, but also upon certain peculiarities which were noticed in every platinum sol titration: all conductivity readings showed a steady drift if followed over some considerable time; the drift was very slow and if time were allowed for each to come to equilibrium, every titration would have spread itself over many days. (An attempt is now being made to follow the complete equilibrium titrations.) Some pre-

liminary investigations showed that these drifts were so slow that if the titrations were carried out fairly rapidly their effects could be neglected. Accordingly all titrations were performed within a total time limit of 80 minutes.

Discussion.

The explanation of the various phenomena outlined above appears to be as follows. The pure platinum sol contains a certain amount of relatively free or "diffused" hydrogen ions which contribute the greater part of the conductivity; further, each platinum anion has a surface layer (or double layer) of non-diffused hydrogen ions. Any temperature change causes a disturbance in the equilibrium between the diffused and the surface hydrogen ions, and all such rearrangements are not instantaneous but measurably slow. This explains the temperature lag invariably obtained with pure platinum sols (see p. 2602). Boiling not only disturbs the equilibrium, but as the conductivity never reverts to its previous value, it would appear that boiling breaks up the complex anion, or at least sets free from it further hydrogen ions, which were probably held in the interior.

On the addition of a small quantity of a base, *e.g.*, sodium hydroxide, we have a particularly favourable and simple colloid system to deal with, for the solution contains only sodium, hydrogen, and colloid complex ions, and no foreign anions at all. The added base immediately neutralises some of the free hydrogen ions, and as this disturbs the hydrogen-ion equilibrium, some of the surface ions diffuse into the solution. In other words, the platinum sol behaves as a weak acid, but with the difference that, whereas weak acid ionic equilibria are instantaneous, these are measurably slow. There is, however, a second and even more important difference. It is well known that coagulated colloids always carry down with them ions of the opposite charge (see, *e.g.*, Whitney and Ober, *J. Amer. Chem. Soc.*, 1901, **23**, 842; Gann, *Koll.-Chem. Beih.*, 1916, **8**, 127; Freundlich, *Z. physikal. Chem.*, 1910, **73**, 385).

It must be concluded, therefore, that in the case under discussion some of the sodium ions go to the surface, and that a definite sodium-ion equilibrium is reached. Platinum sols thus differ from weak acids in that their "salts" are not wholly ionised. The rate of this ionic rearrangement would probably differ for different kations, but in any case the results indicate that it is not instantaneous. If these equilibria were all infinitely slow, then the platinum sols would titrate as strong acids. The curves show that these rearrangements are actually taking place during the time limit of the experiment. All the readings before (and for a short distance after) the neutral point were drifting towards a greater conductivity, due to the greater mobility of the hydrogen ions leaving the surface com-

pared with the sodium ions joining the surface. Towards the latter part of the titration the drift was in the opposite direction owing to the latter effect predominating, the sodium-ion concentration in the solution being now abnormally high.

The difference in the titration end points obtained with univalent and with bivalent bases is due, not only to the difference in the various equilibrium ratios (or equilibrium constants) for the different kations, but also to the different rates at which these equilibria are set up. The fact that the univalent bases give the same acid (titration) values as those obtained on the assumption that the hydrogen ion contributes practically the whole of the conductivity of the pure sol, may be due to a similarity in the univalent equilibrium ratios and equilibrium rates. On the other hand, it is not beyond question that the true acid concentration is really less than that obtained by these methods. An attempt has been made to settle this matter by a determination of the p_H of the pure sol with the quinhydrone electrode. Steady values are obtained and these are always lower than those read off from the titration curves, but it has not yet been determined whether quinhydrone acts normally in the presence of colloidal platinum. Work in this direction is proceeding. Colorimetric tests are out of the question; and the hydrogen electrode itself gives varying and untrustworthy values in these unbuffered solutions.

The slow equilibria between diffused or free ions and ions at the surface seem to be of fundamental importance in the coagulation of colloids. For instance, it is well known that if the bare minimum of electrolyte necessary to produce coagulation is added to a colloidal solution, the coagulation is invariably slow and may extend over several hours and even days. This is evidently due to the slowness of the equilibria under discussion. Further, according to Gann (*Koll.-Chem. Beih.*, 1916, **8**, 65), Steiner (*Z. physikal. Chem.*, 1910, **73**, 507), and Galecki (*Z. anorg. Chem.*, 1912, **74**, 174), the rate of these slow coagulations is best expressed by an empirical autocatalytic equation. No satisfactory explanation has so far been advanced for this, but the following qualitative suggestion may ultimately be of value. Before coagulation can occur a certain quantity of the coagulating ion has to move to the surface. This rearrangement being slow, a definite time interval will elapse over which practically no coagulation occurs. As the colloid particles vary in size, in shape, and in total charge, then, as the necessary equilibria are approached, the particles which are more favourably constituted will reach their coagulation condition first, followed more and more rapidly by the other colloid particles, the tota effect thus appearing to be autocatalytic.

Summary.

Colloidal platinum prepared in water of specific conductivity 0·4 gemmho, and rigorously kept free from contamination, can be made to yield a specific conductivity of 41·2 gemmhos at 25°.

It is suggested that oxidation accompanies the sparking process and that a colloidal complex acid is formed.

Pure platinum sols have been titrated with various bases, and the titration curves are discussed. Whilst the platinum sols titrate more like strong acids than weak acids, they cannot strictly be compared with either.

There appears to be a slow equilibrium between the diffused hydrogen ions and the hydrogen ions held at the surface of the complex platinum anion.

A similar equilibrium exists for any other added kation.

The consequences of the slow velocities of these equilibria are discussed.

[*Received, August 29th,* 1927.]

CCCXLVI.—*The Configuration of the Ammonium Ion. Part II. Geometrically Isomeric Quaternary Ammonium Salts derived from 4-Phenyl- and 4-Hydroxy-piperidine.*

By WILLIAM HOBSON MILLS, JOHN DAVIES PARKIN, and WILLIAM JOSEPH VICTOR WARD.

WITH the view of obtaining experimental evidence with regard to the distribution of the valencies of the nitrogen atom * in the quater-

* With regard to the stereochemistry of tervalent nitrogen I would take this opportunity to point out that the optical activity of the pyridylhydrazone of *cyclo*hexylene dithiocarbonate, which Mills and Schindler (J., 1923, **123**, 312) regarded as evidence of the non-planar distribution of the valencies of the doubly linked tervalent nitrogen atom, is capable of a different interpretation. At the time that the work was carried out we were of opinion that the dithiocarbonate was necessarily derived from the *cis*-form of the dithioglycol and our conclusions were based on this assumption. In view, however, of the remarkable investigations of Hückel and his co-workers (*Annalen*, 1925, **441**, 1; 1926, **451**, 109, 132; 1927, **453**, 163), from which it appears that *trans*-forms of the dicyclic compounds decalin, β-hydrindanone, and decahydroquinoline are not only capable of existence, but may even be more stable than the corresponding *cis*-forms, this view can no longer be upheld and I am now of opinion that the optically active hydrazone is probably to be regarded as a derivative of the *trans*-dithioglycol, and if this is the case the pyridylhydrazone is molecularly dissymmetric however the valencies of the doubly-linked nitrogen atom are disposed.—W. H. M.

nary ammonium ion Mills and Warren (J., 1925, **127**, 2507) prepared and examined some of the salts of 4-phenyl-4′-carbethoxybispiperidinium-1 : 1′-spiran. They showed that these salts could be obtained in optically active forms and pointed out that the pyramidal configuration for the ammonium ion (which might perhaps be regarded as *a priori* the more probable on the older view that the electric charge on the ion was stereochemically equivalent to the directly linked acid radical in the non-ionised salt) was thereby excluded and gave reasons for concluding that the ion consequently had the *tetrahedral* configuration (as was more probable on the electronic theory of molecular structure).

In the present communication an account is given of another and independent method of investigating the same question. Since in the ammonium ion the nitrogen atom and the four attached radicals do not lie in the same plane, it was to be anticipated that geometrical isomerism should occur among the quaternary salts of the 4-substituted piperidine bases. Such isomerism we have found does, in fact, exist and its investigation provides a means of obtaining a decision between the pyramidal and the tetrahedral configuration of the ammonium ion. For if the ammonium ion has the pyramidal configuration, then, as will be evident from Fig. 1,* every 4-substituted quaternary piperidinium salt, $RCH<\begin{matrix}CH_2\cdot CH_2\\CH_2\cdot CH_2\end{matrix}>NR'R''X$, should be capable of existence in two geometrically isomeric forms even although the two radicals R′ and R″ attached to the nitrogen atom might be identical. Each isomeride would be a racemic compound when these radicals were different, and a simple substance when they were identical, but in spite of this, if the isomerism could be detected in the one case it should also be demonstrable in the other. If, on the other hand, the ammonium ion has the tetrahedral configuration (Fig. 2) it is evident that geometrical isomerism could only occur when the radicals R′ and R″ were different and would disappear if they became identical.

We have examined salts of five quaternary bases derived from 4-substituted piperidines, three with different radicals R′ R″ (type I), and two with identical radicals R′R′ (type II) attached to the nitrogen atom.

* The rings in this and the following diagrams are represented plane for simplicity. There is an evident difficulty in representing piperidinium salts according to the Bischoff theory of the pyramidal configuration of ammonium salts, for it involves the replacement in *cyclo*hexane of a methylene group with a valency angle of 110° or more by an ammonium residue with a valency angle of less than 90°.

The difference between the two types proved to be clearly marked. The salts of type I, formed from a tertiary base,

$$RCH<\begin{matrix}CH_2\cdot CH_2\\CH_2\cdot CH_2\end{matrix}>NR',$$

and an alkyl halide, R''X, all showed themselves, when subjected to fractional crystallisation, to be mixtures of pairs of isomerides. On the other hand, the salts of type II, prepared in a corresponding manner, proved to be homogeneous.

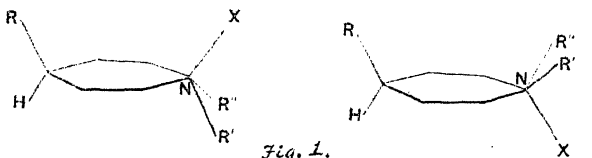

Fig. 1.

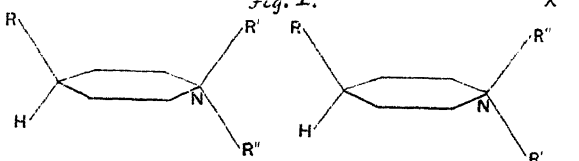

Fig. 2.

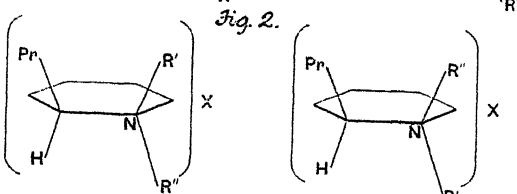

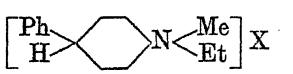

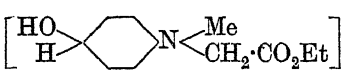

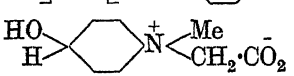

Fig. 3

The salts investigated were prepared from 4-phenylpiperidine and from 4-hydroxypiperidine. From the former compound were obtained the iodides and perchlorates of phenylmethylethylpiperidinium (I) and phenylbenzylethylpiperidinium and also phenyldiethylpiperidinium iodide and phenyldipropylpiperidinium iodide. From the latter compound the methobromides of 4-hydroxypiperidylacetic acid and of its ethyl ester (II) were prepared, as well as

(I.)  (II.) 

 (III.)

the corresponding betaine (III). Each of these salts in which two different radicals were attached to the nitrogen atom (salts of type I) was found to exist in two isomeric forms, as is shown in the following table :

Salts of type I.

Salt.	M. p. of *α*-isomeride.	M. p. of *β*-isomeride.
4-Phenyl-1-methyl-1-ethylpiperidinium iodide...	180°	140°
4-Phenyl-1-methyl-1-ethylpiperidinium perchlorate	135	159
4-Phenyl-1-benzyl-1-ethylpiperidinium iodide ...	240	210—215
4-Phenyl-1-benzyl-1-ethylpiperidinium perchlorate	208	189
Ethyl 4-hydroxy-1-piperidylacetate methobromide	221	206
Ethyl 4-hydroxy-1-piperidylacetate picrate	152—153	126
4-Hydroxy-1-piperidylacetic acid methobromide	170—172	210
4-Hydroxy-1-piperidylacetic acid methylbetaine	271—272	266—267

The salts of type II were found to consist of one form only. They had a sharp melting point and systematic fractional crystallisation gave no indication of the existence of a second modification.

Salts of type II.

	M. p.
4-Phenyl-1 : 1-diethylpiperidinium iodide	177°
4-Phenyl-1 : 1-dipropylpiperidinium iodide	190

In view of the evident possibility of the existence of geometrical isomerism in these salts and the absence, as far as can be seen, of any other cause to which the isomerism could be due, it appears safe to conclude that the isomerism exhibited by the salts of type I actually is a geometrical isomerism of the type sought for dependent on the non-planar distribution of the valencies of the ammonium nitrogen atom. This clear-cut difference between the salts of the two types therefore demonstrates that the quaternary ammonium ion has not a pyramidal configuration. It shows that the two radicals R′ and R″ attached to the nitrogen atom are unequally distant from the group R attached to the 4-carbon atom. The quaternary ammonium ion therefore cannot have the pyramidal configuration, and the valencies of the nitrogen atom in this ion must accordingly be tetrahedrally disposed.

The isomerism exhibited by the salts of type I thus corresponds closely with the *cis-trans* isomerism which occurs among the substitution derivatives of *cyclo*hexane, the relationship between the two forms of, for example, phenylmethylethylpiperidinium being represented by tridimensional formulæ such as those in Fig. 2 (R = Ph, R′ = Me, R″ = Et).

Although it was easy to show by fractional crystallisation that the salts of type I, as produced by the combination of tertiary base and alkyl halide, were not homogeneous, the isolation of both stereoisomerides in a state of purity from the mixtures of the two of which the crude salts consisted was not easily effected. Fractional

crystallisation brought about more or less readily the separation and isolation of the excess of the less soluble (α-) isomeride, but special methods were required to extract the pure β-isomeride from the mixture left in the mother-liquors.

The separation was most easily effected in the case of the phenylbenzylethylpiperidinium iodides. By allowing solutions of the mixed isomerides of appropriate concentration to crystallise under "aseptic" conditions, usually the α-form only separated, the β-form remaining in supersaturated solution. On then decanting the supersaturated solution and scratching, the pratically pure β-isomeride crystallised.

In the other cases the more soluble β-iodide could only be isolated through the replacement of the iodine by another acid radical which gave a less soluble salt with the β- than with the α-base. This β-salt could then be isolated in a state of purity and converted into pure β-iodide.

Thus in the case of α- and β-phenylmethylethylpiperidinium the solubilities of the perchlorates are in the inverse order of those of the iodides. The pure β-perchlorate could accordingly be isolated from the mixed perchlorates and gave on treatment with potassium iodide the pure β-iodide.

Similarly with the 4-hydroxypiperidinium salts; by fractional crystallisation of the mixed ethyl hydroxypiperidylacetate methobromides only the less soluble α-salt could be isolated. The more soluble of the two ester methobromides corresponds, however, with the less soluble of the two methylbetaines and the pure β-methylbetaine could therefore be obtained and from it the other salts of the β-series.

The stereoisomeric salts have considerable stability; no tendency to intertransformation was observed at the ordinary temperature. For example, when α-phenylmethylethylpiperidinium perchlorate was converted into iodide and then reconverted into perchlorate, pure α-perchlorate of melting point 159° was obtained. Transformation from one series to the other could, however, be brought about by heating. The change could be most easily observed with the phenylbenzylethylpiperidinium iodides. The more soluble β-iodide melts at 210—215°. If kept slightly above 215°, the molten salt resolidifies and the resolidified material is the α-isomeride, for it shows the melting point of that modification (240°, decomp.) and on conversion into perchlorate yields the pure α-perchlorate.

The relative quantities of the stereoisomeric salts produced in these additions of alkyl halides to 4-substituted tertiary piperidine bases were examined with the aid of melting point–composition curves in two of the cases investigated, namely, the addition of benzyl

chloride to phenylethylpiperidine and of ethyl bromoacetate to hydroxymethylpiperidine. In each case the quantities of the two isomerides formed were approximately in the ratio of 2 to 3. There is thus no great disproportion in the relative amounts of the two isomerides produced.

The isomerism of the quaternary ammonium salts here described is closely allied to the isomerism observed by Scholtz among the quaternary salts derived from coniine (*Ber.*, 1904, **37**, 3627; 1905, **38**, 595). Scholtz found that when an alkyl halide R'X combined with a 1-alkyl derivative of *d*-coniine, $CH_2<\begin{matrix}CH_2\text{-}CHPr\\CH_2\text{—}CH_2\end{matrix}>NR$, to form a quaternary salt the product was a mixture of two isomerides. Since the salts thus formed necessarily contained two asymmetric atoms, namely, the asymmetric carbon atom already present in the coniine and a newly formed asymmetric nitrogen atom, the isomerides were evidently the diastereoisomeric compounds (*d*C·*d*N), (*d*C·*l*N) and such isomerism should occur whatever the configuration of the quaternary ammonium nitrogen. The observations of Mills and Warren (*loc. cit.*) together with those described in the present communication show, however, that Scholtz's isomeric salts were *cis-trans* isomerides of the type indicated in Fig. 3.

Experimental.

A. Derivatives of Phenylpiperidine.

1-Alkyl Derivatives of 4-Phenylpiperidine.—4-Phenylpiperidine is shaken at the ordinary temperature with the alkyl iodide (1 mol.) and 10% aqueous sodium hydroxide (1·1 mols.). When the interaction is complete, the tertiary base (and unchanged phenylpiperidine) are extracted with ether. To remove the phenylpiperidine, the mixture is shaken with benzoyl chloride and alkali for 5—10 minutes at 50—60°. The tertiary base, and the benzoylphenylpiperidine thus formed, are taken up in ether and the former is extracted with dilute sulphuric acid from the ethereal solution. It is then isolated in the usual way, being finally purified through the crystallisation of an appropriate salt.

4-Phenyl-1-methylpiperidine was prepared from methyl iodide and phenylpiperidine by the above described method, but as the reaction is vigorous ether was used as a diluent. The base can also be prepared, as has been found by one of us and Mr. F. N. Kerr, by heating phenylpiperidine hydrochloride with formalin. It was purified by crystallisation of its perchlorate from ether–alcohol. The perchlorate forms felted needles, m. p. 106—107°, readily soluble in alcohol but sparingly in water and melting under water at about 25°. The pure *base* is a colourless liquid, m. p. 9°, b. p. 122—123°/

11 mm. (Found: C, 82·2; H, 9·8; N, 8·0. $C_{12}H_{17}N$ requires C, 82·2; H, 9·8; N, 8·0%). The *hydrochloride* (platelets from ether–alcohol) melts at 196—198° (Found: Cl, 16·6. $C_{12}H_{17}N,HCl$ requires Cl, 16·75%). The picrate melts at 244° (decomp.).

4-*Phenyl*-1-*ethylpiperidine*. The reaction between ethyl iodide, phenylpiperidine, and aqueous alkali proceeds slowly in the cold, 8—10 hours' shaking being required. The tertiary *base* was purified by crystallising the perchlorate (m. p. 112°) from alcohol. It is a liquid, m. p. 11°, b. p. 137°/11 mm. (Found: C, 82·3; H, 10·1; N, 7·7. $C_{13}H_{19}N$ requires C, 82·5; H, 10·1; N, 7·4%). The *hydrochloride* has m. p. 203—205° (Found: Cl, 15·6. $C_{13}H_{19}N,HCl$ requires Cl, 15·7%).

4-*Phenyl*-1-n-*propylpiperidine* was prepared by shaking *n*-propyl iodide, phenylpiperidine, and aqueous alkali together for 20 hours at room temperature, the final purification being effected through the perchlorate (m. p. 160—162·5°), which was recrystallised from ether–alcohol. The *base* is liquid at the ordinary temperature (m. p. 13°, b. p. 150°/11 mm.) (Found: C, 82·1; H, 10·5; N, 7·1. $C_{14}H_{21}N$ requires C, 82·7; H, 10·4; N, 6·9%). The *hydrochloride*, m. p. 250° (decomp.), is not very soluble in cold water (Found: Cl, 14·7. $C_{14}H_{21}N,HCl$ requires Cl, 14·8%).

α-4-*Phenyl*-1-*methyl*-1-*ethylpiperidinium Iodide*.—The α-modification of this salt is most easily isolated from the mixture formed by the combination of ethyl iodide with 4-phenyl-1-methylpiperidine, the combination being brought about by boiling the base with the alkyl iodide for 2 hours.

The product, after being dissolved in alcohol and precipitated with ether, melted at 152—154°. By fractional crystallisation from ether–alcohol of the mixture of the two iodides it could be resolved into a less soluble fraction, m. p. 170°, and a more soluble fraction, m. p. 148°. Since the iodides were only slowly separated by the fractionation, they were converted into perchlorates by dissolving them in water (10 g. in 500 c.c.) at 40—50° and adding an exactly equivalent quantity of silver perchlorate in aqueous solution, a little perchloric acid being also added to promote the coagulation of the silver iodide.

The less soluble iodide fraction gave a perchlorate which, recrystallised from alcohol, yielded the pure α-perchlorate in felted needles of constant melting point 135°. On conversion of this perchlorate into iodide by dissolving it in a concentrated aqueous solution of potassium iodide, extracting the salt with chloroform, and precipitating it from the dried chloroform solution with ether, the pure α-*iodide* was obtained as colourless plates, m. p. 180—181° (Found: C, 50·7; H, 6·8; I, 38·0. $C_{14}H_{22}NI$ requires C, 50·75; H, 6·7; I, 38·3%).

It melts under water, in which it is not very soluble, dissolves readily in alcohol, and is exceedingly soluble in chloroform.

β-4-*Phenyl*-1-*methyl*-1-*ethylpiperidinium iodide*. This modification is most easily isolated from the mixture of the two forms of the quaternary iodide which is produced by the addition of methyl iodide to phenylethylpiperidine. After completion of the combination, which proceeded with evolution of heat, the resulting crystalline cake was dissolved in a little alcohol and reprecipitated by the addition of 2—3 volumes of ether. The mixture of iodides thus obtained, m. p. 146—147·5°, was converted into perchlorate by treating it with silver perchlorate as described above. The salt which crystallised directly from the aqueous solution consisted almost entirely of the β-form and readily gave the pure β-perchlorate on crystallisation from alcohol. The β-perchlorate crystallises in plates, m. p. 159°, and is sparingly soluble in cold alcohol and very sparingly in cold water. On conversion into iodide the pure β-*iodide* was obtained. This salt crystallises in plates which liquefy in contact with cold water. It is dimorphous, the two forms melting at 140° and 146°. It always crystallises from solution in the form melting at 140°, but usually resolidifies in the form melting at 146° (Found: C, 50·75; H, 6·55; I, 38·3. $C_{14}H_{22}NI$ requires C, 50·75; H, 6·7; I, 38·3%).

The aqueous solution from which the β-perchlorate had crystallised was evaporated almost to dryness at 30—40° under diminished pressure. By fractional crystallisation from alcohol of the salt thus obtained, a further small quantity of pure β-perchlorate could be separated, but the bulk consisted of a mixture melting at 115° and crystallising unchanged from alcohol or water. This mixture, on conversion into iodide, gave a product, melting at 150°, from which, by crystallisation from ether–alcohol, an iodide of m. p. 170° was obtained and this on conversion into perchlorate gave the pure α-perchlorate identical in melting point and mixed melting point (135°) with the α-perchlorate obtained as described in the preceding section.

α- *and* β-4-*Phenyl*-1-*benzyl*-1-*ethylpiperidinium iodides*. Equivalent quantities of 4-phenyl-1-ethylpiperidine and benzyl chloride were heated at 100° for 2—3 hours. The product was dissolved in water, small quantities of unchanged material were removed by extraction with ether, and the mixed quaternary perchlorates, which are almost insoluble in water, were precipitated by adding a concentrated solution of sodium perchlorate.

From the mixture, m. p. 182°, the very sparingly soluble α-salt was obtained by extraction with alcohol. The mixed salt (20 g.) was boiled with alcohol (200 c.c.), and the solution filtered hot.

The mixture of maximum solubility, m. p. 172°, was deposited on cooling and the mother-liquor was used again to extract the undissolved salt; the process was repeated until the crystals deposited showed a melting point distinctly above 172°. The residue, which melted above 200°, was then nearly pure α-perchlorate and was recrystallised from a large volume of alcohol until it melted constantly at 208°, the melting point of the pure salt.

The β-perchlorate was obtained from the mixture of maximum solubility by a method based on its tendency to form supersaturated solutions. Alcohol was stirred with the mixture at 35—40° until practically saturated. The resulting solution was "sterilised" by heating to the boiling point and after being seeded with a few crystals of the carefully purified α-form was allowed to remain overnight, the neck of the flask being plugged with cotton wool. The α-modification then usually crystallised alone in slender needles and the decanted solution deposited the β-modification on scratching. Recrystallised from alcohol, it melted at 189°.

Mixtures of the two perchlorates have the following melting points:

% β-Form	0	20	35	50	63	75	85	100
M. p.	208°	195°	184°	172°	170°	176°	182°	189°

To convert the perchlorates into iodides, the salt (2 g.) was boiled with absolute alcohol (200 c.c.) and finely powdered potassium iodide (10 g.), and the solution filtered after 1 hour. The iodide deposited on cooling the filtrate and adding an equal volume of ether was recrystallised from aqueous alcohol containing 30—40% of water. In this manner from the α- and β-perchlorates the pure α- and β-iodides were obtained.

α-4-*Phenyl*-1-*benzyl*-1-*ethylpiperidinium iodide* crystallises in iridescent plates, m. p. 240° (decomp.) (Found: C, 58·9; H, 6·6; I, 31·2. $C_{20}H_{26}NI$ requires C, 58·9; H, 6·4; I, 31·2%), and β-4-*phenyl*-1-*benzyl*-1-*ethylpiperidinium iodide* in needles, m. p. 210—215° (Found: C, 58·8; H, 6·6; I, 31·2%).

The molten β-iodide resolidifies when kept above its melting point and melts again at 240°, the melting point of the α-iodide. It was shown that the resolidified material was in fact the α-iodide by dissolving it in water and precipitating the pure α-perchlorate with sodium perchlorate.

4-*Phenyl*-1 : 1-*diethylpiperidinium iodide*. Phenylethylpiperidine was boiled with an excess of ethyl iodide for 2 hours. The resulting crystalline cake was fractionally crystallised from alcohol and ether–alcohol, but no separation could be detected, all the fractions melting at 177°, with the exception of the last, which melted at 176°, evidently on account of the presence of a trace of accidental impurity (Found:

C, 52·2; H, 7·0; I, 36·9. $C_{15}H_{24}NI$ requires C, 52·2; H, 7·0; I, 36·9%)

4-*Phenyl*-1 : 1-*di*-n-*propylpiperidinium iodide*. Phenyl-*n*-propylpiperidine was boiled under reflux for several hours with excess of *n*-propyl iodide. The resulting quaternary salt, fractionally crystallised from alcohol and alcohol–ether, showed no sign of resolution into isomeric modifications but melted constantly at 190° (Found: C, 54·7; H, 7·4; I, 34·2. $C_{17}H_{28}NI$ requires C, 54·7; H, 7·5; I, 34·0%).

We are indebted to Mr. D. Webb, of Emmanuel College, for assistance with the preparation and analysis of this and the foregoing compound.

B. Derivatives of Hydroxymethylpiperidine.

4-*Hydroxy*-1-*methylpiperidine*.—1-Methyl-4-pyridone (22·5 g.) (Lieben and Haitinger, *Monatsh.*, 1885, **6**, 300) was dissolved in boiling absolute alcohol (225 c.c.), and sliced sodium (75 g.) added as rapidly as possible. When the action had abated, absolute alcohol (750 c.c.) was added in portions of 50 c.c. After the sodium had dissolved, water was added and the mixture was distilled with steam until 1 litre of distillate had been collected. The product was then driven over with superheated steam. The aqueous distillate (2 l.), acidified with hydrochloric acid and evaporated, left a brownish residue which, crystallised from absolute alcohol, gave 4-*hydroxy*-1-*methylpiperidine hydrochloride* (20 g.) as colourless prisms, m. p. 157—158°; these were hygroscopic, very soluble in water, easily soluble in hot, and sparingly soluble in cold alcohol (Found: Cl, 23·5. $C_6H_{13}ON,HCl$ requires Cl, 23·4%). By decomposing this hydrochloride with alkali the free base (Emmert, D.R.-P. 292871) was obtained as an oil, b. p. 105°/18 mm., which we found to crystallise on keeping (m. p. 28°). The *hydrobromide* formed colourless needles, m. p. 139—140°, from alcohol (Found: Br, 40·9. $C_6H_{13}ON,HBr$ requires Br, 40·8%).

Ethyl α-4-*Hydroxy*-1-*piperidylacetate Methobromide*.—4-Hydroxy-1-methylpiperidine (12·2 g.) and ethyl bromoacetate (23·7 g.) dissolved in benzene (180 g.) reacted at room temperature with the formation of quaternary bromide, the mixture setting to a crystalline mass which was collected after 20—24 hours. The product was a mixture of the α- and β-bromides, m. p. about 204°, and the yield was practically quantitative (Found: Br, 28·2. $C_{10}H_{20}O_3NBr$ requires Br, 28·3%).

The α-modification of the salt was obtained by boiling out the product from the above quantities with absolute alcohol (90 c.c.), filtering the hot solution, and boiling the residue successively with

50 c.c. and 40 c.c. of alcohol. The residue left (6·9 g., m. p. 220°), crystallised from rectified spirit, had m. p. 221° (decomp.), which could not be raised by further treatment.

Ethyl α-4-hydroxy-1-piperidylacetate methobromide forms colourless prisms very soluble in water and sparingly soluble in alcohol (Found: C, 42·7; H, 7·1; Br, 28·3. $C_{10}H_{20}O_3NBr$ requires C, 42·6; H, 7·1; Br, 28·3%). The *picrate* forms yellow needles, m. p. 152—153°, moderately easily soluble in alcohol or water (Found: N, 13·1. $C_{16}H_{22}O_{10}N_4$ requires N, 13·0%).

α-Methylbetaine of 4-Hydroxypiperidylacetic Acid.—An aqueous suspension of freshly prepared silver oxide was gradually added to ethyl α-4-hydroxypiperidylacetate methobromide until the brown colour of the oxide persisted. The filtrate from the silver bromide was evaporated, finally over sulphuric acid in a vacuum, and the residue was dissolved in hot alcohol, a little brown insoluble matter being removed by filtration. On cooling, the betaine was deposited as pearly leaflets, m. p. 271—272°, moderately easily soluble in alcohol and easily soluble in water (Found: C, 55·2; H, 8·4. $C_8H_{15}O_3N$ requires C, 55·4; H, 8·7%).

α-4-Hydroxypiperidylacetic Acid Methobromide.—The above described betaine was converted into the corresponding methobromide by dissolving it in a slight excess of hydrobromic acid and evaporating the solution on the water-bath under diminished pressure. The residue, crystallised from alcohol, gave the *methobromide* as colourless prisms, m. p. 170—172° (Found: Br, 31·2. $C_8H_{16}O_3NBr$ requires Br, 31·5%).

If the betaine is dissolved in less hydrobromic acid, a *basic salt* is obtained containing two molecules of betaine to one molecule of hydrogen bromide. It crystallised from alcohol in clusters of fine, radiating needles, m. p. 215—218° (decomp.) (Found: Br, 18·9. $C_{16}H_{31}O_6N_2Br$ requires Br, 18·7%). Similar compounds were obtained by Krüger from pyridine betaine (*J. pr. Chem.*, 1891, **43**, 289). The substance probably has the constitution

$$\bar{Br}\left[C_5H_9(OH)\overset{+}{N}<\begin{matrix}Me & Me\\ CH_2\cdot CO_2 & \end{matrix}>\overset{+}{N}C_5H_9\cdot OH\right]\begin{matrix}\\ \\ CH_2\cdot CO_2H\end{matrix}$$

the dotted line representing an electro-valency.

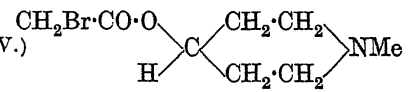
β-Methylbetaine of 4-Hydroxypiperidylacetic Acid.—The filtrate from the first extraction with alcohol of crude ethyl hydroxypiperidylacetate methobromide (p. 2622) was evaporated and the residue (11·5 g.) was converted into betaine with silver oxide. The resulting mixture of the two betaines was extracted with cold alcohol (15 c.c.), which removed most of the more soluble α-compound; the residue, crystallised from rectified spirit, gave the pure *β-methyl-*

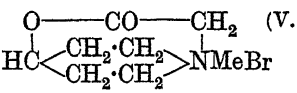
betaine as small, beautifully formed prisms, m. p. 266—267° (decomp.), sparingly soluble in alcohol, easily soluble in water. The crystals contain one molecule of water of crystallisation which is lost at 100° (Found : C, 50·2; H, 9·1; H_2O, 9·4. $C_8H_{15}O_3N,H_2O$ requires C, 50·2; H, 9·0; H_2O, 9·4%. Found for the anhydrous compound : C, 55·6; H, 8·7. $C_8H_{15}O_3N$ requires C, 55·4; H, 8·7%). The hydrated and the anhydrous substance showed the same melting point : a mixture with the α-betaine melted at 249—251°.

β-4-*Hydroxypiperidylacetic acid methobromide* was prepared by treating the corresponding betaine with hydrobromic acid in the manner described for the α-modification; it crystallised from alcohol in prisms, m. p. 210° (decomp.) (Found : Br, 31·5. $C_8H_{16}O_3NBr$ requires Br, 31·5%). A *basic salt* corresponding with that formed from the α-betaine could be isolated by using less hydrobromic acid. It formed colourless needles, m. p. 220—221° (decomp.), from alcohol (Found : C, 44·7; H, 7·2; Br, 18·9. $C_{16}H_{31}O_6N_2Br$ requires C, 44·9; H, 7·3; Br, 18·7%).

Ethyl β-4-*Hydroxypiperidylacetate Methochloride.*—The β-betaine (1 g.) was covered with absolute alcohol (10 c.c.) and dry hydrogen chloride was passed in, with cooling, to saturation; the betaine then gradually dissolved. After standing a day, the mixture was evaporated in a vacuum over sulphuric acid and solid sodium hydroxide; the residue, recrystallised from alcohol, gave the pure *ester methochloride* (0·93 g.) as rosettes of leaflets, m. p. 206° (decomp.) (Found : Cl, 14·9. $C_{10}H_{10}O_3NCl$ requires Cl, 14·9%).

The corresponding *picrate* was prepared from the chloride by double decomposition with sodium picrate; it formed golden-yellow needles, m. p. 126°, from water (Found : N, 13·0. $C_{16}H_{22}O_{10}N_4$ requires N, 13·0%). The pure β-picrate could not be obtained from the mixed picrates formed by the action of sodium picrate on the more soluble fractions of the original ester methobromide. Crystallisation from several different solvents gave only a mixture of unchanged m. p. 118—120·5°.





Ethyl β-4-*Hydroxypiperidylacetate Methobromide.*—The β-betaine (2 g.) and 9% alcoholic hydrogen bromide (30 c.c.) were allowed to stand over-night and then refluxed gently for 8 hours. The solid slowly dissolved on heating and, on cooling, the *ester methobromide* (2·2 g.; m. p. 205°) was deposited. After crystallisation from alcohol, in which it was moderately easily soluble, the pure compound of m. p. 206° was obtained (Found : C, 42·6; H, 7·2; Br, 28·1. $C_{10}H_{20}O_3NBr$ requires C, 42·6; H, 7·1; Br, 28·3%).

A series of mixtures of the α- and β-ester methobromides was prepared and the following melting points were observed :

% α-Salt.	M. p.	% α-Salt.	M. p.
0·0	206°	51·8	205°
13·1	205	69·7	208
26·1	203·8	81·0	211
33·4	203·5	89·0	214·3
41·9	203·8	100	221

A curve plotted from these data indicates that the two salts form a continuous series of solid solutions. The analytically pure mixture of the α- and β-bromides formed by the addition of ethyl bromoacetate to hydroxymethylpiperidine melted at 204°. This indicates that it contained either 22% or 42% of the α-salt, but the amount of α-salt isolated decides for the latter figure.

4-*Bromoacetoxy*-1-*methylpiperidine* (IV). It seemed not impossible that it might prove practicable to determine the configurations of the α- and β-series by relating compounds belonging to the one or the other to the lactone (V).

(IV.)  (V.) 

As neither the α- nor the β-methobromide of hydroxypiperidylacetic acid showed any tendency to lactonise on heating, 4-bromoacetoxy-1-methylpiperidine was prepared as a possible source of the lactone. A solution of 4-hydroxy-1-methylpiperidine (5·1 g.) in benzene (100 c.c.) was dropped with mechanical stirring during ¼ hour into bromoacetyl bromide (9 g.), and the mixture kept overnight. The benzene was decanted from the product, the hydrobromide of the required base, which had been deposited as a gum on the sides of the flask; this gum crystallised from alcohol in clusters of minute, radiating needles, m. p. 172°, very soluble in water and sparingly soluble in alcohol [Found: C, 30·3; H, 4·9; Br (ionic), 25·2. $C_8H_{15}O_2NBr_2$ requires C, 30·3; H, 4·8; Br (ionic), 25·2%]. We were unable to prepare the required lactone from the free base corresponding with this hydrobromide. Heated in benzene solution, it gave an amorphous solid, containing 2% too little bromine for the lactone, which was probably an impure polymeride. Heated in alcohol, it gave a mixture of the α- and β-methobromides of ethyl hydroxypiperidylacetate, indicating that alcoholysis of the bromoacetyl group had occurred followed by recombination of the products, hydroxymethylpiperidine and ethyl bromoacetate. That this lactone could not be prepared is not surprising, as its formation would involve the production of a tricyclic compound containing two 7-membered rings.

The authors desire to express their thanks to the Department of Scientific and Industrial Research for grants which enabled two of

them (J. D. P. and W. J. V. W.) to take part in this investigation, and to the Government Grant Committee of the Royal Society for grants by which part of the cost was defrayed.

UNIVERSITY CHEMICAL LABORATORY,
CAMBRIDGE. [*Received, August 25th,* 1927.]

CCCXLVII.—*The Electrolysis of Potassium Chloride Solutions by Alternating Currents.*

By ARTHUR JOHN ALLMAND and HERBERT CHARLES COCKS.

THIS subject has been studied by Coppadoro (*Gazzetta*, 1905, **35**, ii, 604), using 42-cycle current and 3*N*-potassium or sodium chloride. With polished platinum electrodes and at room temperature, no electrolysis was noticed until a *C.D.* of 0·5 amp./cm.^{2} had been exceeded; above this threshold value, hydrogen was evolved and hypochlorite formed, oxygen also being detected after the electrolysis had been proceeding for some time. The electrodes were corroded, and to some extent went into solution as platinum compounds and as colloidal platinum; if the *C.D.* were not sufficiently high, they became platinised and electrolysis ceased. With graphite electrodes, no hypochlorite was formed below a *C.D.* of 10 amps./cm.^{2}, under which conditions the electrodes were considerably attacked. The hypochlorite current efficiencies were low, *e.g.*, 2% during a 30-minute run at 1 amp./cm.^{2}. After a time, a stationary hypochlorite concentration was reached, and further electrolysis produced chlorate. In a second paper (*ibid.*, 1906, **36**, ii, 321), Coppadoro reports experiments carried out at 50—70°, under which conditions chlorate, and not hypochlorite, is formed.

The work now recorded is a systematic study of the different factors which can affect this electrolysis when carried out at room temperature. In particular, the effects of frequency, current density, and concentration have been investigated. It may be said at once that, in so far as the conditions under which we have worked coincide with those of Coppadoro, our results are in agreement with his.

EXPERIMENTAL.

Apparatus.—The cell used in the great majority of the experiments consisted of a beaker of about 200 c.c. capacity, provided with a wooden lid. This carried (*a*) the capillary exit-tube of a glass hood of bell-jar shape, which dipped below the surface of the electrolyte to within 1—2 cm. of the bottom of the beaker, (*b*) a thermometer, and (*c*) the glass tubes into which the electrodes were sealed. These

tubes were bent back twice through 90°, so as to project upwards below the edge of and into the hood. The electrodes, spaced vertically and parallel to one another about 2 cm. apart, were 1 cm. square, and were carefully polished and burnished before each experiment. The cell itself stood in a large vessel of water, in order to keep down the temperature during electrolysis. The capillary exit led to the three-way tap of a gas-burette, which could also be connected with a Hempel gas-pipette containing alkaline pyrogallol. About 90 c.c. of electrolyte were placed in the cell and, by manipulation of the burette, made to fill completely the hood, the capillary connecting tube, and one bore of the three-way tap. The gas-burette, the other tap-bore, and the second connecting tube were then filled with water, and the whole was attached to the pyrogallol pipette. After electrolysis for a definite period of time, the evolved gases were passed over to the burette (care being taken to transfer all bubbles adhering to the sides of the hood), measured, and the oxygen content was determined. No attempt was made to estimate or to allow for any gases dissolved either in the electrolyte or in the burette liquid. No chlorine was detected at any time, and consequently, after subtracting the oxygen present, the residue was regarded as hydrogen. Immediately after the transfer of the gases, the cell liquid was made up to a definite volume, and analysed by the usual methods for hypochlorite and for total available oxygen. The presence of platinum in the solution caused the iodine–starch end-point to be rather less definite than usual, but did not appreciably affect the accuracy of the analysis.

The current used was hand-regulated by a variable resistance, and measured by a calibrated hot-wire ammeter. It was produced by one of two machines (a G.E.C. 16-pole alternator, capable of being run between the limits of 5 and 240 cycles, and a 24-pole alternator of inductor type, made by the Crocker–Wheeler Company, and giving 350—500 cycles) which have been described elsewhere (*Trans. Faraday Soc.*, 1925, **21**, 1).

Preliminary Experiments.—When graphite electrodes, 3*N*-potassium chloride, and a *C.D.* of 1 amp./cm.^{2} were used, electrolysis was inappreciable with 18 cycles, and only very slight at a frequency of 6 cycles. (With this very low frequency, we made no attempt to use higher *C.D.*'s. This could only have been done by reducing the size of the electrodes, the output of our machine under these conditions being small.) With polished platinum electrodes and a frequency $n = 6$, there was considerable electrolysis even at 0·3 amp./cm.^{2}. If the electrodes were platinised, the results were as with graphite. These experiments also showed the importance of determining the hypochlorite immediately after conclusion of the

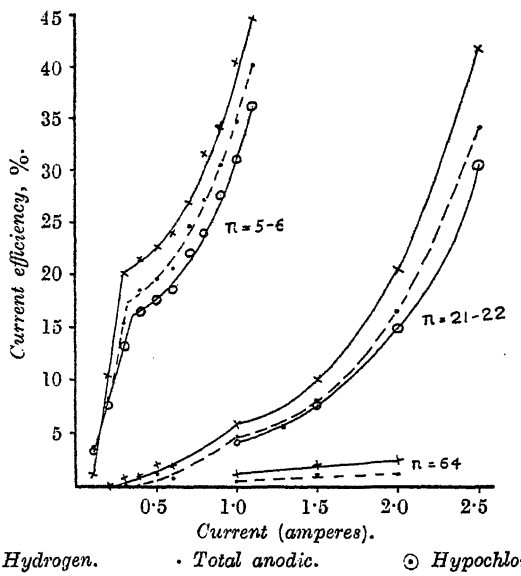
electrolysis. In presence of the 3*N*-potassium chloride, decomposition was fairly rapid, even in the absence of platinum and platinum compounds.

Effect of Frequency and Current Density.—The experiments described in this section were all carried out with 3*N*-potassium chloride. The frequencies employed were $n = 5$—6, 21—22, 41, 50, 64, and 120 cycles per second. Depending on n (and therefore on the available output of the machine), the currents used varied between the limits of 0·1 and 2·5 amps. Low *C.D.*'s and high frequencies favoured platinisation of the electrodes. With $n = 6$, this was hardly perceptible, even with the lowest *C.D.*'s employed (0·1—0·3 amp./cm.^{2}); with $n = 22$, platinisation was appreciable with low *C.D.*'s, but very slight with 2—2·5 amps./cm.^{2}; with the higher frequencies, it was always very noticeable. In addition, a yellow deposit (probably potassium chloroplatinate) was sometimes found on the electrode; it was produced neither at the lowest nor at the highest *C.D.*'s, but usually at about 0·3—1 amp./cm.^{2}. It was less noticeable with high frequencies. Finally, with all except the lowest *C.D.*'s, the electrolyte became yellow or brownish-yellow and finally cloudy, and the more so as the electrolysis proceeded. On the assumption that the lessened tendency to formation of deposits of any kind on the electrodes at high *C.D.*'s is due to their being scoured by the rush of evolved gas, the facts mentioned are qualitatively consistent with the conception that ionisation of the normally passive platinum, like the other electrolytic processes (as will be seen), takes place the more readily during the anodic pulse the lower the frequency and the higher the *C.D.*; and that the reverse change takes place to a greater extent during the cathodic pulse the higher the frequency.

Only in one case ($n = 41$, $i = 2$ amps.) was any chlorate production noticed, and here there was definite local heating.

Table I contains a typical set of results. The current efficiencies are calculated, as throughout the paper, on a basis of actual coulombs passed, *i.e.*, assuming the current to have a sine wave form, the average current used for the calculation is 0·9 of the value in column 2, or $i_{\text{average}} = 2\sqrt{2}/\pi \,.\, i_{\text{effective}} = 0{\cdot}9\ i_{\text{effective}}$.

Fig. 1 shows the effect of *C.D.* on current efficiency for $n = 5$—6, 21—22, and 64. A remarkable feature in the curves for the lower frequencies is the abrupt changes in direction that occur at 0·3—0·4 and at about 1 amp., respectively. Fig. 2 exhibits the effect of frequency for currents of 1, 1·5, and 2 amps.



As Fig. 1 shows the current efficiency (for the lower frequencies) to be increasing very rapidly with the *C.D.*, a few experiments were carried out with very high *C.D.*'s and platinum wire electrodes. In

this case, the gases were not collected, and the cell used, of 35 c.c. capacity, was cooled externally by running water. Each electrode consisted of 8 mm. of platinum wire of 0·38 mm. diameter, and had therefore a total area of 0·09—0·1 cm.^{2}. They were spaced about 1·3 cm. apart. The results (Table II) show that the curves for these frequencies in Fig. 1 must soon bend over with increasing current and, from being convex, become concave.

C.D.'s exceeding 15 amps./cm.^{2} at 22 cycles caused the formation of sparks and arcs around the electrodes, which remained quite clean

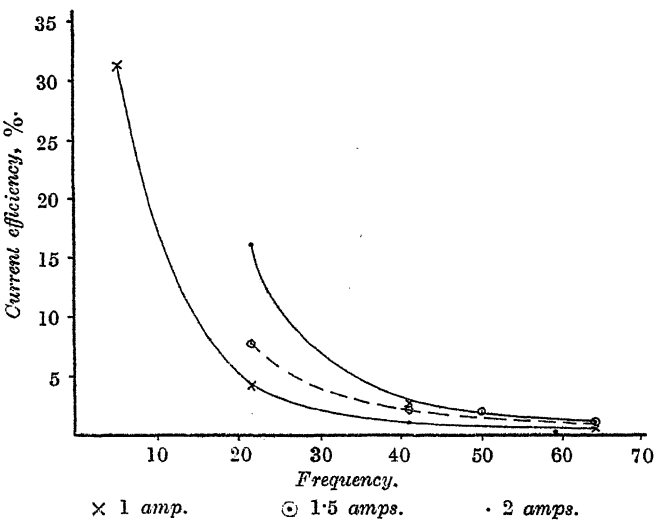

TABLE II.

in every case. At 5—6 cycles, the electrolyte also remained clear at these high *C.D.*'s, but became pale yellow in colour, whilst, with 22 cycles, it became dark brown or black. In all cases, good thiosulphate end-points were obtained (sharp change from blue to colourless).

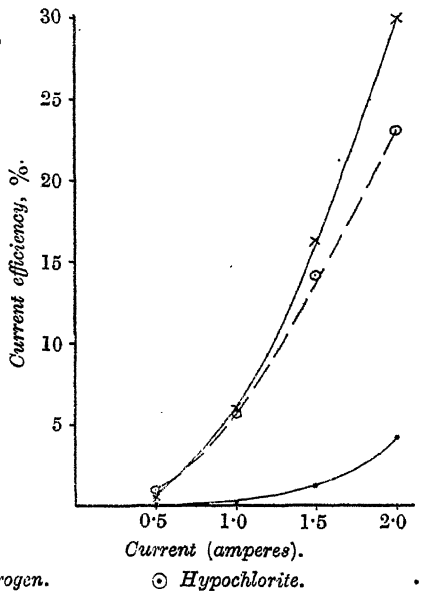

FIG. 2.

Whatever the *C.D.*, the total anodic current efficiency (hypochlorite plus oxygen) was less than the cathodic current efficiency (as in Table I, for $n = 6$). A determination of the quantity of platinum dissolved after one of the experiments indicated that about one-third of the usual deficiency could be accounted for in this way, assuming that the metal had dissolved in the quadrivalent state. In addition, the electrodes, carefully washed after electrolysis and then immersed in a colourless solution of acidified potassium iodide and starch, soon caused a slight colour to develop, showing that they contained traces of some oxidation product of platinum, the amount, however, being negligible in comparison with the "missing" oxygen. Formation of perchlorate was not tested for, but is very unlikely. As the products formed at the two electrodes were

collected together, the cause could not be a slight rectification. With platinum electrodes of unequal size in sulphuric acid, this does take place to a certain extent (Mengarini, *Electrician*, 1891, **27**, 334; Gundry, *Phil. Mag.*, 1906, **11**, 329; Vaillant, *Compt. rend.*, 1919, **168**, 687), and it was also observed by Ayrton and Perry (*Electrician*, 1888, **21**, 299) when using an ordinary Hoffmann voltameter. In our work, it seemed negligible, judging from the results of experiments carried out with a variety of *C.D.*'s and frequencies, a hot-wire ammeter and a moving-coil ammeter being in series in the circuit.

FIG. 3.

In some cases, indeed, we certainly noticed more gas coming off at one of the two apparently quite similar electrodes, but this does not necessarily indicate rectification.

Expressed in terms of oxygen gas, the maximum deficiency was of the order of 1 c.c. One possibility is that the missing gas had dissolved in the electrolyte or in the water in the measuring burette. Perhaps it was formed by spontaneous decomposition of the hypochlorite, and remained in a state of supersaturation, as is the case in the photodecomposition of chlorine water or of hypochlorous acid solutions (J., 1925, **127**, 822). It may be remarked that the alternating-current electrolysis of sulphuric acid between platinum electrodes has, on several occasions, been noticed to give a deficiency

of oxygen (Manœuvrier and Chappuis, *Compt. rend.*, 1888, **106**, 1719; Marsh, *Proc. Roy. Soc.*, 1920, **97**, 124).

Effect of Concentration.—A series of experiments was carried out on N-potassium chloride solutions, with frequencies varying between 6 and 180, and currents up to 2 amps. The electrodes became platinised in every case, but there was no formation of yellow deposit. The electrolyte became increasingly turbid (yellow or brown) as the electrolysis proceeded. Fig. 3 contains graphs of the data for $n = 21$, whilst in Table III are the results for $n = 5$—6 and $n = 21$—22, compared with the corresponding figures given by $3N$-potassium chloride.

TABLE III.

Frequency.	Current (r.m.s.) (amps.).	Cathodic current efficiency, %,		Hypochlorite current efficiency, %,	
		$3N$-KCl.	N-KCl.	$3N$-KCl.	N-KCl.
6	0·1	1·1	0·33	3·3	0·22
6	0·2	10·7	0·78	7·8	2·3
6	0·3	20·3	6·1	13·3	6·4
21	0·5	2·1	0·56	1·2	1·0
21	1·0	6·0	6·0	4·2	5·6
21	1·5	10·3	16·2	7·8	14·1
21	2·0	20·8	29·8	15·2	23·0

It will be noted that the curves for N-potassium chloride do not show the breaks which are such a marked feature in those for the $3N$-solution. Like the latter, their slope must clearly become less at higher *C.D.*'s. Corresponding to their continuous nature, the current efficiencies are seen to be lower at lower, and higher at higher, current densities than is the case with $3N$-potassium chloride. The effect of frequency is similar to that shown in Fig. 2.

A few experiments only were done with $0{\cdot}1N$-potassium chloride solutions, owing to the low conductivity and consequent tendency to temperature rise, with formation of chlorate. The results were of no particular interest.

Effect of Addition of Alkali.—These experiments, carried out with solutions of composition $3N$-KCl + $0{\cdot}1N$-NaOH, were suggested by the well-known fact that hypochlorites are more stable in alkaline than in neutral or acid solution. The results, compared with those given by a neutral solution, are shown in Table IV.

It will be seen that, whilst the yield of hypochlorite is lowered, that of both hydrogen and oxygen is increased by the addition of alkali, whilst the deficiency in the total anodic yield still persists. This last result appears to dispose of the suggested possibility of the deficiency being due to supersaturated oxygen resulting from chemical decomposition of the hypochlorite, for this was found to be very low in the alkaline solution.

0·8	31·8	24·2	3·2	27·4	34·4	22·0	8·3	30·3

Effect of Addition of Potassium Chromate.—It is well known that, in direct-current electrolysis of alkali-metal chlorides, the hypochlorite yield can be markedly increased by the addition of a chromate, its effect being to reduce considerably the cathodic reduction of hypochlorite ions which otherwise takes place, owing to the formation on the electrode of a film (" cathode diaphragm ") which is usually supposed to be chromium chromate. Experiments were consequently done with 3*N*-potassium chloride solutions containing, in addition, 1 g. of potassium chromate per litre. It is unnecessary to give the results in detail, as the effects were small. Quite definitely, however, there appeared to be a decrease in current efficiency at low, and an increase at high, current densities. This was observed with both 6- and 22-cycle current. The platinum also appeared to be less attacked. No platinum-black was formed, nor did the electrolyte become as cloudy as under similar conditions in the absence of chromate.

Effect of Stirring.—Experiments were carried out in the simple type of cell used for investigating the effect of high *C.D.*, a mechanically driven stirrer running at a fairly high speed being used. No attempt was made to collect the gases. The anticipated increase in current efficiency is seen to be marked (Table V).

TABLE V.

6	1·0	31·4	38·7
42	1·0	2·4	6·2
42	1·5	2·1	8·3

Limiting Hypochlorite Concentration.—These experiments were carried out in the same simple cell. Stirring was not employed, but the cell was kept cool by a stream of water running over it. With 25 c.c. of neutral 3*N*-potassium chloride and a current of 1·2 amps.

at a frequency of 6, the hypochlorite concentration rose, first rapidly, then slowly, to about 0·27—0·28*N* after a run of 2½—3 hours. Further electrolysis led to no further increase—on the contrary, a slight decrease was observed after 5 hours, the concentration falling to 0·26*N*. Considerable amounts of a brown precipitate were formed, and the electrodes became covered with a (partly black) deposit. Gas evolution had almost ceased after 4 hours. An experiment with 3 amps. at 21 cycles gave very similar results—a concentration of 0·27*N* after 2½ hours, considerable electrode corrosion and precipitate formation, and gradual elimination of gas evolution. Before this ceased, it was noticed that much of it was taking place throughout the whole bulk of the electrolyte, not merely at the electrodes. In another experiment, after 4 hours' electrolysis with 1·2 amps. ($n = 6$), the solution was 0·32*N* with respect to hypochlorite. Chlorate was present to the extent of 0·095*N*. It was noticed that, in this case, gas evolution was much stronger at the end of the experiment than in the previous cases, and, at the same time, the electrodes were far cleaner. The addition of free alkali to the original electrolyte lowered the limiting hypochlorite concentration. On the other hand, the addition of 1 g./litre of potassium chromate raised it slightly, concentrations of 0·30—0·31*N* being obtained in three separate experiments, using 1·2 amps. and $n = 6$. Both results are in accordance with those recorded earlier.

Voltage Measurements.—Using the same apparatus, measurements were made of the r.m.s. voltage across the cell under varying conditions of electrolysis. In all cases, an unstirred 3*N*-potassium chloride solution was used, and the cell was cooled by running water. The electrodes were 1 cm. squares of polished and of platinised platinum, in addition to graphite electrodes of as nearly as possible the same area. In all cases, they were placed 1·2 cm. apart. The measurements were made by means of a Duddell thermo-galvanometer, previously calibrated by means of a standard *D.C.* voltmeter. Readings were taken immediately on switching in the current, and repeated at 10-minute intervals during 1 hour. With polished platinum, there was generally a fall during the electrolysis, varying from 1 or 2 centivolts up to several decivolts, comparatively rapid at the start, most noticeable when electrolysis was considerable, and obviously connected with the corrosion or platinisation of the electrodes. With platinised platinum and graphite, at which little or no electrolysis took place, the decreases in voltage noticed were correspondingly less. Occasionally a rise in voltage was observed. Under identical conditions of current and frequency, the cell voltage decreased in the order: polished

platinum>platinised platinum>graphite, represented by (A), (B), and (C) respectively in Table VI, which contains typical figures.

Electrolysis	Slight	Nil	Nil	Much	Slight	Slight	Slight	Nil	Nil

Owing to the time effect, the data are, in general, unsuited for exact comparison. It is clear, however, that the cell voltage increased both with increased *C.D.* and with diminished frequency. If the last factor were kept constant, more or less linear voltage–current density plots were obtained, which, on extrapolation to zero current, cut the voltage axis at some distance from the origin. These intercepts, which must be regarded as indicative of residual polarisation at the electrodes, were smaller the higher the frequency. But, even with 480 cycles, they corresponded to about 0·5 volt with polished and 0·2 volt with platinised platinum. This last figure must be regarded as showing the linear extrapolation to be unjustified.

Depolarisation by Chlorine at Platinum and Graphite Cathodes.—The lower r.m.s. voltages obtained with graphite as compared with polished platinum electrodes are in agreement with the much smaller degree of electrolysis found when using graphite, and suggest that, in this case, the electrode processes occurring during the anodic and cathodic pulses to a great extent simply reverse one another. The direct-current chlorine over-voltage is known to be greater, during the early stages of electrolysis, at graphite than at smooth platinum (Knobel, Caplan, and Eiseman, *Trans. Amer. Electrochem. Soc.*, 1923, **43**, 55), which argues for a slower rate of the reaction $2Cl \longrightarrow Cl_2$, and for a relatively great heaping up of chlorine atoms in the graphite surface layers. Under the conditions of alternating-current electrolysis, these might be expected to ionise during the cathodic pulse, whereas, with a platinum anode, hydrogen ions would be discharged. If, however, the reaction $2Cl \longrightarrow Cl_2$ is slow, so will also be $Cl_2 \longrightarrow 2Cl$, and consequently a graphite cathode depolarised by chlorine should be more easily polarised under the same conditions of *C.D.* than a similar smooth platinum cathode.

Experiments were done to test this view. The cell consisted of a U-tube of wide bore, partly filled with N-hydrochloric acid. In one limb was a platinum anode, in the other a 1 cm.-square cathode of either polished platinum or graphite, half immersed in the electrolyte. Against the cathode pressed the tip of a Luggin capillary, sealed in through the wall of the U-tube, and making connexion, through a bridge of $3N$-potassium chloride, with a normal calomel electrode. By means of a jet sealed into the bottom of this limb, a stream of chlorine gas could be bubbled round the cathode. After the electrolyte had been saturated with chlorine, the static cathode potential was measured, and then a series of continuously increasing small measured currents was passed through the cell, and the potential again observed after each alteration in current. The results are contained in Table VII. The differences observed are very marked, and of the nature anticipated.

Average Electrode Potentials during Alternating-current Electrolysis.—These measurements were carried out with currents of frequency 20, polished platinum electrodes in $3N$-potassium chloride being used, and a normal calomel electrode. Prior to them, readings were taken with 1 cm.-square electrodes of platinised platinum in N-sulphuric acid, a normal mercurous sulphate electrode being used as reference electrode, and currents of 17 and of 480 cycles being employed. The results indicated that, whilst a static platinised platinum electrode in N-sulphuric acid acts as an air electrode with a potential of about $\pi_H = +0{\cdot}97$ volt, its oxygen content increases and its average potential becomes more positive as electrolysis proceeds. When the current is cut off, the static potential slowly returns to the original air value. Typical results are contained in Table VIII.

Similar observations on the behaviour of the potentials of platinum electrodes in sulphuric acid under the influence of alternating currents have been made by Ghosh (*J. Amer. Chem. Soc.*, 1914, **36**, 2333) and by Vaillant (*Compt. rend.*, 1919, **168**, 768).

The average potential measured during electrolysis is seen to be less positive than the static air potential, but to increase with increasing *C.D.* As oxygen is liberated during the electrolysis (although only in traces at those *C.D.*'s used in this series of experiments) and in amounts increasing with, and more rapidly than, the *C.D.*, it is reasonable to assume here also, as with platinised platinum in dilute sulphuric acid, that the average electrode potential corresponds to the average oxygen charge in the electrode during the complete cycle. When the current is cut off, the potential rapidly rises, owing to the hypochlorite in the solution, and to an extent determined by the concentration of the latter. Slow decomposition of the hypochlorite will be accompanied by an ultimate gradual potential fall to the air value. It may be mentioned that Ghosh (*loc. cit.*), using platinum electrodes in hydrochloric acid solutions, also found the potentials to become more negative on polarisation with alternating currents. In this case, however, as no oxidising

agent is formed in solution, the electrode potentials, after electrolysis, simply return gradually to the limiting air potential figures.

Discussion.

The main results of this work are in general agreement with the "fundamental laws" of alternating-current electrolysis formulated by Mengarini (*Electrician*, 1891, 27, 304), *viz.*, that the current efficiency (1) decreases with decreasing *C.D.* and falls to zero below a threshold *C.D.* value, and (2) decreases with increasing frequency and becomes zero above a threshold frequency—these threshold frequencies and *C.D.*'s being functions of one another and also of the particular electrolysis in question. The most interesting feature of Figs. 1 and 3 is the discontinuity shown by the 3*N*-potassium chloride curves at low frequencies when compared with the *N*-potassium chloride curves. These breaks could not be correlated with changes in the electrode surface, and they seem difficult of explanation. Systematic measurements of electrode polarisation, best with the aid of an oscillograph, appear necessary. An increase in *C.D.* also increases the current efficiency of *direct-current* hypochlorite production; but, whereas the favourable effect is here probably connected with the more ready formation of an acid diffusion layer, free from hypochlorite ions, around the anode, in the case of alternating currents it is a question of a relative diminution in the extent to which the anodic and cathodic pulses merely neutralise one another's effects, as a result of discharged ions remaining in or on the electrodes.

The addition of *alkali*, obviously owing to the primary discharge of hydroxyl instead of chlorine ions, has been seen to lower the efficiency of hypochlorite production. This is also the fact in direct-current electrolysis; but, in that case, where higher hypochlorite concentrations are encountered, the cause is rather the destruction of the acid "diffusion layer" mentioned above, and the consequent facilitated anodic discharge of hypochlorite ions. The small effect of the addition of *chromate*, compared with its influence on the course of the direct-current electrolysis, results from the fact that the hypochlorite ions are produced inside, or in the pores of, and not outside, the "cathode diaphragm." For similar reasons, stirring increases the current efficiency, whereas the best results are obtained with direct currents when an undisturbed electrolyte is used.

The limiting hypochlorite concentration observed (about 0·3*N*) is, of course, far lower than that given by a direct current under similar conditions of concentration, current density, and temperature. It corresponds, in fact, roughly to the equilibrium concentration obtained at room temperature with 1·7*N*-sodium chloride, and a *C.D.* of 1·7 amps./dcm.^{2} (Foerster and Müller, *Z. Elektrochem.*,

1903, **9**, 196) whereas, in the present experiments, 3*N*-potassium chloride and a *C.D.* of 1·2 amps./cm.^{2} (at 6 cycles) were employed. As mentioned, chlorate was found to be present, and there is no doubt that, with alternating as with direct currents, the limit reached in the hypochlorite concentration is due to hypochlorite-ion discharge.

The electrode potential data have already been discussed. We will only add that oscillographic measurements appear necessary for their more detailed elucidation.

Summary.

(1) The alternating-current electrolysis of solutions of potassium chloride at room temperature, with polished platinum electrodes, has been investigated.

(2) The influence on the hypochlorite current efficiency of changes in concentration, current density, and frequency have been studied, as have also the effects of adding free alkali or a chromate.

(3) The maximum hypochlorite concentration possible under the conditions of electrolysis has been determined.

(4) Measurements have been made of the average electrode potentials during electrolysis under different conditions.

This work was carried out during the year 1923.

UNIVERSITY OF LONDON,
KING'S COLLEGE. [*Received, September 20th*, 1927.]

CCCXLVIII.—*The Formation of the Sulphites of Azo-compounds.*

By ALBERT THEODORE KING.

THE sodium bisulphite derivatives of azo-compounds, being markedly different in colour from the original azo-compounds, are of great technical interest in relation to commercial azo-dyes. The readiness or otherwise of their formation under various conditions determines the degree of fastness of the dye on wool to stoving (bleaching with sulphur dioxide) and to exposure to town air containing sulphur dioxide.

From preliminary observations that the effect of sulphur dioxide upon azo-compounds is greatly dependent on the conditions under which it is allowed to react, it appeared desirable to examine this reaction further, in relation both to the degree of departure shown, under optimum conditions, from the accepted commercial standards of fastness to stoving and to the influence of constitution and of substituent groups on the ease of sulphite formation.

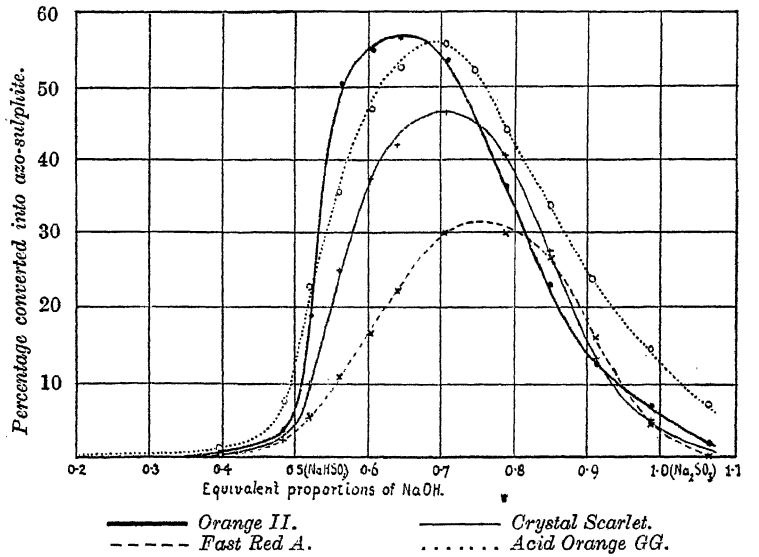
Spiegel (*Ber.*, 1885, **18**, 1479) prepared a number of these compounds of azo-dyes by reaction of the dyes with warm aqueous or aqueous-alcoholic solutions of sodium hydrogen sulphite, and observed that they were very stable towards dilute acids, but were decomposed by heat and by alkalis into the original dye and alkali sulphite. He regarded them as hydrazo-*N*-derivatives of the general formula $NHX{\cdot}NY{\cdot}SO_3Na$.

Voroschtsov (*J. Russ. Phys. Chem. Soc.*, 1911, **43**, 771; 1915, **47**, 1669), on the other hand, regards them as salts of sulphurous esters, *e.g.*, $C_6H_5{\cdot}N{:}N{\cdot}C_{10}H_6{\cdot}O{\cdot}SO_2Na$. He assumes that sulphurous acid is added to the naphtholic nucleus in the ketonic form, the product losing a molecule of water. He found that the reaction was characteristic of hydroxyazo-compounds, and that the corresponding aminoazo-compounds, on boiling with aqueous-alcoholic bisulphite, formed the sulphite, not of the aminoazo- but of the hydroxyazo-compound. He also found that the reaction was confined to the azo-derivatives of α- and β-naphthols. These reacted readily, whereas *o*- and *p*-hydroxyazobenzenes and benzeneazo-*o*- and -*p*-cresols underwent no change even on prolonged boiling.

He and his collaborators prepared the sulphites of a number of substituted azonaphthols, but did not make anything more than qualitative observations on their relative ease of formation.

A simple method of measuring the rate of formation of the sulphites of soluble azo-compounds is provided by the fact that these derivatives are very stable not only towards dilute mineral acids, but also towards acidified iodine solution. Thus by running the reaction mixture into excess of acidified iodine solution, and titrating back with thiosulphate, the amount of sulphur dioxide which has become inactive by combination with the azo-compound is readily ascertained. The method is free from the difficulties associated with the estimation of ketone bisulphites (Stewart, J., 1905, **87**, 185).

For the series of experiments to be described, the sodium salts of *p*-sulphobenzeneazo-β-naphthol (Orange II), 4-sulpho-α-naphthaleneazo-β-naphthol (Fast Red A), benzeneazo-β-naphthol-6 : 8-disulphonic acid (Acid Orange GG), and α-naphthaleneazo-β-naphthol-6 : 8-disulphonic acid (Crystal Scarlet) were selected, these having different degrees of fastness to stoving * (1—2, 2—3,



* The standard test for fastness of dyes on wool to stoving is carried out as follows : The dyed sample is soaked in 2% Marseilles soap solution, wrung out, placed in a vessel filled with sulphur dioxide by burning an excess of sulphur, left in for 12 hours, rinsed well in cold water, and dried. The dyes are placed in five classes according to the extent of colour change, class 1 being fast, and 5 the most fugitive.

1, and 2 respectively) and providing some indication of the influence of substitution on the ease of sulphite formation.

The measurements recorded were confined to 2-hour periods of reaction at 25°. Fig. 1 illustrates the percentage converted into sulphite by the equivalent quantity of sulphur dioxide, with various SO_2/NaOH ratios, the reaction mixture corresponding initially to N/50-sulphurous acid.

The most striking variation is shown by Orange II. The reaction is negligible with sulphurous acid alone, and the sharp rise in the

FIG. 1.

percentage of azo-sulphite formed occurs beyond the molecular ratio SO_2/NaOH = 1 (representing the formula $NaHSO_3$), the maximum being with about 1·3 mols. of sodium hydroxide. On either side of this maximum the reaction is extremely sensitive to variation of the SO_2/NaOH ratio.

On the assumption that the reaction consists in direct addition of sodium hydrogen sulphite to the dye to give the hydrazo-*N*-derivative as suggested by Spiegel (*loc. cit.*), $\cdot N{:}N\cdot + NaHSO_3 \longrightarrow \cdot NH\cdot N(SO_3Na)\cdot$, it would be expected that sulphurous acid and caustic soda in equimolecular proportion would effect the most rapid conversion.

Hägglund and Ringborn (*Z. anorg. Chem.*, 1926, **150**, 231) conclude that the addition of bisulphite to ethylenic linkages proceeds according to the similar equation $:C{:}C: + NaHSO_3 \longrightarrow :CH\cdot C(SO_3Na):$.

They found the velocity to depend on the concentration of sodium bisulphite (or the ion HSO_3'), and with normal sulphite there was no action.

Certainly with additional alkali (which readily decomposes azo-sulphites) it would be expected that the reaction would be arrested : $\cdot N{:}N\cdot + Na_2SO_3 + H_2O \rightleftharpoons \cdot NH\cdot N(SO_3Na)\cdot + NaOH$.

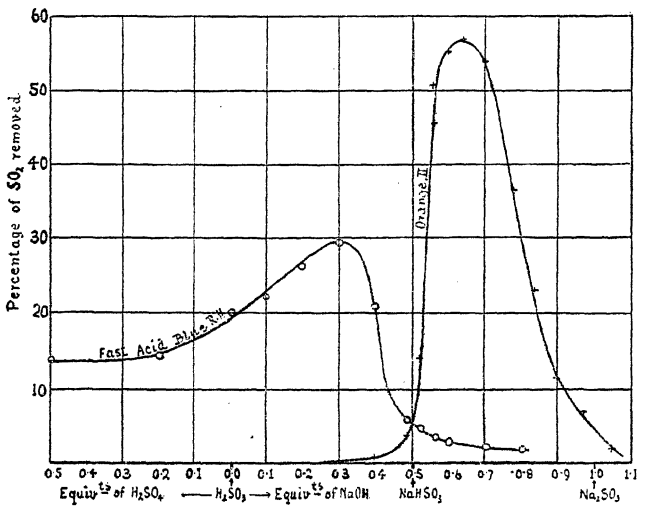
With normal sulphite, the reaction is in fact only slight (Fig. 1), although a small excess of sodium hydroxide beyond this proportion is needed to inhibit the reaction completely.

The above optimum ratio of greater than unity accords with the view that the hydroxy-group is participating in the reaction, and that theoretically the most rapid conversion would occur with a further molecular proportion of alkali, but that actually this is balanced by the simultaneous decomposing action of the latter.

It is known (Stewart and Baly, J., 1906, 89, 489) that the bisulphite compounds of ketones are formed much more rapidly in the case of tautomeric compounds like acetoacetic ester, the reactivity being presumed to be inherent, not in the carbonyl group itself, but in its tautomeric character, which is governed by the action of the adjacent groups upon the carbonyl radical.

Evidence has been advanced, principally by Goldschmidt and Löw Beer (*Ber.*, 1905, 38, 1908), refuting the quinonoid structure of *p*-hydroxyazo-compounds, but there is still a conflict of opinion on this point (compare Puxeddu and Germain, *Gazzetta*, 1922, 52, i, 216) and Voroschtsov's view can be supported, even accepting the azophenolic structure, by assuming a similarly tautomeric hydroxyl group. This may also be the determining factor in the velocity of reaction, as Stewart and Baly maintain in the case of ketones. In the tautomerism of the latter, however, alkali favours the enol form, and the precise rôle of the excess of alkali above mentioned in accelerating the formation of azo-sulphites is not at present clear.

So far as is indicated by the four azo-β-naphthols examined, the sulphonaphthalene group obviously has a retarding effect compared with the benzene derivative, and the benzeneazonaphtholdisulphonate also is more reactive than the corresponding naphthaleneazonaphtholdisulphonate, but any generalisation must be deferred pending results over a wider range of azo-derivatives.



This preliminary series is, however, sufficient to illustrate both the varying reactivity of azo-compounds to sulphur dioxide under different conditions and also the anomalous behaviour at times encountered with dyes scheduled as of good fastness to sulphur dioxide under the special conditions of the stoving test, owing to their unsuspected sensitiveness to this reagent under favoubrale

conditions which can in various ways be fortuitously realised in practice.

As previously mentioned, the formation of azo-sulphites is not general with azo-dyes. The examples above were selected on account of their observed susceptibility and are all β-naphthol derivatives. The α-naphthol derivatives would appear to be generally less sensitive, and similar work on these is projected.

In addition, a third type, principally aminoazo-compounds, does not, according to Voroschtsov, give bisulphite derivatives, but either through fission or other form of decomposition is destroyed by bisulphite and is thus not regenerated by subsequent treatment

FIG. 2.

with caustic soda. As an example of such compounds, the sodium salt of 3 : 6-disulpho-8-hydroxy-α-naphthaleneazo-α-naphthylphenylamine-8-sulphonic acid (Fast Acid Blue RH),

$$OH\cdot C_{10}H_4(SO_3Na)_2\cdot N{:}N\cdot C_{10}H_5(SO_3Na)\cdot NHPh,$$

was investigated. This is very fugitive to stoving, turning eventually yellow, and is entirely different in behaviour towards sulphur dioxide from the sulphite-forming azo-compounds (Fig. 2). The extent of reaction in the 2-hour period employed is most marked with about 0·3 equivalent of alkali, and under the optimum sulphite-forming conditions the dye scarcely reacts at all.

Thus the foregoing results indicate that more precise information on the reactivity of sulphur dioxide towards the various types of azo-dyes is desirable from both the theoretical and the practical aspect, and further work is in progress with this end in view.

EXPERIMENTAL.

The dyes in question readily lend themselves to purification. Orange II, already practically pure in commercial form, was recrystallised twice from 90% ethyl alcohol. Acid Orange GG, Crystal Scarlet, and Fast Red A were first separated from inorganic salts by solution in pyridine and reprecipitation with ether; the Fast Red A was then recrystallised from amyl alcohol, and the other two from 90% ethyl alcohol. Their purity was checked by evaluation with titanous chloride, which gave Orange II 99·93%, Acid Orange GG 100·3%, Crystal Scarlet 99·0%, and Fast Red A 99·1%.

Preparation of Azo-sulphites.—The sulphites of the above-mentioned azo-compounds were obtained by stirring the powdered dye into excess of concentrated sodium bisulphite solution, gently warming the liquid, and keeping it over-night. The bisulphite solution is conveniently made by adding 10% sodium hydroxide solution to commercial bisulphite solution (20% SO_2) until the latter reacts only faintly acid to litmus paper. The ease of isolating the azo-sulphite varies with the azo-compound employed.

Sodium 4-*Sulpho*-α-*naphthaleneazo*-β-*naphthyl Sulphite* (Bisulphite Compound of Fast Red A).—The reaction mixture was filtered, and the solution saturated with sodium chloride. The precipitate thus obtained was twice again salted out from aqueous solution and was then deposited from aqueous-alcoholic solution, by gradual addition to ether, as a reddish-orange, crystalline, hygroscopic powder (Found: S as sulphite, 6·65. Calc. for $C_{20}H_{12}O_6N_2S_2Na_2$: S as sulphite, 6·6%).

The sulphite sulphur was estimated by adding the substance, dissolved in excess of air-free aqueous sodium hydroxide, to excess of acidified iodine solution and titrating the residual iodine with thiosulphate. Estimations of total sulphur by the Carius method gave low results, presumably through incomplete breaking down of the sulphonic group.

Sodium p-*Sulphobenzeneazo*-β-*naphthyl Sulphite* (Bisulphite Compound of Orange II, commercial name "Narceine").—The reaction mixture deposited a portion of the azo-sulphite on cooling. The bulk was separated by adding a little sodium chloride. It was again salted out and then recrystallised by cooling a warm concentrated aqueous solution, being thus obtained in buff-yellow crystals (Found: S as sulphite, 7·3. Calc. for $C_{16}H_{10}O_6N_2S_2Na_2$: S, 7·3%).

Sodium Benzeneazo-6 : 8-*disulpho*-β-*naphthyl Sulphite* (Bisulphite Compound of Acid Orange GG).—This substance, which is not precipitated from its aqueous solution by sodium chloride, was

isolated by adding to the reaction mixture twice its volume of alcohol, which left it in solution together with some sodium bisulphite. The solution was evaporated to small bulk at a low temperature and fractionally precipitated by careful addition of alcohol. The inorganic salt was precipitated first, and the azo-sulphite was obtained, by pouring the filtrate slowly into alcohol–ether, in fairly pure condition as a canary-yellow, hygroscopic powder.

Sodium α-naphthaleneazo-6 : 8-*disulpho*-β-*naphthyl sulphite* (bisulphite compound of Crystal Scarlet) was isolated by the method described under Acid Orange GG and obtained as a reddish-orange powder deliquescing in air.

Stability of Azo-sulphites towards Acidified Iodine Solution.—The azo-sulphite (0·5 g.) was added to 25 c.c. of acidified iodine solution and kept for 24 hours. The blank required 21·9 c.c. of thiosulphate, and the azo-sulphites required: Fast Red A (A) 21·9 c.c., Acid Orange GG (B) 21·9 c.c., Orange II (C) 20·9 c.c., Crystal Scarlet (D) 19·6 c.c. The low results for (C) and (D) were mainly due to contamination with inorganic sulphite, since it was found that by adding iodine to the azo-sulphite in solution until the latter reacted to starch paper, and then pouring the mixture into 25 c.c. of acidified iodine, the thiosulphate figures were 21·54 and 21·4 c.c. respectively. The reaction, if any, after 24 hours' contact with iodine is thus so small as to warrant the accuracy of the method described below of estimating mixtures of alkali- and azo-sulphites.

Determination of Azo-sulphite Formation.—The purified anhydrous azo-compounds were dissolved in boiled-out water and made up to *M*/40-solutions, 20 c.c. thus being equivalent to 10 c.c. of *N*/10-sulphurous acid. To 20 c.c. of each dye solution were added first the desired volume of *N*/10-sodium hydroxide, then water (to make up eventually to 50 c.c.), and finally the sulphurous acid, the solution thus being *N*/50 as regards both azo-compound and sulphite. The reaction mixtures were contained in stoppered tubes of slightly greater capacity, to reduce air-oxidation of the sulphur dioxide to the minimum. After remaining 2 hours in a water-bath at 25°, the contents of the tube were washed out into excess of acidified iodine solution, which was thereafter titrated with thiosulphate. The highly coloured solutions necessitated the use of starch as indicator. The end-point was very sharp.

Preparation of the Sulphurous Acid Solution.—In the initial experiments concordant results could not be obtained owing to the changing strength of the sulphurous acid and simultaneous formation of free sulphuric acid, each of which changed the SO_2/NaOH ratio and thus greatly affected the rate of reaction. To obviate this, a Winchester filled with boiled-out water was allowed to cool

with wash-bottles of alkaline pyrogallol attached, and sulphur dioxide from a syphon was passed in to give an approximately $N/10$-solution. A self-filling burette was fitted so that air entering by displacement was deprived of oxygen by alkaline pyrogallol; the absorption bottles were cut off except during the running off from the burette, to avoid any loss of sulphur dioxide from the inside atmosphere by absorption in the pyrogallol. This solution remained practically constant in strength throughout the whole series of analyses. It gave a normality of 0·1423 as sulphurous acid, and 0·1444 as total sulphur, estimated as barium sulphate, the free sulphuric acid present thus involving the small correction of 0·15 c.c. to the calculated volumes of $N/10$-sodium hydroxide added.

Tabulated Results.

C.c. of 0·103N-NaOH added (expressed as c.c. of $N/10$-NaOH and corrected).	SO_2 combined (c.c. of $N/10$-soln.).			
	A.	B.	C.	D.
—	(−0·05)	(−0·03)	0·05	0·10
3·97	(−0·15)	0	0·07	0·13
4·86	0·35	0·78	0·37	0·16
5·21	0·55	1·81	1·90	1·0
5·62	1·10	3·58	5·05	2·5
6·03	1·65	4·68	5·50	3·79
6·44	2·20	5·38	5·65	4·20
7·06	3·00	5·60	5·35	4·65
7·47	—	5·24	—	—
7·88	3·00	4·43	3·65	4·05
8·50	2·70	3·43	2·30	2·75
9·12	1·60	2·43	1·25	1·30
9·86	0·45	1·46	0·70	0·45
10·66	0	0·73	0·20	0·2

The percentage of sulphur dioxide combined is obtained by multiplying the number of c.c. of $N/10$-solution by 10.

The curves plotted from these values are shown in Fig. 1. The values for sulphurous acid have been disregarded, since even after 24 hours no reaction could be detected with certainty; also no correction has been made for any loss of sulphurous acid by oxidation, blank determinations having shown that the loss during 2 hours, although increasing slightly with alkalinity, involved no serious error.

Reaction with Fast Acid Blue RH.—In this case, the deep blue colour obscures the colour change of starch in the solution, but by using starch as external indicator the end-point can be determined with fair precision.

The following results were obtained, the same quantities of dye and sulphurous acid being used as before, for a 2 hours' period of reaction (see Fig. 2):

N/10-H_2SO_4 added (c.c.).	% SO_2 combined.	N/10-NaOH added (c.c.).	% SO_2 combined.

BRITISH RESEARCH ASSOCIATION FOR THE WOOLLEN AND WORSTED INDUSTRIES, TORRIDON, HEADINGLEY, LEEDS. [*Received, August 17th*, 1927.]

CCCXLIX.—*The Relative Directive Powers of Groups of the Forms* RO *and* RR'N *in Aromatic Substitution. Part VIII. The Nitration of* 4-n-*Butoxyanisole.*

By JOHN CLARKE, ROBERT ROBINSON, and JOHN CHARLES SMITH.

A STUDY of the nitration of 2-alkyloxyanisoles (Part I, Allan and Robinson, J., 1926, 376) showed that the directive powers of some alkyloxy-groups are in the order EtO > *n*-PrO > *n*-BuO > MeO, whilst in the nitration of 4-alkyloxyanisoles the order found was *n*-PrO > EtO > MeO (Part III, Robinson and Smith, J., 1926, 392). We have now determined the directive power of the *n*-butoxy-group in the quinol series and it is appreciably greater (186) than that of the *n*-propoxy-group (180). In view of the high yields obtained in the nitrations, the fact that only two monosubstituted derivatives are possible, and the precautions observed in applying the method of thermal analysis, we have little doubt that this difference is real and lies beyond the limits of experimental error. The small fall in the directive powers in the pyrocatechol series in passing from *n*-PrO (128) to *n*-BuO (123) and the small corresponding rise (180—186) in the quinol series may now be disregarded, if desired, in favour of a comparison of EtO and *n*-BuO in both series. In the pyrocatechol series, we find EtO = 135 and *n*-BuO = 123, and in the quinol series, EtO = 163 and *n*-BuO = 186. A theoretical explanation embracing these phenomena was advanced in Part IV of this investigation (Allan, Oxford, Robinson, and Smith, J., 1926, 402), and the result for *n*-BuO is in agreement with its requirements.

EXPERIMENTAL.

Purification of Materials.—The methyl alcohol was free from acetone and distilled completely within 0·1°. The acetic acid was distilled and repeatedly frozen until the m. p. was 15·8—16·0°.

Pure nitric acid of constant b. p. was distilled (d 1·41). A good specimen of *n*-butyl alcohol was washed with dilute sulphuric acid and sodium bisulphite solution, and then boiled for 1·5 hours with 20% aqueous sodium hydroxide; it was separated, dried with potassium carbonate, and later with barium oxide. On distillation through an efficient column, a fraction, b. p. 117·6°/760 mm., $d_4^{25°}$ 0·8056, was obtained (Brunel, Creashaw, and Tobin, *J. Amer. Chem. Soc.*, 1921, **43**, 561, give b. p. 117·71°/760 mm. and $d_4^{25°}$ 0·8057). This specimen was unchanged by further attempted purification, as mentioned below, and was employed in our work. The alcohol was converted into *n*-butyl salicylate and subsequently treated as described by Orton and Jones (J., 1919, **115**, 1198); the recovered material had b. p. 117·6°/762 mm. and $d_4^{25°}$ 0·8056; $d_4^{20°}$ 0·8094; $d_4^{15°}$ 0·8132; $d_{14·4}^{14·4°}$ 0·8141. A second portion was converted into *n*-butyl gallate, which crystallised readily from toluene in needles, m. p. 143—144° (Found: C, 58·3; H, 6·2. Calc. for $C_{11}H_{14}O_5$: C, 58·4; H, 6·2%). Subsequent to the completion of our work, we found that *n*-butyl gallate had been described by Christiansen (*J. Amer. Chem. Soc.*, 1926, **48**, 1358), who gives the m. p. 133—134°. This derivative was hydrolysed by means of aqueous sodium hydroxide in an atmosphere of hydrogen, and the recovered alcohol had b. p. 117·5°/760 mm., $d_4^{20°}$ 0·8094. Commercial *n*-butyl alcohol (600 c.c.) esterified with gallic acid (250 g.) gave about 200 g. of the ester, m. p. 141—143°, and after one crystallisation from toluene the m. p. was 142—144°. The alcohol obtained on hydrolysis all distilled at 117·9—118·1°/769 mm. (117·6—117·8°/760 mm.) and had $d_4^{20°}$ 0·8099. This experiment seemed to show that the process of purification we contemplated was satisfactory, but it cannot be trusted in all circumstances, as the following observations clearly proved. In the first place, a mixture of *n*-propyl and *n*-butyl alcohols was esterified with gallic acid and the ester isolated had m. p. 148—149°, or by a different method, m. p. 150—151°. Recrystallisation from toluene gave a crop, m. p. 152—153°, and another, m. p. 151—153°. We then prepared *n*-propyl gallate, m. p. 147—148° (see below), and found that a mixture of equal quantities of *n*-propyl and *n*-butyl gallates, mixed dry, had m. p. 152—154°, with no sign of sintering at 143° or 147°. On cooling, the liquid crystallised at 145°; it then fused again at 152—154°. This is, therefore, an addition to the small number of recorded cases of binary mixtures that melt at a higher temperature than either of the components.

n-Butyl bromide was prepared by the method of Kamm and Marvel (*J. Amer. Chem. Soc.*, 1920, **42**, 299) and had b. p. 101·2°/759 mm., $d_4^{20°}$ 1·2764.

n-*Propyl Gallate*.—A mixture of propyl alcohol (50 c.c.), sulphuric acid (1 c.c.), and gallic acid (17 g.) was boiled under reflux for 4 hours (in the case of *n*-butyl gallate, the period of heating should not exceed 3 hours) and then concentrated somewhat by distillation under diminished pressure. The residue crystallised, and was thoroughly washed with water and dried at 80°. The almost colourless crystals were practically pure and the substance crystallised from water in long needles, m. p. 147—148° (Found: C, 56·7; H, 5·7. $C_{10}H_{12}O_5$ requires C, 56·6; H, 5·7%). This ester is rather more readily soluble in water than is *n*-butyl gallate, whilst it is the more sparingly soluble of the two in toluene.

2-*Nitro*-4-n-*butoxyanisole*.—Potassium (3·9 g.) was dissolved in methyl alcohol (100 c.c.), and after the successive introduction of 3-nitro-4-methoxyphenol (16·9 g.) (Part III, *loc. cit.*) and *n*-butyl bromide (15 c.c.), the mixture was refluxed for 3 hours; as the colour was still red, a further 5 c.c. of butyl bromide were added and the boiling was continued for 2 hours. The greater part of the solvent was removed by distillation under diminished pressure, and an ethereal solution of the residue was twice washed with aqueous sodium carbonate, thrice with water, and then dried. After removal of the ether, the yellow oil distilled at 143°/1 mm. and had f. p. 12·4°, m. p. 12·5° (yield, 17 g. or 76%). After one recrystallisation from methyl alcohol at — 15° (the filter was cooled by a jacket containing a mixture of solid carbon dioxide and ether) and removal of the adherent solvent at 110° in a vacuum, the values observed were: f. p. 13·1°, m. p. 13·25°, $n_D^{14\cdot4°}$ 1·5382 (Found: C, 58·6; H, 6·7. $C_{11}H_{15}O_4N$ requires C, 58·7; H, 6·7%). The f. p. and m. p. were not raised by a further recrystallisation. A second preparation (yield, 81%) had f. p. 12·6°, m. p. 12·7°, raised on recrystallisation to the constant values 13·15° and 13·20°, respectively; $n_D^{14\cdot4°}$ 1·5382.

3-*Nitro*-4-n-*butoxyanisole*.—A solution of potassium (7·8 g., 0·92 mol.) in *n*-butyl alcohol (100 c.c.) and 2-nitro-4-methoxyphenol (33·8 g., 1 mol.) (Part III, *loc. cit.*) were mixed, and after the addition of *n*-butyl bromide (21 c.c.) the mixture was refluxed for 20 hours with the gradual further addition of *n*-butyl bromide (29 c.c.). After cooling, the brown liquid was decanted from the potassium bromide, which was washed with a little butyl alcohol, and the solvent completely removed by distillation under diminished pressure. An ethereal solution of the residue was washed with aqueous sodium carbonate and water, then dried and distilled. A pale yellow oil (18·75 g.), b. p. 137°/1 mm., was obtained and 2-nitro-4-methoxyphenol (11·5 g.) was recovered from the alkaline extracts. A second preparation on half the scale gave a rather larger yield (53% calculated on the potassium) of an identical

product, and both specimens, after being crystallised thrice from methyl alcohol at — 50°, gave long, yellow needles, which, after separation and complete removal of adhering solvent at 110° in a vacuum, had m. p. — 9·7°, $n_D^{14\cdot0°}$ 1·5358 (Found: C, 58·6; H, 6·8. $C_{11}H_{15}O_4N$ requires C, 58·7; H, 6·7%). The m. p.'s were determined as follows: the substance in a tube was cooled to — 20° and stirred until crystallisation began; it was then placed in an air-jacket fitted into a transparent Dewar vessel containing brine at — 12°. While the cold bath was stirred occasionally and the nitro-compound regularly (and vigorously on account of the viscosity of the material), the temperature gradually rose until the thermometer in the nitro-compound registered — 9·7° and remained steady for some minutes.

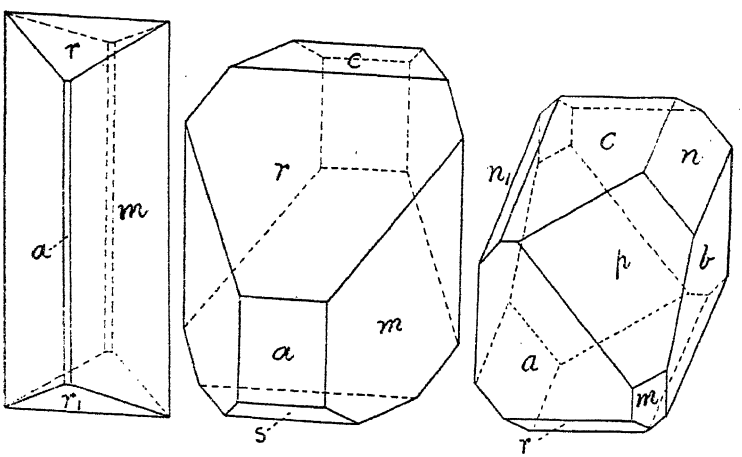
Mixtures of 3-*Nitro*-4-n-*butoxyanisole and* 2-*Nitro*-4-n-*butoxyanisole.*—The mixtures were rather viscous below 0°, and reproducible values could only be obtained over the composition range given below. It was found that characteristic values could best be assigned by taking the mean of the f. p. and m. p. of each mixture. A series of 4—6 determinations was made in each case as in the example: Composition, 94·3% of 2-nitro-4-*n*-butoxyanisole; f. p.'s, 11·40°, 11·30°, 11·35°, 11·40°; m. p.'s, 11·50°, 11·50°, 11·45°, 11·45°; mean, 11·42°. It was found necessary to eliminate water from the mixtures every 2—3 hours and also after any operation involving dismantling. The water did not actually depress the f. p.'s, but it retarded crystallisation. It was evaporated at 110°/20 mm. in a stream of dry air introduced through a fine tube; care was taken not to lose any of the material adhering to this tube or to the silver wire stirrer and thermometer—during temporary removal, these details were protected from dust. For the determination of the f. p.'s and m. p.'s, the apparatus mentioned above was employed; the temperature of the bath in the Dewar vessel could be raised or lowered by admission of water at different temperatures from reservoirs. In the first place, the m. p. was roughly determined while the bath was kept at a temperature 0·5—1° lower than that of the nitro-compound. The tube was then removed from the air-jacket and allowed to warm until almost all the solid had melted; it was then cooled to 2° below the m. p. and stirred to initiate crystallisation. After the tube was replaced in the apparatus, the bath was kept at 1° below the m. p., and the f. p. determined. As a rule, the temperature remained constant for some minutes. The temperature of the bath was then raised to about 0·5° below the f. p. and stirring continued, so that heat might enter and cause the mixture to melt. In this way, the temperature of the mixture usually rose 0·1—0·15° and remained steady at the m. p. until

almost all the solid had disappeared; a sudden rise supervened. The following f. p.–m. p. means were determined, the first number of each pair indicating the % of the 2-nitro-isomeride in the mixture: 100, 13·20°; 94·3, 11·42°; 86·4, 9·12°; 82·65, 7·88°; 79·58, 6·95°; 77·08, 6·00°; 73·77, 4·90°; 71·94, 4·09°; 69·06, 3·00°. The corresponding graph is a smooth curve.

4-n-*Butoxyanisole.*—Pure quinol monomethyl ether (6·2 g.) was added to a solution of sodium *n*-butoxide (from 1·15 g. of sodium) in *n*-butyl alcohol (30 c.c.), and after the introduction of *n*-butyl bromide (6·5 c.c.) the mixture was refluxed for 2 hours. After removal of the solvent at 50—70° in a vacuum, the product was steam-distilled and crystallised in contact with ice-water (yield, 7·6 g. or 85%). The substance crystallised from methyl alcohol containing a little water in large, pearly plates, m. p. 24·5—25·5° (Found: C, 73·4; H, 9·1. $C_{11}H_{16}O_2$ requires C, 73·3; H, 8·9%). This ether was also satisfactorily obtained by the use of sodium methoxide in acetone solution.

Nitration of 4-n-*Butoxyanisole.*—4-*n*-Butoxyanisole (2·0 g.), dissolved in acetic acid (4 c.c.), was nitrated by means of nitric acid (1·03 g.) in acetic acid (1 c.c.), and the product isolated as in the case of the nitration of 4-*n*-propoxyanisole (Part III, *loc. cit.*). The products were, however, washed with sodium carbonate instead of with the bicarbonate in order to avoid effervescence; yields, (*a*) 96·4%, (*b*) 97·2%, (*c*) 97·4% (Found: N, 6·2. Calc.: N, 6·2%). Specimens (*c*) and (*d*) were isolated without the aid of methyl alcohol, the washed oil being siphoned through a Pregl micro-filter into the freezing-point tube. Specimen (*b*) was orange-yellow and was not further examined, whilst (*c*) was specially prepared for analysis; (*a*), (*c*), (*d*), and (*e*) were clear, pure yellow oils. The following table displays the results; 6—8 determinations of each f. p. and m. p. were made.

Specimen.	Mixture taken, g.	2-Nitro-isomeride added, g.	F. p. (mean).	M. p. (mean).	Mean.	% of 2-nitro-isomeride indicated.	% of 3-nitro-isomeride in nitration product.
(*a*)	1·0052	1·4758	4·72°	4·88°	4·80°	73·7	64·9
		1·9920	6·41	6·53	6·47	78·3	64·7
(*c*)	0·5993	1·0141	5·46	5·59	5·53	75·7	65·4
		1·3133	6·82	6·98	6·90	79·6	65·1
(*d*)	0·5027	0·8216	5·35	5·46	5·41	75·35	64·9
							Mean 65·0



Hence the directive power of *n*-BuO is 186 (MeO = 100).

In order to determine the effect of the process of isolation on the composition of the nitration product the following experiment was carried out. The product (*d*) (1·25 g.) was dissolved in acetic acid (3 c.c.), cooled to 0°, and a mixture of acetic acid (3 c.c.) and nitric

acid (0·7 g.) added. The concentrations of the nitro-compounds were then exactly half of those at the end of a normal nitration, and dilution and washing were carried out in the normal way. When the last water layer had been removed, the entire process was repeated; the specimen was thus subjected to a process which should produce four times the normal change. The weight of re-washed oil was 1·172 g. (loss, 6·24% or 1·6% for the normal process). 0·5029 G. of this with 2-nitro-4-*n*-butoxyanisole (0·8215 g.) had f. p. 5·37°, m. p. 5·48°, mean, 5·42°. Hence the loss is mechanical and involves no change in composition.

Crystallographic Measurements.—Mr. H. E. Buckley of the Crystallography Department of this University submits the following reports relating to substances described in Part III (*loc. cit.*).

FIG. 1. FIG. 2. FIG. 3.

2-Nitro-4-methoxyphenol. The crystals (Fig. 1) are of a short-prismatic habit and deep orange colour. Symmetry: Monoclinic (pseudo-orthorhombic). $a : b : c = 1{\cdot}0234 : 1 : 0{\cdot}5732$; $\beta = 90°$. Forms developed: $m(110)$, $r(101)$, $r_1(10\bar{1})$, $a(100)$, and occasionally $l(210)$, $n(120)$, $s(320)$, and $t(230)$.

	Angles observed.	Calc.
110—1$\bar{1}$0	91° 21′ (8)	—
110—101	70° 1′	—
100—101	60° 44′	60° 45′
110—320	11° 32′	11° 21′
110—210	18° 35′	18° 34½′

Cleavage parallel to $r(10\bar{1})$ perfect.

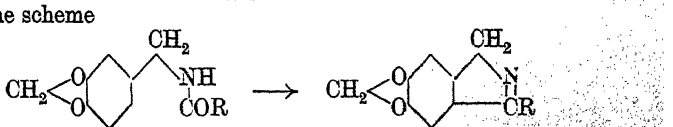
Double refraction appears to be very strong, the interference figure being practically in the plane of cleavage 101. There is a slight pleochroism, varying from orange through yellow to pale green.

2-*Nitro*-4-*ethoxyanisole* (Fig. 2). Symmetry: Monoclinic [holohedral]. $a : b : c = 1{\cdot}431 : 1 : 1{\cdot}569$; $\beta = 77° 23'$. Forms developed: $a = 100$, $c = 001$, $r = 101$, $s = 10\bar{1}$, $m = 110$, and $p = 111$ (infrequent).

	Angles observed.	No. measured.	Limits.	Calc.
100—001	77° 2½′	7	76° 58′—77° 8′	—
100—110	53° 42′	11	53° 35′—53° 58′	—
101—001	35° 52½′	6	35° 48′—35° 56′	—
101—100	41° 10′	6	40° 59′—41° 16′	41° 10′
100—10$\bar{1}$	55° 40′	6	55° 36′—55° 47′	55° 39′
110—10$\bar{1}$	70° 26′	7	70° 14′—70° 34′	70° 30½′
110—101	63° 26½′	11	63° 10′—63° 44′	63° 32′
110—001	82° 18′	8	82° 6′—82° 36′	82° 26′
001—111	50° 57′	3	50° 41′—51° 15′	51° 10′

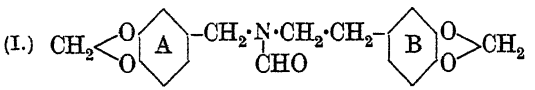
2-*Nitro*-4-n-*propoxyanisole*. System: Triclinic (pinacoidal). $a : b : c = 0{\cdot}7831 : 1 : 1{\cdot}030$; $\alpha = 92° 54'$, $\beta = 55° 32'$, $\gamma = 87° 12'$. Forms developed: $a = 100$, $b = 010$, $c = 001$, $m = 110$, $r = 10\bar{1}$, $n = 011$, $n_1 = 0\bar{1}1$, and $p = 111$. The habit is often tabular on the 111 face (Fig. 3).

Angular elements.	Observed.	No. measured.	Limits.
a—p (100—111)	31° 3′	4	31° 0′—31° 5′
a—b (100—010)	88° 33′	3	—
a—c (100—001)	55° 48′	8	55° 34′—56° 11′
n—p (011—111)	31° 58′	4	31° 56′—32° 3′
n—b (011—010)	50° 35′	4	50° 33′—50° 39′



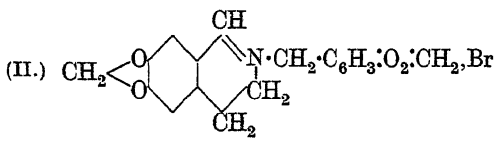
The crystals are of considerable interest in that they exhibit remarkably well their anorthic optical properties. The first mean line, which varies a little for different colours, is nearly normal to 111, on which the crystal is tabular, and the optic axial plane for the sodium yellow line is turned through practically a right angle from that for the mercury violet line.

THE UNIVERSITY, MANCHESTER. [*Received, August 20th*, 1927.]



CCCL.—*Facile Ring-closure to a Derivative of Dihydro*isoquinoline *contrasted with the Difficulty of Analogous Formation of a Derivative of* iso*Indole.*

By JACQUES MALAN and ROBERT ROBINSON.



EXAMPLES of the production of *iso*indole derivatives by a reaction analogous to the Bischler–Napieralski synthesis of dihydro*iso*quinolines have not been recorded, and our own attempts to dehydrate aceto- and benzo-piperonylmethylamides in accordance with the scheme

have been fruitless. Such negative results are often attributable to various fortuitous causes, *e.g.*, unsuitable conditions, impure or too pure reagents, but, in the course of some preliminary synthetical experiments in the *iso*quinoline group of the alkaloids, we encountered a case free from such objections, and one that proves that the difficulty experienced in closing the *iso*indole ring is not fortuitous. The complex formamide (I) might give either a five-membered or a six-membered heterocyclic ring on dehydration, but, actually, a substance containing the latter is the only product of the action of phosphoryl chloride on the amide. The constitution of the

(I.) 

quaternary ammonium salt obtained was proved by an independent synthesis. Interaction of methylenedioxydihydro*iso*quinoline and piperonylmethyl bromide yielded the bromide (II), which was

(II.) 

convertible into a *picrate*, *pseudo-cyanide*, and an *anhydro-base-nitromethane* derivative identical, each to each, with the same series obtained from (I).

One of the factors controlling the direction of the ring closure is doubtless the field associated with the positive charge of the nitrogen atom, which is probably in the ammonium state under the conditions of the reaction. This field is evidently more intense over nucleus (A) than over nucleus (B), and as it should tend to inhibit union of the nuclear carbon with that of the $-CHO$ group, itself kationoid, an adequate explanation of the formation of the *iso*quinoline derivative is forthcoming. For a similar reason, the formation of *iso*quinoline derivatives from substances of the form $Ar{\cdot}CH_2{\cdot}CH_2{\cdot}N{\cdot}CO{\cdot}$ should be more facile than from substances of the form $Ar{\cdot}CH_2{\cdot}N{\cdot}CH_2{\cdot}CO{\cdot}$, provided that the carbonyl group has an approximately equal reactivity in each case. Several illustrative cases have been recorded (Mannich and Kuphal, *Arch. Pharm.*, 1912, **250**, 539).

Experimental.

Piperonylmethylamine Derivatives.—Piperonylmethylamine, b. p. 172°/50 mm., was obtained in 70% yield by the reduction of piperonaldoxime by means of zinc dust in boiling 50% acetic acid solution (Mannich and Kuphal, *Ber.*, 1912, **45**, 314). The *chloroplatinate* crystallises from much hot water in orange needles [Found :

Pt, 27·7. $(C_8H_9O_2N)_2,H_2PtCl_6$ requires Pt, 27·6%]. The *picrate* crystallises from water in yellow needles, m. p. 198°. *Piperonylmethyltrimethylammonium iodide*, $CH_2O_2{:}C_6H_3{\cdot}CH_2{\cdot}NMe_3I$, obtained by the action of an excess of methyl iodide on the base, crystallises from alcohol in minute, yellow prisms, m. p. 219° (decomp.) (Found: C, 41·0; H, 5·1; I, 38·7. $C_{11}H_{16}O_2NI$ requires C, 41·1; H, 5·0; I, 39·2%).

Benzylidenepiperonylmethylamine, $CH_2O_2{:}C_6H_3{\cdot}CH_2{\cdot}N{:}CHPh$, readily obtained by condensation of the base with benzaldehyde, crystallises from aqueous alcohol in colourless needles, m. p. 51—52° (Found: C, 75·5; H, 5·7. $C_{15}H_{13}O_2N$ requires C, 75·3; H, 5·4%); its *picrate* crystallises from alcohol in light yellow needles, m. p. 206°.

2-*Carbomethoxyveratrylidenepiperonylmethylamine*,

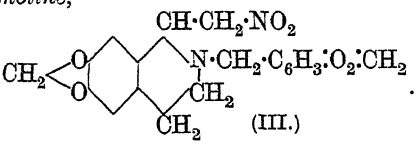
$$CH_2O_2{:}C_6H_3{\cdot}CH_2{\cdot}N{:}CH{\cdot}C_6H_2(OMe)_2{\cdot}CO_2Me,$$

is obtained by heating methyl opianate and piperonylmethylamine in molecular proportion at 150°. It crystallises from alcohol in flocculent masses of colourless, microscopic needles, m. p. 181° (Found: C, 63·2, 63·8; H, 4·8, 5·0; N, 4·1. $C_{19}H_{19}O_6N$ requires C, 63·8; H, 5·0; N, 4·1%). An interesting transformation of this substance occurs under the influence of sodium methoxide in hot methyl-alcoholic solution. The elements of methyl alcohol are eliminated and the neutral product crystallises from methyl alcohol in glistening, hexagonal prisms, capped with pyramids, m. p. 159° (Found: C, 66·1, 66·4; H, 4·9, 4·9; N, 4·5. $C_{18}H_{15}O_5N$ requires C, 66·5; H, 4·6; N, 4·3%). The most natural hypothesis is that this substance is 4-*hydroxy*-5:6-*dimethoxy*-3-*piperonyl*isoquinoline, but its properties are somewhat at variance with such a view. For example, the action of boiling methyl iodide gives rise to an *iodide*, m. p. 172° (Found: C, 36·8, 36·3; H, 4·1, 4·0; I, 41·7; and, for instance, $C_9H_{12}O_2NI$, piperonylmethylmethylamine hydriodide, requires C, 36·8; H, 4·1; I, 43·3%). Evidently the molecule has been broken up, and this is difficult to reconcile with the *iso*quinoline formulation. A by-product in the preparation of piperonylmethylamine is *di(piperonylmethyl)amine*, b. p. 230°/50 mm., which crystallises from alcohol in silky needles, m. p. 114°. The foregoing experiments were made by Miss B. Dobson in these laboratories in 1910.

Acetopiperonylmethylamide crystallises from benzene in colourless needles, m. p. 103° (Found: C, 62·2; H, 5·3. $C_{10}H_{11}O_3N$ requires C, 62·2; H, 5·7%). Attempts to dehydrate this substance, and similar trials with benzopiperonylmethylamide, m. p. 117° (Mannich and Kuphal, *loc. cit.*), by means of phosphoryl chloride, phosphoric anhydride, sulphuric acid, zinc chloride and stannic chloride failed, the amides being either recovered unchanged or converted into dark violet substances that could not be purified.

It is relevant to mention here that the ring closure of *phenacyl veratrate*, $C_6H_3(MeO)_2 \cdot CO \cdot O \cdot CH_2 \cdot COPh$, to an *iso*coumarin derivative has been unsuccessfully attempted. The ester is obtained in good yield by the interaction of ω-bromoacetophenone and silver veratrate in boiling alcoholic solution. It crystallises from alcohol in well-defined, elongated prisms, m. p. 122° (Found: C, 68·0; H, 5·4. $C_{17}H_{16}O_5$ requires C, 68·0; H, 5·3%).

Piperonylmethyl-β-piperonylethylamine,



$$CH_2O_2{:}C_6H_3 \cdot CH_2 \cdot NH \cdot CH_2 \cdot CH_2 \cdot C_6H_3{:}O_2{:}CH_2.$$

—A warm solution of piperonylidene-β-piperonylethylamine (22 g.) (Decker and Becker, *Annalen*, 1913, **395**, 342) in absolute alcohol (500 c.c.) was added as quickly as possible through a long reflux condenser to sodium (35 g.) in a flask immersed in an oil-bath at 140°. When all the sodium had passed into solution, the mixture was cooled and added to water (2000 c.c.). On keeping, colourless crystals separated (15 g.). The base crystallises from light petroleum (b. p. 40—60°) in needles, m. p. 53° (Found: C, 68·0; H, 5·7. $C_{17}H_{17}O_4N$ requires C, 68·2; H, 5·7%). It is readily soluble in alcohol or benzene. The *hydrochloride* is very sparingly soluble in dilute hydrochloric acid and crystallises from much boiling water in flocculent masses of colourless needles. The *nitroso*-derivative, obtained in the usual way, crystallised from alcohol in clusters of minute, colourless needles, m. p. 127—128°. The *dinitro*-derivative, prepared in acetic acid solution, crystallised from alcohol in colourless, diamond-shaped plates, m. p. 134—135°. The N-*formyl* derivative was obtained by refluxing (oil-bath at 180°) a mixture of the base (5 g.) and anhydrous formic acid (25 c.c.) for 2 days. The emulsion obtained on the addition of water resolved into crystals and the solid was purified by trituration with dilute acetic acid (yield, 70%). The substance, which is readily soluble in most organic solvents, crystallised with difficulty from light petroleum in colourless, microscopic prisms, m. p. 89—90° (Found: C, 65·8; H, 5·3. $C_{18}H_{17}O_5N$ requires C, 66·0; H, 5·2%).

6 : 7-*Methylenedioxy*-2-*piperonylmethyl*-3 : 4-*dihydro*isoquinolinium *Picrate and Bromide* (II).—(A). A mixture of formopiperonylmethyl-β-piperonylethylamide (5 g.) and phosphoryl chloride (30 g.) was heated on the steam-bath for 20 minutes and then added to crushed ice. Picric acid (4 g.) was added to the filtered solution and the pasty, yellow mass of the picrate was collected and obtained crystalline by rubbing under alcohol. The derivative crystallised from boiling acetone in microscopic, transparent, yellow rhombs, m. p. 184—185° (yield, 7·2 g.) (Found: C, 53·4; H, 3·4; N, 10·5. $C_{24}H_{18}O_{11}N_4$ requires C, 53·5; H, 3·3; N, 10·4%). (B). Solutions of 6 : 7-methylenedioxy-3 : 4-dihydro*iso*quinoline (3·5 g.) and of

piperonylmethyl bromide (4·4 g.) in benzene (20 c.c. each) were mixed and then heated for 10 minutes on the steam-bath. The yellow crystals (6·8 g.) deposited on cooling separated from alcohol in minute, yellow needles, m. p. 230° (Found: Br, 21·0, 20·4. $C_{18}H_{16}O_4NBr$ requires Br, 20·5%). The salt is sparingly soluble in water, more readily in alcohol, giving pale yellow solutions exhibiting a blue fluorescence. The addition of picric acid to an alcoholic solution gave the picrate, m. p. 184—185°, which was identified by direct comparison with the product obtained in (A).

6 : 7-*Methylenedioxy*-1-*nitromethyl*-2-*piperonylmethyl*-1 : 2 : 3 : 4-*tetrahydro*isoquinoline,

(III.)

—The carbinol from 6 g. of the above-described bromide was extracted with ether, the extract dried with potassium carbonate, and the solvent removed. All these operations should be conducted expeditiously. The residue was dissolved in alcohol (20 c.c.), and nitromethane (1 g.) in alcohol (5 c.c.) introduced. After heating on the steam-bath for a few minutes, the mixture was cooled; the crystals that separated were obtained, after three recrystallisations from alcohol, in short, colourless prisms, m. p. 124—125° (Found: C, 61·5; H, 4·9. $C_{19}H_{18}O_6N_2$ requires C, 61·6; H, 4·9%). The picrate was similarly treated and gave the same derivative with nitromethane; a mixture of the two specimens had m. p. 124—125°.

6 : 7-*Methylenedioxy*-1-*cyano*-2-*piperonylmethyl*-1 : 2 : 3 : 4-*tetrahydro*isoquinoline (III with CN instead of $CH_2{\cdot}NO_2$).—When potassium cyanide is added to an aqueous solution of the bromide or of the chloride (derived from the picrate by addition of dilute hydrochloric acid and removal of the picric acid with ether), a curdy, white precipitate is thrown down: this rapidly becomes crystalline. The substance crystallises from alcohol in hexagonal plates, m. p. 151° (Found: C, 67·8; H, 4·8. $C_{19}H_{16}O_4N_2$ requires C, 67·9; H, 4·8%), and has the properties of a pseudo-cyanide. It is insoluble in cold 7% sulphuric acid and, on warming, a yellow solution is obtained and hydrogen cyanide liberated. It dissolves in concentrated hydrochloric acid to a colourless solution and after dilution the unchanged base may be precipitated by ammonia. On heating, however, a yellow solution is obtained.

THE UNIVERSITY, MANCHESTER. [*Received, July 26th,* 1927.]

CCCLI.—*Mercury Derivatives of Acetic Acid.*

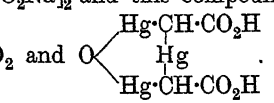
By JAMES ERNEST MARSH and ROBERT DE JERSEY FLEMING STRUTHERS.

As is well known, some metallic acetates on being heated break up into acetone and the carbonate of the metal, whilst others, such as those of copper, silver and mercury, give no acetone but pure acetic acid. At about 170—180° mercuric acetate forms a well-defined, intermediate compound which was first described, but not analysed, by F. Stromeyer in 1809 (Göttingen Comment., I, 1808–1811, "De Connubio Hydrargyri cum Acido Acetico." The short paragraph referred to was translated in Gmelin's "Handbook"). The compound has the composition represented by the formula $C_2H_2O_2Hg$ (I) (Found: Hg, 77·2; C, 9·1; H, 0·9. Calc.: Hg, 77·6; C, 9·3; H, 0·7%).

Compounds of the composition $C_2H_2O_2Hg$, and in some cases probably identical with Stromeyer's, have been obtained. Sand and Singer (*Ber.*, 1903, **36**, 3707), by heating dry mercuric acetate with acetic anhydride, obtained a compound to which they gave the constitution $(C_2H_3O_2Hg)_2C<\begin{matrix}CO\\Hg\end{matrix}>O$.

Schrauth and Schoeller (*Ber.*, 1908, **41**, 2090) obtained from mercurimalonic acid a compound to which they gave the formula $CH_2<\begin{matrix}CO\\Hg\end{matrix}>O$ and the name "oxyquecksilber essigsäure anhydrid." The properties of this compound as described by them differ considerably from those of Stromeyer's substance. Biilmann and Witt (*Ber.*, 1909, **42**, 2067) throw doubt on the production of this substance from mercurimalonic acid.

A substituted mercuriacetic acid of a different kind, to which he gave the formula HO·Hg·C(:Hg)·CO_2M, was obtained by K. A. Hoffmann (*Ber.*, 1899, **32**, 875) by heating mercuric oxide with sodium acetate in concentrated alkaline solution.



Stromeyer gave no name to his compound, which was probably the first organo-metallic compound to be discovered. We suggest the name *mercuretin*. We have found that mercuretin is formed in other ways than by Stromeyer's method. It gradually separates (Found: Hg, 77·4; C, 8·9; H, 0·9%) when mercuric acetate is boiled with glacial acetic acid, and it is formed completely and at once on addition of acetic anhydride to such a solution (Found: Hg, 77·2; C, 9·2; H, 0·7%). It is known that the reaction is complete when a sample dissolves completely in sodium hydroxide solution without any yellow precipitate of mercuric oxide. Mercurous acetate, which is generally present in mercuretin prepared

by either of these methods or by Stromeyer's, is easily removed by boiling water. The purified mercuretin remains white when treated with ammonia and gives a clear solution with sodium hydroxide. The formation of mercurous acetate is avoided by keeping the temperature as low as possible during the early stages of the reaction, and also when the conversion is carried out in a sealed tube at 190°; no permanent gas is given off in the latter circumstance.

Mercuretin is not soluble in water, but it slowly dissolves with some decomposition in boiling glacial acetic acid. On cooling, crystals are obtained different from the original substance; the composition corresponds with the formula $C_{12}H_{14}O_{12}Hg_5$ (II) (Found: Hg, 74·5; C, 10·4; H, 1·0. Calc.: Hg, 74·6; C, 10·7; H, 1·0%) and the structure may be represented by the formula

$$Hg[C(C_2H_3O_2Hg)_2\cdot CO_2H]_2.$$

When mercuric acetate is heated with sodium acetate a different condensation occurs. The insoluble *substance*, after being washed free from sodium acetate and mercurous acetate, has the composition $C_4H_4O_5Hg_3$ (III) (Found: Hg, 81·2; C, 6·3; H, 0·5. Calc.: Hg, 82·0; C, 6·3; H, 0·5%). The formation and probable structure of this compound can be explained by supposing that the sodium acetate is attacked by the mercuric acetate with the formation of $Hg[CH(CO_2H)\cdot HgC_2H_2O_2Na]_2$ and this compound by the action of water gives $2NaC_2H_3O_2$ and

Mercuric acetate condenses with lead acetate to give a compound completely soluble in sodium hydroxide. The condensation of the two salts may also be brought about by the addition of acetic anhydride to a boiling solution of the two salts in glacial acetic acid. The product remains dissolved in the acetic acid and is obtained by evaporation. Mercuric oxide (2 mols.) also condenses with lead acetate with elimination of water (2 mols.).

Action of Nitric Acid.—Mercuretin dissolves readily and without oxidation in warm nitric acid (*d* 1·4). Crystals are obtained on cooling which, after being washed with nitric acid and dried, have very nearly the composition represented by the mixture

$$(HgNO_3)_3C\cdot CO_2H + (HgNO_3)_2CH\cdot CO_2H \quad (IV)$$

(Found: Hg, 69·9; C, 3·2; H, 0·4; N, 5·3. Calc.: Hg, 70·2; C, 3·2; H, 0·2; N, 4·9%).

If the solution in nitric acid is poured into water a *substance* is precipitated which, after being washed with water and dried, has the composition represented by the formula $Hg_5(NO_3)_2C_4O_4$ (V) (Found: Hg, 80·2; C, 4·1; H, 0·3; N, 2·2. Calc.: Hg, 80·9;

C, 3·9; N, 2·2%). The formation of this compound is readily explained by loss of nitric acid from the substances in solution:

$$\left.\begin{matrix}(NO_3Hg)_3C\cdot CO_2H\\(NO_3Hg)_2CH\cdot CO_2H\end{matrix}\right\} \xrightarrow{-3HNO_3} O_3NHg\cdot\underset{\displaystyle CO\cdot O\cdot Hg}{\overset{\displaystyle Hg\cdot O\cdot CO}{\overset{|}{\underset{|}{C}}}}\cdot Hg\cdot C\cdot HgNO_3$$

Another nitrate was made by boiling a solution of mercuric nitrate in glacial acetic acid. The conversion was complete when a sample dissolved in excess of sodium hydroxide solution without any precipitation of mercuric oxide. The substance crystallised on cooling and had the composition represented by the formula $Hg_5(NO_3)_4C_4H_2O_4$ (VI) (Found: Hg, 73·8; C, 3·4; H, 0·3; N, 3·8. Calc.: Hg, 73·4; C, 3·5; H, 0·15; N, 4·1%). We suggest for it the structure $Hg[C(HgNO_3)_2\cdot CO_2H]_2$.

Action of Ammonia.—Mercuretin is soluble neither in ammonia nor in ammonium acetate, but it dissolves easily in a mixture of the two. On evaporation a nearly white powder is obtained which is not soluble in water but is easily dissolved by an aqueous solution of ammonium acetate and ammonia. After being washed with water and dried, the *substance* had the composition represented by the formula $C_6H_5O_6NHg_5$ (VII) (Found: Hg, 83·1; C, 6·0; H, 0·7; N, 1·3. Calc.: Hg, 84·0; C, 6·0; H, 0·4; N, 1·2%). This compound may be represented as formed by the replacement of two $C_2H_3O_2$ groups in $Hg_5C_{10}H_{10}O_{10}$ by the group NH.

Conclusion.—We think that Stromeyer's compound, which we have called mercuretin, has the molecular formula $C_{10}H_{10}O_{10}Hg_5$. In support of this view, we have the persistence of five mercury atoms in the two nitric acid derivatives (V and VI), in the compound (II), and in the ammonia derivative (VII). The removal of some of the acetic groups by nitric acid and the easy removal of two acetic groups by the action of ammonia indicate that two of the five acetic groups are much less firmly held than the other three. Thus the formula $C_6H_4O_6Hg_3(HgC_2H_3O_2)_2$ is indicated. We suggest for mercuretin accordingly the structure

$$\begin{matrix}Hg\cdot C_2H_3O_2 & & Hg\cdot C_2H_3O_2\\ | & & |\\ CH & — & CH\\ CO\cdot O\cdot Hg & & Hg\cdot O\cdot CO\\ & & |\\ & & CO_2H\end{matrix}$$

and this structure explains readily the simple relationship between mercuretin and substance II, and also its feebly acid nature.

UNIVERSITY MUSEUM, OXFORD. [*Received, September 13th*, 1927.]

CCCLII.—*The Two* o-*Cyanocinnamic Acids.*

By WILLIAM DAVIES and HARRY GORDON POOLE.

ALTHOUGH the two theoretically possible stereoisomeric forms of *o*-cyanocinnamic acid exist, only one form of *o*-carboxycinnamic acid is known, and this is obtained when either of the cyano-acids is hydrolysed (Edwards, J., 1926, 816). It gives the lactone of β-*o*-carboxyphenylhydracrylic acid on heating or on treatment with dehydrating agents, and attempts to prepare the true anhydride failed.

The *o*-cyanocinnamic acid melting at 256° can be obtained in 36% yield by heating the sodium salt of 1-nitroso-2-naphthol with a solvent of suitable boiling point, whereas with the use of sand as diluent (D.R.-P. 116,123) the yield is not more than 5% (Gabriel, *Ber.*, 1916, **49**, 1611). The *o*-cyanocinnamic acid melting at 137° has been prepared after D.R.-P. 411,955 by the action of *p*-toluenesulphonyl chloride on 1-nitroso-2-naphthol in the presence of aqueous alkali. During a large-scale preparation in which the heating during evaporation was very prolonged, an appreciable quantity of acetophenone-*o*-carboxylic acid was produced, possibly owing to the following changes in the $CH{:}CH{\cdot}CO_2H$ group of the carboxycinnamic acid formed by hydrolysis of the cyanocinnamic acid initially produced: $\cdot CH{:}CH{\cdot}CO_2H \longrightarrow \cdot C(OH){:}CH{\cdot}CO_2H \longrightarrow \cdot CO{\cdot}CH_2{\cdot}CO_2H \longrightarrow \cdot CO{\cdot}CH_3$. It is, however, not clear whether the atmosphere or part of the nitrosonaphthol is the oxidising agent, and this abnormal reaction will be further examined.

EXPERIMENTAL.

The Preparation of o-*Cyanocinnamic Acid* (m. p. 256°).—A series of experiments was carried out with *p*-cymene, *o*-nitrotoluene, and nitrobenzene as solvents and the following process was found satisfactory. The dry, finely powdered sodium salt of 1-nitroso-2-naphthol (20 g.) and nitrobenzene (120 c.c.) were heated at 205° for 2 hours. The dark mixture was shaken with a warm aqueous solution of sodium acetate, and the aqueous portion was boiled with animal charcoal and acidified with hydrochloric acid; the buff-coloured precipitate obtained (yield, 6½ g. or 36%) crystallised from nitrobenzene in colourless needles, m. p. 256° (decomp.).

This *o*-cyanocinnamic acid sublimes almost unchanged at 225°/1 mm. It is not attacked by cold concentrated sulphuric acid exposed to air, and no trace of an acid amide is formed on prolonged standing. Hydrolysis with concentrated aqueous alkaline solutions gives a large quantity of tar and only a small amount of

o-carboxycinnamic acid (m. p. 184°). The identity of this carboxycinnamic acid with that from *o*-cyanocinnamic acid (m. p. 137°) was proved by the method of mixed melting points.

Preparation of o-*Cyano*allo*cinnamic Acid* (m. p. 137°) *after* D.R.-P. 411,955.—To a solution of 1-nitroso-2-naphthol (from 50 g. of β-naphthol *) in aqueous sodium hydroxide [45 g. (3¼ mols.) in 1 l.] at 75°, *p*-toluenesulphonyl chloride (65 g.) was added all at once. The temperature was then rapidly raised to 100° and maintained for 15 minutes; a vigorous reaction began at 85°. Some tar was filtered off when cold, and after acidification a large, orange-yellow precipitate settled out. When this was crystallised from hot water, 15 g. of cyanocinnamic acid (m. p. 137°) were obtained, and subsequently 6 g. of a yellow, granular material.

Acetophenone-o-carboxylic Acid.—In a preliminary experiment (1-nitroso-2-naphthol from 200 g. of β-naphthol; 10 l. of water; 3¼ mols. of sodium hydroxide; 320 g. of *p*-toluenesulphonyl chloride) the procedure was as described above. After the 15 minutes' heating at 100°, the mixture was rapidly cooled to 40° with ice. A large amount of a green substance like the sodium salt of nitrosonaphthol was left. The filtrate from this was evaporated to 4½ litres, and the green substance (assumed to be the sodium salt of nitrosonaphthol) then added together with the requisite amounts of sodium hydroxide and toluenesulphonyl chloride. The mixture was kept at 100° for 15 minutes, and on cooling, a green precipitate was again formed. The filtrate when acidified with hydrochloric acid gave much tar, and after the removal of this the solution was again made alkaline with sodium hydroxide solution; a dark substance slowly separated from the deep red solution. This solution was concentrated and acidified with hydrochloric acid, whereby, instead of *o*-carboxycinnamic acid, a deep red oil was produced. This was extracted with ether, the ether removed, and the pasty residue crystallised from water, 20 g. of crude crystalline acetophenone-*o*-carboxylic acid being obtained. This crystallised from benzene in colourless prisms, which melted at 114—115° and had a sweet taste (Found: equiv., 165·4; *M*, by Rast's method, 163, 171; H, 5·2. Calc. for $C_9H_8O_3$: equiv. and *M*, 164; H, 4·9%) (compare Gabriel and Michael, *Ber.*, 1877, **10**, 1554. Rule and Smith, J., 1926, 556, record m. p. 112°). The *oxime* crystallised from alcohol in colourless needles, m. p. 156—157°, and the p-*nitrophenylhydrazone* in minute, yellow, felted needles, m. p. 211°. The *phenylhydrazone*

* β-Naphthol is nitrosated in about 85% yield after Lagodzinski and Hardine (*Ber.*, 1894, **27**, 3075), and is most conveniently used moist. The nitrosonaphthol is difficult to dry completely, and the sodium salt when dry is very sternutatory.

is too soluble in water to be a convenient derivative for identification. The acid was smoothly converted into phthalic acid by oxidation with permanganate solution.

Properties and Derivatives of o-*Cyano*allo*cinnamic Acid.*—On being heated slightly above its melting point under 1 mm. pressure, this acid distils with some decomposition. The oily distillate, which has the odour of styrene, contains the isomeric *o*-cyanocinnamic acid, m. p. 256°. The *allo*-acid is easily hydrolysed to the corresponding dicarboxylic acid (m. p. 184°).

o-*Cyano*allo*cinnamyl chloride* is best prepared by heating the corresponding acid with a slight excess of thionyl chloride for 1 hour; the excess of thionyl chloride is then removed in a vacuum. The residual acid chloride crystallises from petroleum (b. p. 120°) in colourless needles, 2 cm. long (Found: Cl, 18·4. $C_{10}H_6ONCl$ requires Cl, 18·5%). It melts at 50°, and is extremely soluble in benzene, ether, or dichloroethylene, and sparingly soluble in cold light petroleum. Ethyl and methyl alcohol convert it into the ethyl and methyl esters of the lactone of β-*o*-carboxyphenylhydracrylic acid (Roth, *Ber.*, 1914, **47**, 1598), m. p. 76° and 62°, respectively.

The authors wish to thank Mr. F. C. Woods, M.Sc., for assistance in preparing the *o*-cyanocinnamic acid of m. p. 256°.

MELBOURNE UNIVERSITY, AUSTRALIA. [*Received, April 20th*, 1927.]

CCCLIII.—*Beryllium Dialkyls.*

By HENRY GILMAN and F. SCHULZE.

IN continuation of studies on organoberyllium halides (Gilman, *J. Amer. Chem. Soc.*, 1925, **45**, 2693; see also Durand, *Compt. rend.*, 1926, **182**, 1162) it was necessary to prepare some beryllium dialkyls for comparative purposes, inasmuch as the two classes of compounds appear to be interconvertible.

Cahours (*Ann. Chim. Phys.*, 1860, **58**, 22) claimed to have prepared beryllium diethyl by heating the metal with ethyl iodide in a sealed tube. Later (*Compt. rend.*, 1873, **76**, 1383. Cahours's work on beryllium dialkyls has been discussed by Frankland, J., 1861, **13**, 181, 194) he reported the preparation of beryllium diethyl and beryllium dipropyl by heating the metal with the corresponding mercury dialkyls in a sealed tube at 130°. It is highly probable that Cahours's work on beryllium diethyl is incorrect. His beryllium diethyl was distilled in an atmosphere of carbon dioxide and boiled

at 185—188°. We have found that beryllium diethyl not only reacts with carbon dioxide, but also boils at a much higher temperature range (with decomposition) than that reported by Cahours. Furthermore, we had no success in the preparation of beryllium diethyl and beryllium di-*n*-butyl from the mercury dialkyls as recommended by Cahours. Incidentally, Cahours incorrectly described magnesium diethyl as a liquid, inasmuch as it is a solid (Gilman and Schulze, *J. Amer. Chem. Soc.*, 1927, **49**, 2328).

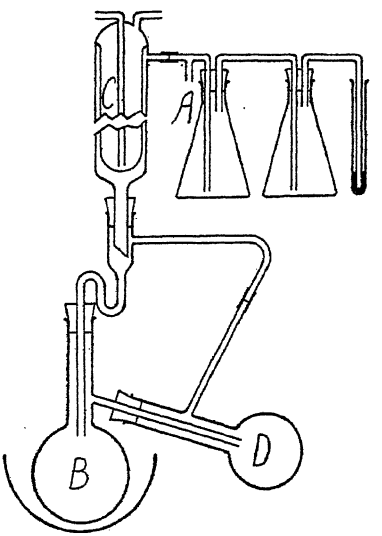
Lavroff (*J. Russ. Phys. Chem. Soc.*, 1884, **16**, 93; *Bull. Soc. chim.*, 1884, **41**, 548) very briefly mentioned the preparation of beryllium dimethyl by the action of beryllium on mercury dimethyl in a sealed tube at 130°. We have found no further mention of his work. Despite the very meagre detail in his preliminary communication, it is quite probable that he did have beryllium dimethyl.

Krause and Wendt (*Ber.*, 1923, **56**, 467, footnote 2) state that beryllium dialkyls may be prepared by the reaction between beryllium chloride and an excess of Grignard reagent.

Experimental.

Several unsuccessful attempts were made to prepare beryllium diethyl and beryllium di-*n*-butyl from finely crushed beryllium and equivalent quantities of the corresponding mercury dialkyls. No evidence of reaction was obtained when the mixtures were kept in sealed tubes for 3 weeks at room temperature; when they were heated for 3 weeks at 90°, some free mercury was formed, and heating for 15 hours at 130°, 175°, 200°, and 225° apparently induced only decomposition of the mercury dialkyls; in no case was there evidence of the formation of beryllium dialkyls.

Beryllium diphenyl and beryllium di-*p*-tolyl may be readily prepared by heating beryllium with equivalent quantities of mercury diphenyl and mercury di-*p*-tolyl and a trace of mercuric chloride in sealed tubes at 225° for 6 hours.



In the experiments with mercury dialkyls, no mercuric chloride was added. Other studies (Gilman and Schulze, *loc. cit.*) have shown that mercuric chloride is an almost indispensable catalyst in the preparation of some metallic dialkyls, like magnesium diethyl. No attempt was made to prepare beryllium dimethyl from beryllium and mercury dimethyl. It is quite reasonable to assume that traces of some mercuric halide were contained in the materials used by Lavroff. The beryllium used in the present studies was obtained from the Beryllium Corporation of America and contained more than 99·5% of beryllium.

It is possible to prepare beryllium dialkyls by heating beryllium with the appropriate alkyl halides, an alkylberyllium halide being

an intermediate product. Here, again, mercuric chloride is a very helpful catalyst.

However, it appears that the most convenient method for the preparation of beryllium dialkyls is the reaction between anhydrous beryllium chloride and the appropriate Grignard reagent. We have prepared beryllium dimethyl, diethyl, and di-*n*-butyl by this method.

Preparation of Beryllium Dialkyls.—Because of the highly hygroscopic nature of anhydrous beryllium chloride and the ready decomposability of beryllium alkyls and the Grignard reagent by air, all operations were carried out in pure dry hydrogen or nitrogen, admitted through the tube *A*. Anhydrous beryllium chloride (8 g.; 0·1 g.-mol.) is dissolved in 50 c.c. of anhydrous ether, cooled by running water. The filtered oily solution, which may be either colourless or pale yellow and separates into a lower layer of beryllium chloride etherate and an upper layer consisting largely of ether, falls directly into 75 c.c. of 4*M*-magnesium methyl iodide (0·3 g.-mol.) contained in a 250 c.c. flask, *B*, the Grignard solution being gently shaken during addition. There is little heat of reaction if the beryllium chloride solution is pure and anhydrous. The formation of white clouds on the surface of the reaction mixture is indicative of the presence of air or oxygen.

The excess of ether is removed by stopping the circulation of water in the condenser, *C*, until the oil-bath attains a temperature of 150°. The water is then turned on slowly in order to prevent a too sudden contraction (due to the condensation of ether) that might draw air into the condenser and receiving flask. Distillation is continued at 150—200° for 6 to 15 hours, so long as an ethereal solution of beryllium dimethyl collects in the receiving flask, *D*. Heat radiating from the oil-bath is sufficient to keep the temperature of the receiver above the boiling point of ether and thereby prevent the condensation of more ether than is necessary to hold the beryllium dimethyl in solution. The distillation may be continued overnight, as it requires no attention. Should the ether be driven out

completely from the distilling flask, *B*, so that no more ether vapour circulates, it is necessary merely to heat the receiver gently to return the ether to flask *B*. Such heating should be moderate, otherwise some of the beryllium dimethyl will be driven back into *B* and so extend the time of recovery of the compound.

The ethereal solution of beryllium dimethyl obtained in this manner is clear and colourless (when care has been taken to exclude air), and it may be used directly in a study of the reactions of the compound. When not in use, it is kept preferably in sealed glass containers. Pure, ether-free beryllium dimethyl is obtained by heating the distillate. At about 100—125°, most of the ether is expelled and the whole solution suddenly turns to a mass of white needles containing some ether, which may be removed by heating to 200°. At 200° (external temperature), the compound commences to sublime rapidly, and part of it solidifies in the capillary when a constricted test-tube is used for the collection of ether-free samples. However, the capillary can be kept open prior to sealing by applying a small luminous flame. A repetition of this process of distillation in a sealed U-tube arrangement originally filled with ether vapour makes it possible to obtain material free from oxide or methoxide by alternately heating and cooling each part of the U-tube. The samples used for analysis were prepared in this manner.

3·5 G. (90% yield) of beryllium dimethyl were obtained from 0·1 g.-mol. of beryllium chloride; with 0·3 g.-mol., the yield was 84·7%.

Beryllium diethyl and di-*n*-butyl were prepared in essentially the same way as beryllium dimethyl. However, it is possible to distil beryllium diethyl and di-*n*-butyl directly in a vacuum. Because of the higher vapour pressure of beryllium di-*n*-butyl, it would probably be more advantageous to use a vacuum distillation rather than the ether distillation or ether sublimation process used for the dimethyl compound.

Analysis of Beryllium Dimethyl.—After being weighed, one of the sealed tubes, containing beryllium dimethyl prepared by distillation at 200°, was broken in a vessel filled with dry ether, and the volume of methane liberated on the addition of water and then dilute hydrochloric acid was measured in a special eudiometer containing concentrated sulphuric acid. An aliquot portion of the evolved gas, when exploded with a measured volume of oxygen, was shown to consist of pure methane.

The beryllium was analysed as beryllium oxide after careful removal of the glass, which was weighed to determine the weight of beryllium dimethyl originally present in the sealed container [0·1501 g. of beryllium dimethyl gave 173·2 c.c. (corr.) of methane

and 23·33% of beryllium. Calc.: 171·4 c.c. and 23·25%. 0·1771 G. gave 200·7 c.c. of methane. Calc.: 202·2 c.c.].

Properties of Beryllium Dialkyls.—Beryllium dimethyl crystallises from hot concentrated ethereal solution in snow-white needles (see Preparation). It is also deposited in the same form when it sublimes, without melting, at about 200°. The method of preparation is based on its high volatility in ether, and these ethereal solutions fume strongly when exposed to the atmosphere. When suddenly overheated, it undergoes partial decomposition, leaving a brown or grey mirror.

Beryllium diethyl is a colourless liquid, b. p. 93—95°/4 mm. and 110°/15 mm. It distils between 180° and 240° at atmospheric pressure with considerable decomposition. The compound is only distilled with difficulty because of its pronounced tendency to become superheated and then break suddenly into foam. This may be due to the decomposition of an etherate. A part of the purest material solidified, in a carbon dioxide–ether freezing mixture, to white crystals which on warming melted at −13° to −11°.

Beryllium di-*n*-butyl is a clear, colourless liquid having a mercaptan-like odour. The boiling point, 170°/25 mm., was determined with a rather small quantity of material and so may not be taken with too much credence.

Both beryllium dimethyl and diethyl are spontaneously inflammable in the air, and especially so in a humid atmosphere. Even concentrated ethereal solutions are inflammable spontaneously in the presence of moist air. The compounds burn with luminous flames, evolving dense white fumes of beryllium oxide. Their very high sensitivity to oxygen made it difficult, at first, to purify the hydrogen or nitrogen to such an extent that it would not give a white cloud of beryllium oxide when passed over the ethereal solutions of the dialkyls. For this reason, a magnesium phenyl bromide solution was inserted in the drying and purifying train in order to remove a residuum of oxygen. Beryllium di-*n*-butyl is not spontaneously inflammable when exposed to the air. But it does oxidise rapidly, when so exposed, with the evolution of heat. Very probably, beryllium butyloxide is a product of such oxidation, inasmuch as the odour of *n*-butyl alcohol becomes quite pronounced after a short air exposure.

The reaction of the dialkyls with water is violent, and in the presence of small amounts of water the materials frequently inflame. Methane and ethane are evolved when the corresponding dialkyls are decomposed by water.

Beryllium dimethyl in the solid state inflames when treated with carbon dioxide. With an ethereal solution, however, the reaction

is quite mild and acetic acid is formed. An ethereal solution of beryllium diethyl reacts with carbon dioxide to give triethylcarbinol.

Phenylcarbimide in ethereal solution reacts with extreme violence with the three dialkyls studied. In each case, a white solid separated at first, and then dissolved in the excess of beryllium dialkyl. The expected anilides were obtained, the valeranilide as an oil. This anilide is known to crystallise with difficulty, so that its identity has not been confirmed, as was done with the other two anilides, by a mixed-melting point determination with an authentic specimen. Aceto-α-naphthalide was obtained from beryllium dimethyl and α-naphthylcarbimide.

The three dialkyls give an immediate positive colour reaction with Michler's ketone according to the test described by Gilman and Schulze (*J. Amer. Chem. Soc.*, 1925, **47**, 2002) for RMgX and some other organometallic compounds. The blue instead of green colour given by beryllium di-*n*-butyl indicates that this dialkyl probably reduced the ketone to Michler's hydrol (*loc. cit.*).

Beryllium dimethyl with benzophenone gave diphenylmethylcarbinol, which was identified as αα-diphenylethylene. Beryllium diethyl, on the other hand, reduced benzophenone to benzhydrol. In the latter reaction, a bright orange-red colour was present transitorily at the junction of the two liquids. This may be indicative of the intermediate formation of a free radical.

Beryllium dimethyl with benzoyl chloride gave phenyldimethylcarbinol, and this was identified by the formation of *iso*propenylbenzene when the carbinol was distilled. The reaction product was probably free from acetophenone as indicated by a test with semicarbazide.

The beryllium dialkyls appear to have high solvent characteristics, for all the intermediate reaction products dissolved in an excess of the dialkyl. Equally striking is the fact that beryllium diethyl dissolved the beryllium oxide and ethoxide formed by partial decomposition of the dialkyl, as well as the brown or grey mirror formed by the high-temperature decomposition of the dialkyl.

Beryllium dimethyl and diethyl react vigorously with iodine. When 1·343 g. of beryllium dimethyl were treated with 1 equiv. (4·353 g.) of iodine, the solution still contained some dialkyl, as was evidenced by the fuming on air exposure and by a slight positive test (Gilman and Schulze, *loc. cit.*). After standing for several days in a cork-stoppered flask, the solution no longer fumed and gave a negative test. Very probably beryllium methyl iodide was formed as a result of the iodine reaction, because the solution gave acetanilide on treatment with phenylcarbimide, and when heated it fumed and gave a positive test. These are among the criteria

included for the characterisation of beryllium alkyl halides (Gilman and Schulze, *J. Amer. Chem. Soc.*, 1927, **49**, Nov.).

Beryllium diethyl reacts with an excess of an ethereal solution of beryllium chloride to give a solution with the characteristics of beryllium ethyl chloride. In view of these latter experiments, the following equilibrium is probable under certain conditions:

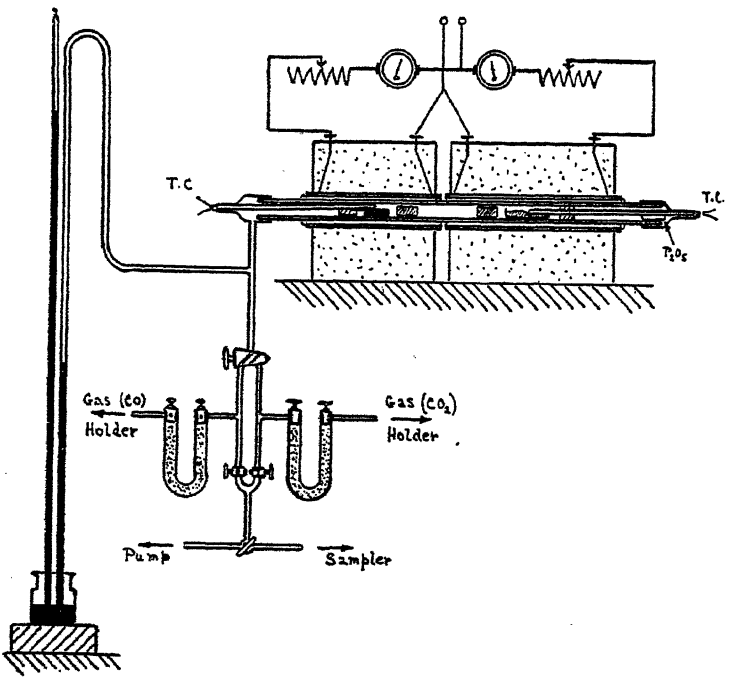
$$BeR_2 + BeX_2 \rightleftharpoons 2RBeX.$$

In general, the beryllium alkyl halides are less active than the beryllium dialkyls, and the beryllium dialkyls are at least equal in activity to the Grignard reagents.

IOWA STATE COLLEGE,
AMES, IOWA, U.S.A. [*Received, August 2nd*, 1927.]

CCCLIV.—*The Thermal Dissociation of Strontium Carbonate.*

By EDWARD OSWALD JONES and MAURICE LUND BECKER.



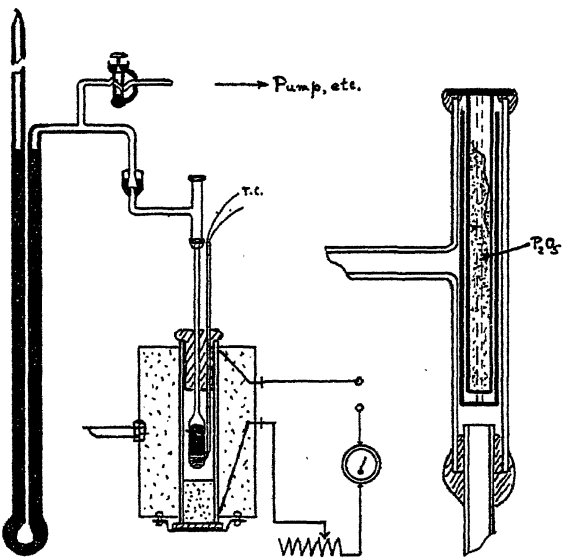
DURING their work on the effect of temperature and pressure on the progress and equilibrium of certain reactions, the authors were faced with the problem of devising a suitable means by which the composition of a gas phase consisting of carbon monoxide and dioxide could be readily determined at any instant. It occurred to one of them (E. O. J.) that a suitable method of attack would be to fix the partial pressure of the carbon dioxide by maintaining the gas phase in contact with a carbonate heated to a known temperature. The pressure of this gas would be the dissociation tension of the carbonate for that particular temperature, and by subtraction from the total pressure of the system the partial pressure of the monoxide could be found.

The alkaline-earth carbonates naturally suggested themselves as being suitable materials for the purpose, and a study of the literature led to the selection of strontium carbonate. The only work on the dissociation tension of this carbonate at different temperatures to which reference could be found was that of Pott (Diss., Freiburg, 1905; see also Mellor, "Treatise on Inorganic and Theoretical Chemistry," III, 655). Two other workers, Brill (*Z. anorg. Chem.*, 1905, **45**, 275) and Hedvall (*ibid.*, 1916, **98**, 47), record determinations of the temperature at which the tension attains 1 atm. Unfortunately, their work is not in good agreement with that of Pott, and it was further noted that Pott's curve is of quite a different shape from those given for calcium and barium carbonates, and actually cuts the first of these two curves. It

was thought advisable, therefore, to make a series of determinations of the dissociation tension of strontium carbonate at different temperatures in the same apparatus and under the same experimental conditions as those in which it was proposed to use this material for carbon dioxide-pressure control.

During the course of the investigations, two distinct types of apparatus were employed. These are diagrammatically represented in Figs. 1 and 2. The first was designed for use where it was neces-

FIG. 1.



Apparatus No. 1. (Diagrammatic.)

sary to keep the carbonate separate from the other reactants with the gas phase, and where independent temperature control, both of the reactants and of the dissociating carbonate, was desirable. The second, which is simpler, was utilised when the above-mentioned limitations did not apply.

Apparatus 1 consists essentially of a long porcelain tube (800 mm. × 18 mm. internal diameter) heated by two independently controlled electric resistance furnaces. The ends of the tube were closed by glass caps hermetically sealed to the heating tube by white wax. Each of these caps had a small-bore extension to

take the thermocouple sheath, and one of them was also provided with a side tube which gave connexion to the manometer, evacuating pump, gas holders, etc. The Vitreosil thermocouple sheaths were sealed into the extension tubes of the caps by means of white wax, and it was also found advisable to close the open ends of these sheaths with wax, since, after being maintained at high temperatures for a considerable time, they developed slight porosity at the heated end, due to devitrification. Heat-insulating plugs, made of kieselguhr bonded with a small proportion of sodium silicate, were placed in the furnace tube to lessen heat radiation

FIG. 2.

Apparatus No. 2. (Diagrammatic.)

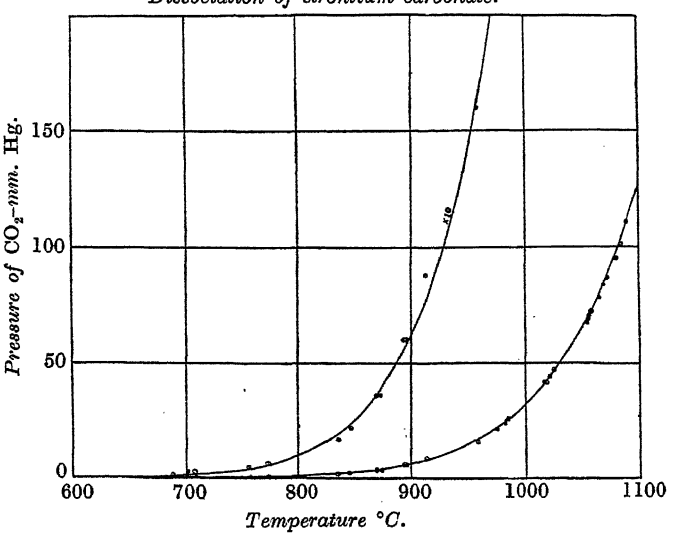
and to provide zones of uniform temperature. A boat containing phosphorus pentoxide, placed at one end of the tube, served to absorb all the water vapour.

Apparatus 2 is essentially a small, transparent silica bulb of about 10 c.c. capacity fused to a silica tube (30 mm. × 5 mm.), the other end of which is sealed by white wax into a glass T-piece. This serves to accommodate a small container for phosphorus pentoxide and to give connexion to the manometer, etc. A small resistance furnace, which may be raised or lowered, serves to heat the bulb to the required temperature, which is measured by a thermocouple in contact with the bulb wall.

This second form of apparatus is more suitable for measuring

dissociation tension, since equilibrium conditions are attained much more rapidly as a result of its small volume and its relatively larger carbonate content. Nevertheless, since it was necessary to use the first form of apparatus for some of the investigations, it was considered desirable to study the thermal dissociation of the carbonate in both forms of apparatus as a matter of precaution and for the sake of calibration. The results obtained were found to agree within the limits of experimental error, and this concordance is considered good presumptive evidence of the correctness of the values obtained.

The experimental details were essentially the same for each type of apparatus. A sufficient quantity of pure strontium carbonate (about 1 g. in the case of the bulb, and 4—5 g. in a porcelain boat in the case of the tube) having been introduced, the apparatus was hermetically sealed and then evacuated by means of a " Cenco Hyvac " pump. The temperature was now raised gradually to about 600°, during which time the evolved gases (largely water vapour) were removed at frequent intervals by pumping. When no more gas appeared to be given off, the temperature was raised to 1000° and maintained at this value for about 12 hours. During this time the pressure increased gradually, due probably to further expulsion of occluded gas and to a slow reaction between the carbonate and the silica walls of the bulb where contact occurs, whereby carbon dioxide was liberated. The apparatus was then evacuated rapidly, the tap to the pump closed, and the pressure allowed to attain a steady value. This was lower than the initial one obtained and the process was repeated as often as was necessary to obtain two consecutive equal values for the gas pressure. This procedure ensured (*a*) removal of all occluded gas, and (*b*) the presence of more strontium oxide than that equivalent to the carbon dioxide liberated by the slow reaction already mentioned. That this is so is shown by the fact that, on allowing the furnace to cool to 600°, the resulting vacuum was of a higher order than could be obtained by the pump alone, *i.e.*, less than 0·05 mm.



The apparatus was now ready for use. The strontium carbonate was slowly heated, and pressure and temperature readings were taken. In the case of the bulb apparatus, the rate of heating was sufficiently slow to ensure that the pressure corresponding to a given temperature was the equilibrium pressure until about 900° had been reached. Beyond this temperature, the furnace was allowed to reach a steady state before readings were taken. In the case of the tube furnace, the method of allowing the furnace to reach a steady temperature was practised from the beginning, as the gas evolution involved was so much larger.

The temperature was measured by means of carefully calibrated thermocouples and is considered accurate to within $\pm 3°$; pressures less than 10 mm. were read by means of a cathetometer to within $\pm 0{\cdot}05$ mm.; higher pressures were read directly on a metre scale fixed alongside the manometer. This gave readings to within $\pm 0{\cdot}5$ mm., which is as close as is justified by the accuracy of the temperature measurements.

Values of the dissociation tension for given temperatures were obtained on both ascending and descending temperature scales and

FIG. 3.

Dissociation of strontium carbonate.

further checked by haphazard alteration of the temperature; the concordance was good. In view of this agreement, there is no need to quote more than one set of results. Those obtained by one of the authors (M. L. B.) are recorded in Table I (in mm. Hg) and shown graphically in Fig. 3.

TABLE I.

Temp.	p, obs.	p, calc.	Temp.	p, obs.	p, calc.
689°	0·1	0·07	975°	21	21·5
708	0·3	0·12	984	25	24·5
756	0·5	0·35	1020	42	42
775	0·6	0·55	1027	47·5	47
835	1·7	1·85	1059	72·5	72
846	2·2	2·3	1070	84	84
869	3·6	3·5	1081	95	97
896	6·0	5·8	1090	111	110
913	8·8	7·8	1103	123	130
958	16·0	16·3			

The dissociation tensions of calcium and barium carbonates determined by various workers have been found to fit closely to curves of the form

$$\log p_1 - \log p_2 = -K(1/T_1 - 1/T_2)$$

where p_1 and p_2 are the pressures (mm. Hg), T_1 and T_2 the absolute temperatures, and K is a constant. It was of interest, therefore, to see whether the dissociation of strontium carbonate could be similarly expressed. If the value of the dissociation tension at 928° be taken as 10 mm. and K as $1{\cdot}05 \times 10^4$, then the values of the carbon dioxide pressure for other temperatures can be calculated. The resulting graph, as will be seen, agrees very satisfactorily with the observed values over the entire range investigated. Table II gives calculated values of the dissociation pressure for temperature increments of 50°.

TABLE II.

Temp.	p, mm.	Temp.	p, mm.	Temp.	p, mm.
650°	0·023	900°	6·19	1150°	231
700	0·090	950	14·36	1200	411
750	0·30	1000	31·22	1258	760
800	0·91	1050	63·98	1300	1167
850	2·47	1100	124·5		

It has already been pointed out that good concordance existed between the results obtained in the different apparatus, and further confirmation, particularly of the lower values as corrected to the calculated curve, is given by later work on the C–CO–CO_2 equilibrium where the carbon dioxide pressure is controlled by means of strontium carbonate. The values of the equilibrium constant thus determined for this system at different temperatures lie closely on Tigerschiöld's curve (*Jernkontoret's Annaler*, 1923, 67; see also Johansson and von Seth, *J. Iron and Steel Inst.*, 1926, **114**, 313) which correlates satisfactorily the work of Boudouard (*Ann. Chim. Phys.*, 1901, **24**, 5), Schenck (*Ber.*, 1905, **38**, 2139), and Rhead and Wheeler (J., 1910, **97**, 2178) on this equilibrium. This agreement justifies the acceptance of the results, and, in particular, the validity of the formula for calculating the dissociation tension in the lower temperature range.

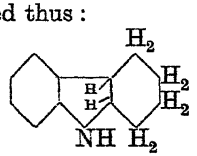
The authors' value for the temperature at which the dissociation pressure is equal to 1 atm. is approximately 100° higher than those reported by Brill (*loc. cit.*) and Hedvall (*loc. cit.*). Although the authors' result has been obtained by extrapolation of the curve, whereas the others have experimental basis, it is regarded as more accurate for the following reasons. (*a*) Brill noted the temperature at which loss of weight just occurred from calcium carbonate in a

carbon dioxide atmosphere of approximately 760 mm. pressure, and obtained a value 75—100° lower than those recorded by other workers who measured the actual dissociation tension. This discrepancy for calcium carbonate is of the same order as the difference between Brill's result for strontium carbonate and the one put forward in this paper.

(*b*) Hedvall, who used the thermal arrest in the heating curve for fixing the dissociation temperature, gives 1141° as the temperature at which carbon dioxide evolution commences. It is of interest, however, that he quotes 1255° (only 3° different from the value put forward by the authors) as the temperature at which carbon dioxide evolution becomes rapid, and further states that a small quantity of strontium carbonate was not completely decomposed on being heated for 5 minutes at temperatures between 1141° and 1255°.

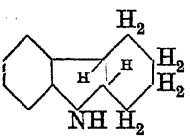
The authors' curve lies wholly between the accepted curves for calcium carbonate (Johnston, *Z. physikal. Chem.*, 1908, **62**, 330; *J. Amer. Chem. Soc.*, 1910, **32**, 938) and barium carbonate (Finkelstein, *Ber.*, 1906, **39**, 1585), thus differing from that of Pott. It is suggested that the higher values obtained by Pott in the lower temperature range are due to the absence of sufficient oxide phase to absorb the excess carbon dioxide liberated by some such slow carbonate–silica reaction as was noticed by the authors in their work. At higher temperatures, where the extent of dissociation involves the production of larger quantities of strontium oxide, this source of error tends to disappear, and it is of interest to note that Pott's results for 1256° and 1263° (744 mm. and 785 mm., respectively) would lie satisfactorily on the extrapolated portion of the authors' curve.

In view of the fact that Finkelstein (*loc. cit.*) obtained evidence of the formation of a basic barium carbonate ($BaO,BaCO_3$), the authors sought for indications of a similar basic strontium carbonate. When the dissociation tensions at 1000° and 1100° were being measured, a known volume (approximately one-sixth of the available carbon dioxide) was drawn off and the system allowed to return to equilibrium. The resulting pressure was the same as in the initial determination. This process was repeated until six withdrawals had been made. In every case, except the last, the pressure returned to the recorded equilibrium value, whilst on the last occasion the pressure only rose a few mm., showing that the solid phase was now wholly the oxide. This series of experiments shows that over the range 15—85 mols. % of strontium oxide the solid phase does not change in character, and therefore affords no evidence for the existence of a basic carbonate under these conditions.



The work here described was carried out in the Metallurgical Department, Manchester University, and the authors desire to express their thanks to Prof. F. C. Thompson, D.Met., for the facilities provided and also for his interest and helpful criticisms and suggestions during the course of the work. Acknowledgment is also due to the Department of Scientific and Industrial Research and to the British Cast Iron Research Association for their financial grants and for their permission to publish the results.

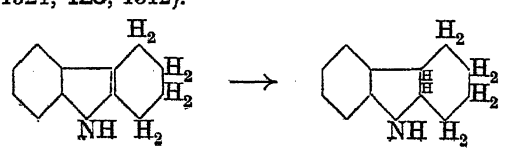
THE UNIVERSITY, MANCHESTER. [*Received, September 7th*, 1927.]



CCCLV.—*A New Stereoisomeride* (trans-) *of Hexahydrocarbazole.*

By JOHN GURNEY, WILLIAM HENRY PERKIN, jun., and SYDNEY GLENN PRESTON PLANT.

DURING the course of experiments on octahydroacridine, Perkin and Sedgwick (J., 1924, **125**, 2437) showed that this substance exists in two stereoisomeric, externally compensated modifications, namely (A), m. p. 82°, and (B), m. p. 72°, and these they subsequently resolved (J., 1926, 438) each into its optically active components. In the earlier paper, it was pointed out that hexahydrocarbazole also should exist in two analogous stereoisomeric forms, which may be represented thus :



cis.

trans.

and it was proposed to investigate this point.

Hitherto only one form of hexahydrocarbazole (m. p. 99°) has been described. Although this substance has been obtained by the reduction of carbazole under various conditions (Graebe and Glaser, *Ber.*, 1872, **5**, 14; *Annalen*, 1872, **163**, 352; Schmidt and Sigwart, *Ber.*, 1912, **45**, 1784), the only practicable method for preparing relatively large quantities is by the hydrogenation of the double bond in tetrahydrocarbazole (Borsche, Witte, and Bothe, *Annalen*, 1908, **359**, 70; Carrasco, *Gazzetta*, 1908, **38**, ii, 303; Perkin and Plant, J., 1924, **125**, 1512).

By reducing a large quantity (900 g.) of tetrahydrocarbazole with tin and hydrochloric acid we have now succeeded in isolating a small amount (about 12 g.) of the second isomeride of hexahydrocarbazole, and we find that this melts at 127°. Its identity has been confirmed by making the *picrate* and *acetyl* and *benzoyl* derivatives, and comparing these with the corresponding derivatives of the ordinary form. Both modifications of hexahydrocarbazole have been shown to be unimolecular, they distil unchanged at the ordinary pressure at approximately the same temperature, and are both exceptionally volatile in steam.

The existence of two stereoisomerides of hexahydrocarbazole can be predicted from the Sachse–Mohr theory of multiplanar rings and forms an interesting addition to the cases of this kind which have been already described. This type of stereoisomerism has been recently well established by several investigators in the decahydronaphthalene series, and in a few other dicyclic systems composed of two six-membered rings (see, *e.g.*, Windaus, Hückel, and Reverey, *Ber.*, 1923, **56**, 91; Perkin and Sedgwick, *loc. cit.*; Helfer, *Helv. Chim. Acta*, 1926, **9**, 814; Hückel and Stepf, *Annalen*, 1927, **453**, 163). In all these cases, both the *cis*- and the *trans*-modifications can be regarded as strainless. The points of particular interest involved in the case of hexahydrocarbazole are (1) that the stereoisomerism is a feature of a dicyclic system composed of one six-membered carbon ring and one five-membered ring containing nitrogen, and (2) that both isomerides are produced together from the same substance in the same reaction. It is quite apparent that in this system there is far more strain in the *trans*-structure than in the *cis*-, a fact which is easily demonstrated with the aid of models. It is to be expected, therefore, that in the formation of such a dicyclic system by the hydrogenation of the double bond common to both rings the *cis*-modification will be produced to a much greater extent than the *trans*-modification, and this is exactly what is observed in the case of the hexahydrocarbazoles. There can be little doubt that the modification, m. p. 99°, which constitutes almost the entire product, is the *cis*-, and that the new substance, present to the extent of 1—2%, is the corresponding *trans*-form.

Hückel and Friedrich (*Annalen*, 1926, **451**, 132) have isolated the *cis*- and *trans*-modifications of the hexahydro-β-hydrindones and the three hexahydro-β-hydrindols, which contain dicyclic carbon systems composed of one six-membered and one five-membered ring, but each of these isomerides was obtained synthetically by independent reactions starting with the *cis*- and *trans*-forms of ethyl *cyclo*hexane-1 : 2-diacetate, respectively. These authors also point

out that the *trans*-configuration in these systems is marked by considerable strain. The anhydrides of *cis*- and *trans-cyclo*hexane-1 : 2-dicarboxylic acid (Windaus and Hückel, *Nachr. Ges. Wiss. Gottingen, Math.-physik. Klasse*, 1920, **11**, ii, 181) also may be considered as examples of the type of dicyclic system which is being discussed in this communication. We are engaged in the attempt to resolve the *cis*- and *trans*-modifications of hexahydrocarbazole into their active components.

EXPERIMENTAL.

A mixture of tetrahydrocarbazole (900 g.), alcohol (1800 c.c.), concentrated hydrochloric acid (1800 c.c.), and granulated tin (1800 g.) (compare Borsche, Witte, and Bothe, *loc. cit.*) was heated on the steam-bath for 5 hours, as much alcohol as possible was then distilled off and the residue was poured into beakers and allowed to cool. The product partly solidified to a crystalline mass, which was pulverised, and the whole was then made strongly alkaline by the addition of concentrated aqueous sodium hydroxide. The solid was collected on asbestos, pressed as dry as possible, and then extracted in portions twice with ether. The solid remaining was ground to a paste with more aqueous sodium hydroxide, collected, and again extracted twice with ether. After removal of the ether by distillation, the crude reduction product was crystallised from alcohol and a large quantity of *cis*-hexahydrocarbazole (m. p. 99°) was obtained. By concentrating the mother-liquor three times, further quantities of *cis*-hexahydrocarbazole were obtained. The alcohol was then removed as completely as possible on the steam-bath from the remaining mother-liquor, the residual product dissolved in 60% sulphuric acid, and the solution poured into much water. The small quantity (38 g.) of unchanged tetrahydrocarbazole thus precipitated was removed, and the aqueous solution made alkaline by the addition of concentrated ammonia, which precipitated the crude mixture of the hexahydrocarbazoles as a colourless solid. The product was made into a paste with water, added to an excess of dilute aqueous sodium hydroxide, and shaken with an equal weight (130 g.) of benzoyl chloride. After a few hours, the solid product was collected and crystallised from alcohol; a considerable amount of practically pure 9-benzoyl-*cis*-hexahydrocarbazole then separated. After filtration, the alcoholic mother-liquor was added to an excess of aqueous-alcoholic potassium hydroxide, the mixture boiled under reflux for 3 hours, as much alcohol as possible distilled off, and the residual mixture diluted with water. The sticky product was washed by decantation and crystallised from alcohol; almost pure trans-*hexahydrocarbazole* then separated,

On recrystallisation from alcohol, it was obtained in colourless needles (about 12 g.), m. p. 127° (Found: C, 83·2; H, 8·7; N, 8·1. $C_{12}H_{15}N$ requires C, 83·2; H, 8·7; N, 8·1%). Molecular-weight determinations by Rast's method (*Ber.*, 1922, **55**, 1051) gave for *trans*-hexahydrocarbazole a value of 170 and for the *cis*-form 163, theory requiring 173. *trans*-Hexahydrocarbazole, like the *cis*-modification, is readily soluble in dilute hydrochloric acid and is reprecipitated on addition of ammonia. Both modifications distilled unchanged: *trans*-, b. p. 286°/769 mm.; *cis*-, b. p. 280°/769 mm.

trans-Hexahydrocarbazole (0·5 g.) and picric acid (0·65 g.) were mixed in hot alcohol; the *picrate* separated, on cooling, in yellow needles, m. p. 179° (Found: N, 13·9. $C_{18}H_{18}O_7N_4$ requires N, 13·9%). The *picrate* of the ordinary *cis*-modification, prepared in the same way, was obtained in yellow needles, m. p. 166° (Found: N, 13·7%).

After *trans*-hexahydrocarbazole had been boiled with an excess of acetic anhydride for an hour, the mixture shaken with much water, and the product crystallised from dilute alcohol, 9-*acetyl*-trans-*hexahydrocarbazole* separated in long, colourless needles, m. p. 113° (Found: N, 6·4. $C_{14}H_{17}ON$ requires N, 6·5%). 9-Acetyl-*cis*-hexahydrocarbazole melts at 98° (Graebe and Adlerskron, *Annalen*, 1880, **202**, 25).

When *trans*-hexahydrocarbazole was made into a paste with water, an excess of dilute aqueous sodium hydroxide added, and the mixture shaken with benzoyl chloride, 9-*benzoyl*-trans-*hexahydrocarbazole* separated; it crystallised from alcohol in colourless needles, m. p. 133° (Found: N, 5·2. $C_{19}H_{19}ON$ requires N, 5·1%). The m. p. of 9-benzoyl-*cis*-hexahydrocarbazole is 106° (Gurney and Plant, this vol., p. 1320).

THE DYSON PERRINS LABORATORY,
OXFORD. [*Received, October 12th*, 1927.]

CCCLVI.—*The Hydrolysis of Solutions of Sodium Palmitate as measured by Extraction with* p-*Xylene.*

By JAMES WILLIAM MCBAIN and REGINALD BUCKINGHAM.

AFTER long uncertainty and widely conflicting opinions, it is now commonly accepted that the hydrolysis alkalinity of soap solutions is of the order of only $N/1000$ (conductivity: McBain and Taylor, *Z. physikal. Chem.*, 1911, **76**, 179; hydrogen electrode: McBain

and Martin, J., 1914, **105**, 957; catalysis: McBain and Bolam, J., 1918, **113**, 825; Beedle and Bolam, *J. Soc. Chem. Ind.*, 1921, **40**, 27T; ultrafiltration: McBain and Jenkins, J., 1922, **121**, 2325; indicators: McBain and Hay, unpublished). The presence of free fatty acid in all soap solutions is readily demonstrated by shaking them with any suitable solvent such as light petroleum or toluene (Krafft and Stern, *Ber.*, 1894, **27**, 1747, 1755; Krafft and Wiglow, *ibid.*, 1895, **28**, 2566, 2573; Lewkowitsch, *Z. angew. Chem.*, 1907, **20**, 951; Fendler and Kuhn, *ibid.*, 1909, **22**, 107; Holde, *Z. Elektrochem.*, 1910, **16**, 436; S. von Schapringer, Dissert., Karlsruhe, Freiberg, 55—67; Reychler, *Int. Congr. Appl. Chem.*, 1912, **22**, 221), which always extracts fatty acid although the amount is only a small fraction of that which the soap would yield if completely decomposed. As will be seen, such extraction occurs from all soap solutions, whether neutral or containing excess of acid or of alkali. In every case, likewise, the solutions are definitely alkaline even when as much as a complete equivalent of excess of fatty acid has been added to the soap.

Even now, however, the statement is frequently made that soap solutions contain emulsified free fatty acid. This is never true. In spite of the low solubility of the higher fatty acids, there is never enough free fatty acid to saturate the solution, much less to give an excess. If the aqueous layer is saturated with fatty acid, then any non-aqueous layer in equilibrium with it would also be saturated, but in no case has this been observed.

The higher fatty acids must be almost as strong as acetic acid, as is evident from a study of the dissociation constants of the lower acids of the homologous series. The only reason why soap solutions are appreciably hydrolysed is that the free fatty acid formed by hydrolysis is almost wholly removed from solution in the form of acid soap. Such acid soaps form a conspicuous, but often almost unweighable, sediment in dilute soap solutions, and the gross composition of these sediments has often been determined (see McBain and Taylor, *loc. cit.*; Krafft and Stern, *loc. cit.*; McBain, Taylor, and Laing, J., 1922, **121**, 621; McBain and Stewart, this vol., p. 1392), although the elucidation of their exact constitution awaits more rationally planned experiments. There is no similar outlet for the alkali formed by hydrolysis, and it therefore accumulates in the solution. The hydrolysis alkalinity, *i.e.*, the concentration of free hydroxyl ions, is therefore always much greater than the mere trace of free fatty acid present in the solution. Addition of a very small amount of alkali scarcely increases the hydrolysis alkalinity, because it is compensated by removal of acid soap.

It is evident, therefore, that extraction with solvents does not

measure the hydrolysis alkalinity, but that when equilibrium is attained the concentration of the free fatty acid in true solution in the final aqueous layer is indicated. The value of the distribution ratio is such that the concentration of fatty acid in the non-aqueous layer is of the order of 10^6 times greater than that in the aqueous layer. Two kinds of experiments may be carried out, *viz.*, those in which soap solutions are extracted with solvent and therefore changed in composition, and those in which approximately the right amount of fatty acid is previously added to the non-aqueous layer, so that the final equilibrium is determined without appreciable alteration of the aqueous solution. Both methods have here been adopted. When a large excess of fatty acid is added in advance to the non-aqueous layer, it passes into the soap solution, thus again demonstrating the formation of acid soap, since the non-aqueous layer is left unsaturated. It is important that true reversible equilibrium between the two layers was readily obtained in our experiments; the position of equilibrium was obtainable from both sides and did not alter with time at 90°.

Experimental.

All the work was carried out at Bristol University. Mr. H. H. Cole studied toluene, xylene, and deca- and tetra-hydronaphthalene with a view to find a solvent which would fulfil the following conditions: it should be (1) of fairly high boiling point, (2) non-miscible with water, (3) a non-solvent for soap and sodium hydroxide, and (4) only a moderate solvent for fatty acid, which should dissolve as unassociated molecules. He found that the solubility of palmitic acid in twice-distilled *p*-xylene (b. p. 137—138° under 760 mm. pressure) was 33·8 g. in 100 g. of *p*-xylene at 50° and 73·5 g. at 90°, and ebullioscopic measurements showed that the fatty acid was mainly present as simple molecules (Found: *M*, 322, 322, 328, 336. Calc.: 266), but the boiling point constant was found only by calculation. Blank experiments showed that if 9·5 g. of palmitic acid were added to 12 c.c. of xylene, the residue after evaporation showed a loss of only 0·1—0·2 mg. of the acid. Further, xylene was found to dissolve only 0·06% of its weight of sodium palmitate when shaken at 95—97° for 22 hours, thus showing that for the purpose of the present experiments sodium palmitate is insoluble in xylene.

The method here employed is substantially that developed by Miss A. M. King. The greatest practical difficulty is due to the extreme readiness with which these soap solutions become more or less permanently emulsified with the xylene layer, so that separation for analysis becomes impossible. This was finally avoided by carrying out the extraction in horizontal sealed tubes, about

23 cm. long and 1·3 cm. in diameter, tied parallel to the axis of a slowly rotating horizontal stirrer making 20—60 revs. per min. Even under these conditions, if the tubes contained a very large excess of fatty acid or nearly enough salt to salt out the soap, frothing occurred extensively. Between 7000 and 8000 revs. were allowed for attainment of equilibrium, and after 15 minutes' further standing the xylene layer was usually quite clear. Thereupon, the top of the tube was cut off without removal from the thermostat, and as much as possible of the xylene layer was drawn off and weighed; the xylene was then evaporated at 80°, a tube attached to a filter-pump being kept near the surface of the solution in an evaporating dish to renew the air. After 2 hours' drying the residue of fatty acid was weighed.

Two specimens of sodium palmitate, specially made for us by Kahlbaum, were employed. Specimen A contained 4·5% of water and an excess of alkali amounting to 0·0001 equiv. of sodium per equiv. of soap. Specimen B contained 3·47% of water and 0·0008 equiv. excess of sodium. These amounts of alkali and water are allowed for in recording the composition of the solution. All solutions were made with boiled-out conductivity water (1×10^{-6}) in Jena glass flasks. In experiments involving excess of fatty acid or alkali, palmitic acid ("Kahlbaum") or drippings from sodium, free from carbon dioxide, were used, respectively. The salts used were Kahlbaum's "for analysis," dried at 120—130°. Sodium carbonate was heated to bright redness in a platinum crucible for 3 hours. In each case it was found that the salts were insoluble in xylene. All solutions were made up by weight, and concentrations are expressed in weight normality (equivs. per 1000 g. of solvent, water, or xylene). About 7 c.c. of soap solution were used in each experiment. In all cases the temperature was 90° ±0·1°.

Results.

Proof that True Equilibrium is attained.—In order to attach significance to the results, it is necessary to demonstrate that true reversible equilibrium is attained between the two phases. This is conclusively shown by the experiments in Table I, in which identical results were obtained from two series of experiments approaching equilibrium from opposite sides. In the first series, a $0{\cdot}0774N_w$-solution of sodium palmitate was shaken with an approximately equal quantity of pure xylene. In the second series, a $0{\cdot}0774N_w$-solution of sodium hydroxide was shaken with an equivalent quantity of palmitic acid dissolved in xylene. In the first series, after equilibrium had been attained, 17·1% of the total palmitate radical in the system was present in the xylene layer as

palmitic acid. In the second series, 17·3% of the original palmitic acid was finally left in the xylene layer, the remainder having gone into the aqueous layer to react with sodium hydroxide. Thus for the first time it is shown that true equilibrium can be attained in suitably planned experiments on the extraction of soaps.

* Specimen A.

‡ HP = palmitic acid.

† The numbers recorded do not include the hydrolysis alkalinity due to the soap, but only the excess of sodium hydroxide left in the soap solution corresponding with the palmitic acid extracted. The total final alkalinity is not the sum of the original and that shown, because some of the acid extracted comes from acid soap.

§ A saturated solution would be 2·93N_w-palmitic acid.

In order to determine the effects of varying the concentration of soap and the amounts of the aqueous and xylene layers, data are given in Table II for the proportion of the total palmitate radical present in the system which is finally found as palmitic acid in the xylene layer when neutral soap solutions are shaken with xylene.

In all the foregoing experiments the soap solution is robbed of part of its palmitic content by the xylene. Hence the experiments in Table III were carried out by adding excess of palmitic acid to the original xylene, various concentrations being tried until palmitic acid was neither given up to nor extracted from the soap solution. This not only yields the concentration of palmitic acid that is in equilibrium with the unaltered soap solution, but it also affords conclusive proof that true reversible equilibrium was attained in these experiments. The results are plotted in Fig. 1.

Increased experimental difficulties are encountered when the concentration of palmitic acid in xylene exceeds 0·25N_w, *i.e.*, 6%: it was difficult to effect complete evaporation of the xylene if the

* A saturated solution of palmitic acid would have been $2·93N_w$.

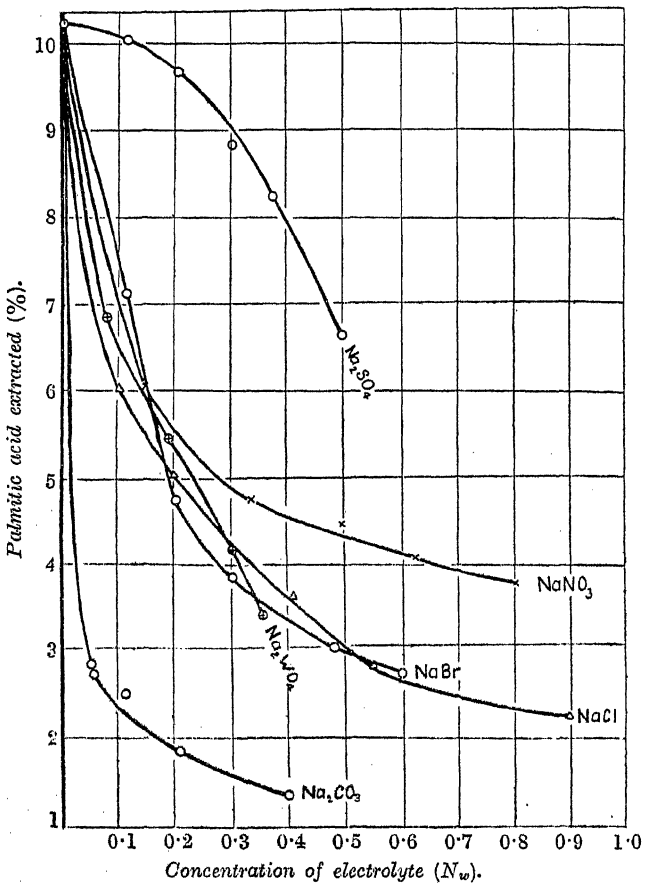
usual amount of solution was used; hence, the solutions were evaporated at 80° under 20 mm. Hg. There is also a strong tendency to emulsification when the xylene contains between 10% and 20% of palmitic acid, but this diminishes again at higher concentrations. The formation of acid soap is indicated by the soap layer becoming absolutely opaque. An experiment with 25% palmitic acid ($0·9545N_w$) is given in Table III and is also included in Fig. 1.

Effect of Electrolytes upon the Extractability.—Table IV and Fig. 2 record experiments in which various pure salts were dissolved in

the $0{\cdot}1N_w$-sodium palmitate solution at 90° before it was shaken with xylene. The salts increased the tendency to frothing, and as the concentration of salt required for salting into two aqueous layers was approached, emulsification became so prominent that the xylene layer finally could not be analysed. The salts made the

FIG. 1.

Hydrolysis equilibria in aqueous sodium palmitate containing excess or deficiency of either sodium hydroxide or palmitic acid. The curve for hydrolysis alkalinity is that obtained by McBain and Martin by the E.M.F. *method. The other curve shows the concentrations of palmitic acid in xylene when the xylene layer is in equilibrium with the soap solution of the final concentration indicated (one experimental point lies off the left of the diagram). Were the palmitate ion constant throughout, the concentrations of hydroxyl ion and of free palmitic acid in the aqueous phase would be inversely proportional to each other.*



originally clear soap solution cloudy. All the experiments were carried out with Specimen B of sodium palmitate.

Discussion and Interpretation of Results.

The outstanding result of these measurements is that there is scarcely any free fatty acid in a soap solution even when it is appreciably hydrolysed. There is practically quantitative conversion of the fatty acid formed into insoluble acid soap. For

example, a $0{\cdot}1N_w$-solution of exactly neutral sodium palmitate is in equilibrium with the xylene layer containing $0{\cdot}143N_w$-palmitic acid. The saturation concentration or solubility of palmitic acid in xylene is $2{\cdot}93N_w$; hence the xylene layer, and therefore likewise

FIG. 2.

The effect of the addition of salts to aqueous sodium palmitate at 90° upon the amounts of palmitic acid passing into the non-aqueous layer when the soap solution is shaken with an approximately equal volume of p*-xylene.*

the aqueous layer, is not more than 5% saturated with palmitic acid. McBain and Taylor (*loc. cit.*) found the solubility of the undissociated palmitic acid in water at 90° to be $0{\cdot}6 \times 10^{-5}N_w$, and therefore, if the distribution ratio between water and xylene is a constant, the concentration of free palmitic acid in the aqueous layer is only $3 \times 10^{-7}N_w$, whereas the hydroxyl-ion concentration

or hydrolysis alkalinity is $0{\cdot}0013N_w$, as found by several independent methods. Hence, all the palmitic acid representing the difference between these two numbers is removed from solution in the form of acid soap.

It is possible from the data of McBain and Taylor to predict

what concentration of palmitic acid should have been found in $0{\cdot}1N_w$-aqueous sodium palmitate at 90°. Taking the dissociation constant of palmitic acid as 1×10^{-5}, that of water as 33×10^{-14}, the concentration of simple palmitate ion in the solution as $0{\cdot}035N_w$, and the concentration of hydroxyl ion as $0{\cdot}0013N_w$, one can predict the concentration of palmitic acid as $9 \times 10^{-7}N_w$. The $3 \times 10^{-7}N_w$ was estimated above on the assumption that palmitic acid has the same solubility in pure water as it has in $0{\cdot}1N_w$-sodium palmitate saturated with xylene; this is probably not quite correct and may account for the small discrepancy.

The possible influence of salts upon the distribution coefficient, and still more upon the degree of insolubility of acid soap, constitutes the chief uncertainty in interpreting the results in Table IV and Fig. 2. It is clear that the addition of salts to the soap solution diminishes the extractability and probably the hydrolysis, although this should be checked by direct measurement of hydrolysis alkalinity. All these soap solutions were rendered alkaline by the abstraction of palmitic acid, those containing most salt being least affected and yet giving up least palmitic acid. The behaviour of all salts is very similar with the exception of sodium carbonate and sodium sulphate; the difference in the case of the former is clearly due to its alkalinity, but no explanation is forthcoming as to the peculiar shape of the curve for sodium sulphate unless the salt was slightly acid, which was not tested at the time. The effect of the various salts bears no relation to their effect upon salting out of soaps, to the Donnan equilibrium, or to the Hofmeister series, and shows no influence of valency, because all the salts replace each other mol. for mol. with the exception of the carbonate and sulphate. The effect is undoubtedly due to diminution in the concentration of simple palmitate ion (the substance that hydrolyses) and its replacement by colloid. The same explanation would account for the rapid fall in the % hydrolysis with increasing concentration of soap as is illustrated in Table II; 17% of the total palmitate in $0{\cdot}0774N_w$-solution was extracted by an equal amount of xylene, whereas from a solution of twice the concentration only 5% was extracted.

In conclusion, attention may be directed to the series of buffer reactions which occur within a soap solution and render its hydrolysis alkalinity less dependent upon extraneous additions than is usually the case with standard buffers. For example, large change of concentration of the soap, addition of acid or even of a small amount of alkali, and variation of the amount of any non-aqueous solvent with which the solution is shaken all effect only a small change in the concentration of hydroxyl ion. The hydrolysis is chiefly regulated by the insolubility of the acid soap, which is

greatest for the highest fatty acids and distinctly less for unsaturated fatty acids. Further experimental work is now in progress at Stanford University.

Summary.

1. Contrary to the opinions hitherto expressed by most writers, no soap solution contains more than the merest trace of uncombined fatty acid, and even that is completely dissolved, none being in the emulsified or free condition. Thus, in spite of the sparing solubility of the higher fatty acids, soap solutions are unsaturated with respect to them. This is conclusively proved by the fact that any non-aqueous solution brought into equilibrium with an aqueous soap solution is very far from being saturated with fatty acid, even when a large excess of the acid has originally been added to the system.

2. Practically all of the fatty acid corresponding to the hydrolysis alkalinity is locked up in combination as (insoluble) acid soap. Soap solutions are excellent buffers.

3. Electrolytes, even up to high concentrations, diminish the extractability, and probably the hydrolysis, of dissolved soap.

STANFORD UNIVERSITY, CALIFORNIA. [*Received, August 18th*, 1927.]

CCCLVII.—*The Effect of Electrolytes upon the Viscosity of Solutions of Sodium Palmitate.*

By JAMES WILLIAM MCBAIN, HERBERT JAMES WILLAVOYS, and HAROLD HEIGHINGTON.

MANY investigators have studied the viscosity of soap solutions and the effect of electrolytes thereon (Mayer, Schaeffer, and Terroine, *Compt. rend.*, 1908, **146**, 484; Bottazzi and Victoroff, *Atti R. Accad. Lincei*, 1910, (v), **19**, i, 659; Farrow, J., 1912, **101**, 354; Goldschmidt and Weissmann, *Z. Elektrochem.*, 1912, **18**, 380; *Koll. Z.*, 1913, **12**, 18; *Seifensieder Ztg.*, 1913, **40**, 263; Hatschek, *Koll. Z.*, 1913, **12**, 238; *Trans. Faraday Soc.*, 1913, **9**, 80; Kurzmann, *Koll.-Chem. Beih.*, 1914, **5**, 427; Arndt and Schiff, *ibid.*, 1914, **6**, 201; Goldschmidt, *Seifensieder Ztg.*, 1914, **41**, 337; Fischer and Hooker, *Chem. Eng.*, 1919, **27**, 223; Clarke, *Medd. K. Vetenskapsakad. Nobel-Inst.*, 1922, **6**, No. 1, 1; King, *J. Soc. Chem. Ind.*, 1922, **41**, 147T; Bircumshaw, J., 1923, **123**, 91; Prasad, *J. Physical Chem.*, 1924, **28**, 636; Freundlich and Schalek, *Z. physikal. Chem.*, 1924, **108**, 153; Freundlich and Kores, *Koll. Z.*, 1925, **36**, 241; Jajnik and Malik, *ibid.*, p. 322; Hahne, *Z. deut. Oel-Fett Ind.*, 1925, **45**,

245, 263, 274, 289, 308), but their work has always been broken off in the region where the viscosity was rising rapidly with increasing concentration of added salt. It remained for Miss A. M. King, in a communication from Bristol University (*J. Soc. Chem. Ind.*, 1922, **41**, 147T), to discover the remarkable fact that further addition of salt produces a sharp maximum of viscosity, which thereafter falls rapidly with still further addition. The last effect continues right up to the limit of possible existence of the soap solution as a single homogeneous phase. The present paper gives further information with regard to this effect (see, *e.g.*, Fig. 1).

Solutions of sodium palmitate at 80° and 90° were chosen for study because of the large amount of other information already available, and also because their properties are independent of time at these high temperatures.

Once again it is shown that, if sufficient care is taken to control the factors involved, even such a property as the viscosity of soap solution is definite and reproducible. For example, we have taken the viscosity of a solution $0{\cdot}5N_w$ with respect to both sodium chloride and sodium palmitate at 81·0° as a point of reference. Miss King published the values for its absolute viscosity in c.g.s. units, $\eta = 10{\cdot}63$ and 10·54; one of us (H. J. W.) obtained 10·07, another (H. H.) 10·06, and Mr. H. Horwood 10·39, all with different specimens of pure sodium palmitate. In other series of experiments, the viscosity of the original soap solution was first taken, then successive amounts of pure electrolyte were added, thus giving a range of viscosity readings up to the limit of existence of isotropic soap solutions. Thereupon, the final solution was diluted with successive portions of the original soap solution, retracing the curve, and yielding confirmatory values.

For details of the experimental method reference may be made to the communication cited. A Wenner stop-watch reading to 0·01 sec. was employed. Temperatures were read on standardised thermometers. The steel balls required were heated before being dropped through the tube in order to avoid solidification of the soap solution on them. All concentrations are expressed in weight normalities (N_w), *i.e.*, g.-mols. per 1000 g. of water.

The results were calculated according to the formula $\eta = K(s - D)T$, where K is the tube constant $\eta_1/(s - \sigma)T_1$, η is the viscosity of the soap solution in c.g.s. units, D its density, s the density of the steel ball, T and T_1 are the times of fall in soap solution and castor oil respectively, η_1 is the viscosity of castor oil = 16·46 c.g.s. units at 14·1°, and σ the density of castor oil = 0·963. The value of K depends upon the dimensions of the tubes and balls, and the values used are given in Table I.

TABLE I.

Calibration of the falling balls and tubes with castor oil (Kahlbaum).

Horwood	14·1°	0·316 cm.	7·595	6·0	0·4136
„	14·1	1/8 in.	7·720	6·2	0·3928
Heighington	14·1	1/8 in.	7·697	6·2	0·3943
Willavoys	15·7	0·163 cm.	7·554	29·32	0·0731

The results for 0·75, 1·0, and $1{\cdot}5N_w$-solutions of sodium palmitate with added sodium chloride are in Table II. The $1{\cdot}5N_w$-solutions are so viscous that for determining the density a specially wide pipette was employed, closed at the bottom with a flattened glass rod held in place by rubber tubing, and continued at the top with a small tube also held in place by rubber tubing so that when temperature equilibrium was attained this could be slipped off, leaving the pyknometer exactly filled with soap solution. Thereupon the tube was cooled and the contents were solidified for weighing.

Results for approximately $1{\cdot}5N_w$-sodium palmitate with added sodium carbonate or acetate at 81° are given in Table III.

Discussion.

The experimental results for added sodium chloride at 81° are shown in Fig. 1 and those for the acetate and carbonate in Fig. 2. The outstanding effect is that the addition of medium concentration of electrolyte enormously increases the viscosity of soap solution. Without salt, the viscosity is only a few centipoises, and it is increased 600—700-fold at the maxima by the addition of the salt. It may be recalled that with many soaps at lower temperatures the soap solutions in these intermediate concentrations of salt actually set to a jelly, but the effect there also passes through a maximum, and further addition of salt reliquefies the jelly.

The most striking feature of the curves is the existence of these sharp maxima at which the effect of salts is reversed, the viscosity with further increase of salt falling off as rapidly as it had risen. For example, in the curve for carbonate (Fig. 2) the highest viscosity measured was 102 poises, which fell on further addition of carbonate to 6 poises. With the most concentrated soap and sodium chloride, the fall is from 55 to 3 poises. The limited extent of the fall is, however, shown by the fact that when the soap solution contains all the salt that can be added without the formation of several layers, the viscosity is still 20—50 times higher than that of the original soap without salt.

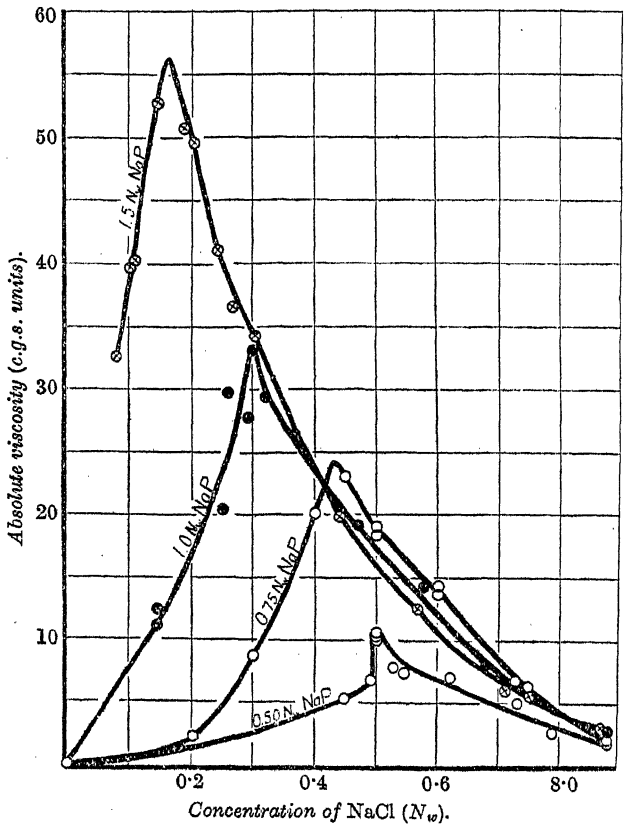
* Experiments by H. J. W.

The higher the concentration of soap, the less salt is required to produce the maximum viscosity, as the following tabulation shows :



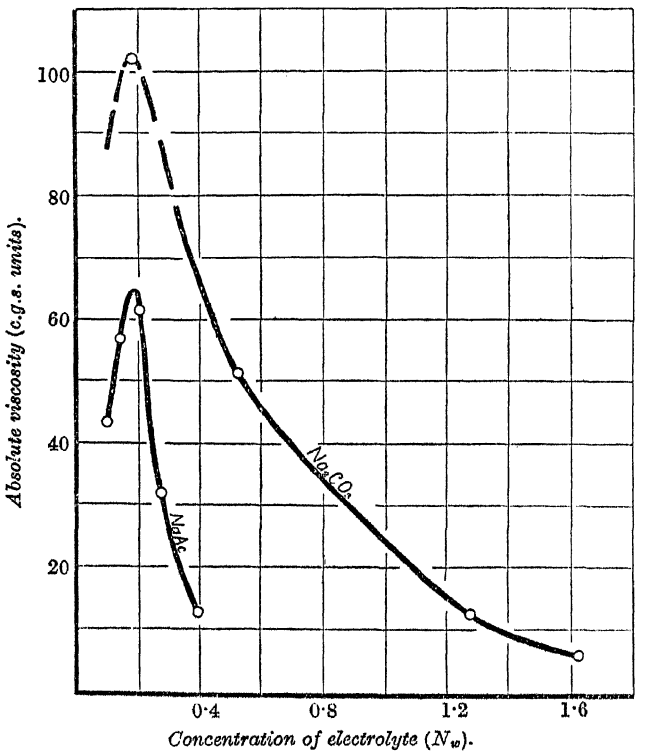
Conc. of soap (N_w)	0·5	0·75	1·0	1·5
Max. viscosity (poises)	10	24	33	56
Conc. (N_w) of salt at max. viscosity	0·50	0·43	0·30	0·16

The enormous increase in viscosity of a soap solution when moderate quantities of salt are added to it again shows the inadequacy of the emulsoid theory of colloids. In these strong soap solutions the soap is all in colloidal form already, before any salt is added. According to the emulsoid theory, addition of salt should shrink the globules of soap, and the viscosity should be diminished instead of being increased many hundred-fold. That the salt is less soluble in a soap-rich phase has been definitely proved by the numerous studies of phase-rule equilibria now available, and, indeed, by the experience of any soap boiler. This affords, therefore, yet another reason for replacing the emulsoid hypothesis by the view that the colloidal soap in solution is present in the form of solid particles or micelles.

Superficially, the curves look like any of Loeb's for the Donnan equilibrium. However, they differ in two respects. In the first place, Loeb's experiments never involved more than a five-fold increase in viscosity, whereas these involve increases of a higher order of magnitude. In the second place, Loeb's maxima arose from the fact that he was adding an acid or an alkali to an amphoteric colloid and producing colloidal electrolyte with high conductivity, osmotic activity, etc., whereas here, salts are being added and should have a uniformly depressing action on the viscosity, as was indeed observed by Loeb for salts when added to the systems he studied.

The problem then is to explain why fully formed colloid may have its viscosity increased many hundred-fold through the addition of salt. The only possible explanation seems to be the general hypothesis advanced by one of us (McBain, *J. Physical Chem.*, 1926, **30**, 239), that the viscosity of a reversible colloid, such as nitro-

FIG. 1.



The viscosity of solutions of sodium palmitate at 81° *as affected by addition of sodium chloride up to the maximum amount which can be added without salting out the solution into two layers.*

cotton, soap, rubber, or protein, is not to be accounted for by the individual particles (micelles) either through their number or individual bulk, but that it is due to their loose aggregation into structures which effectively enmesh large tracts of the solvent or solution.

Hatschek (*J. Physical Chem.*, 1927, **31**, 353) has recently published a communication which is ostensibly an attack upon McBain's

general hypothesis of aggregation, but which is really an adoption and endorsement of one particular form of the general hypothesis, being a modification of that of Loeb. In general, there is a great variety of possible forms of aggregation. For example, if all the particles were to be joined end to end to form innumerable filaments, the medium in which they lay could be so effectively enmeshed as to

FIG. 2.

The viscosity of solutions of $1{\cdot}5N_w$*-sodium palmitate at* 81° *over the whole range of existence of isotropic solution in the presence of sodium acetate and sodium carbonate, respectively.*

have the properties of a jelly. Another form of loose ramifying aggregation is that of a pile of brushwood, or again seaweed in a rock pool. Hatschek would prefer to specify only one kind of ramifying aggregate like a lot of separate bushes not entangled but separate from each other, so that each aggregate could be treated approximately as a polyhedron, or even as a sphere. To call this loose ramifying aggregate the micelle is to introduce fresh confusion into the subject. We should prefer to retain the general hypothesis,

which includes Hatschek's as one possibility. We use the term micelle to indicate each of the single ultimate particles of colloid.

Attention may be directed to another influence which greatly enhances the effect of the presence of either particles or ramifying aggregates in their influence upon the apparent viscosity of the system. Hatschek has demonstrated that even in a suspension in which aggregation does not occur and in which hydration in the chemical sense is absent, the system does not show a true viscosity coefficient like a pure liquid, but the viscosity coefficient obtained is a function of the rate of shear. He has been at a loss to account for this effect, and similarly Porter and Rao (*Trans. Faraday Soc.*, 1927, **23**, 311) were unable to offer an explanation, but made a purely empirical attempt to obtain an equation to fit the results. As part of a general theorem relating to the structure of surfaces, one of us (J. W. McB.) and G. P. Davies (Address to the Mid-West Regional Meeting of the American Chemical Society, Madison, June, 1926; *J. Amer. Chem. Soc.*, 1927, **49**, 2230) have shown that this effect is a necessary result. On the basis of accurate absolute measurements on the amount of adsorption, now available for the first time, and of a survey of the results obtained in such fields as that of adhesives, etc., the authors concluded that any surface possesses considerable depth due to chains of oriented molecules extending inwards from points on the outer unimolecular layer. The effective length of these chains is conditioned by thermo-vibration and, of course, by rate of shear, the latter accounting for the results obtained by Hatschek and Porter. Hence a liquid in the neighbourhood of surfaces such as those of particles, filaments, or ramifying aggregates is semi-rigid, enhancing greatly the effectiveness of the aggregates in immobilising liquids, and producing a high apparent viscosity.

According to previous studies of soap, it is the neutral micelle, and not the ionic micelle, that has the power of forming ramifying aggregates. Salt does promote the formation of neutral micelles at the expense of ionic micelles, but this effect is too unimportant for our present purpose. We should ascribe the aggregation of the neutral micelles to partial dehydration on the addition of salt owing to the lowering of the vapour pressure of the solution. This is the first main factor involved in the action of salts upon soap solutions.

The maximum and the subsequent lowering of viscosity have still to be explained, and any explanation has to be sufficiently general to account for the salting out and phase-rule equilibria of soap, together with the formation of liquid crystals. We would seek this in a combination of the principles of dehydration through lowering

of vapour pressure (as above), of orientation of like molecules when held sufficiently close together, and of the principle underlying the Donnan equilibrium. The dehydration facilitates aggregation by exposing unsaturated valence bonds (compare McBain, *J. Physical Chem.*, *loc. cit.*), thus tending to make the aggregates denser and less voluminous. The principle of constancy of ionic product, as exemplified by solubility of precipitates, utilised by Donnan and generalised by Wilson, must now be made use of to explain further the effect of salts upon the charges and the volumes within the colloidal aggregates.

Almost all surfaces, even those of the neutral micelles, show slight electrical charges (see Laing, *J. Physical Chem.*, 1924, **28**, 673). Particles of like charge tend to repel each other, probably not merely through direct electrostatic repulsion (the usual belief), but also through the excess osmotic pressure set up in the neighbourhood of all charges through the Donnan equilibrium. The effect of large excess of salt is two-fold: first, to reduce these charges, and, secondly, to minimise their effect upon the Donnan osmotic pressure in their neighbourhood. These two influences contribute to the collapse, or rather the closer packing, of the structures built up from the micelles, thus reinforcing the effect of increased intensity of aggregation. This releases a part of the liquid, or better, less of it is immobilised, and hence the apparent viscosity falls. This would appear to explain the decline in viscosity that occurs in more concentrated solutions of salts, whilst still leaving the viscosity higher than that of the original soap solution. This explanation embraces that given by Laing and McBain (J., 1920, **117**, 1507) for the formation of true soap jellies which occur in the middle of the isotropic region and are liquefied by excess of added salt. It should be noted that the curves in Fig. 1 cover practically the whole field of the possible existence of isotropic solutions of sodium palmitate (compare McBain and Langdon, *loc. cit.*). Throughout, the chief factor involved in apparent viscosity of colloids is the extent to which the solution or solvent is immobilised through entanglement in colloidal structures.

When aggregation, brought about through dehydration and segregation as detailed above, becomes extreme, and the micelles are therefore more tightly packed in clumps, the tendency towards orientation must strongly assert itself (orientation of molecules accounts for the existence of micelles in the first place). Excess of salt always produces neat soap and lye, the latter being an ordinary salt solution containing most of the salt and scarcely any soap; the neat soap is liquid crystal. The common feature of all present hypotheses regarding the structure of liquid crystals is that they are

full of tracts in which molecules or micelles are in an approximately parallel arrangement.

Whilst the above description appears to afford a reasonable explanation of the phenomena here discussed, searching tests are required to afford independent proof of the truth of each of the mechanisms involved. Again, far too little is known with regard to the structure of liquid crystals. Indeed, soap solutions afford the only examples of liquid crystals readily accessible for experimental study. The position of middle soap has still to receive adequate explanation. If a soap solution containing no added salt is sufficiently concentrated, middle soap separates as a new phase, and, within a certain range of concentration, soap solutions consist only of this form. Middle soap is a colloidal electrolyte, just like the isotropic solutions it has replaced. A small amount of salt may be added to middle soap, but it is destroyed by further salt, being replaced by isotropic soap solution. This is the significance of the curves for $1{\cdot}5N_w$-sodium palmitate in Figs. 1 and 2, which necessarily have their beginning as shown in the diagrams in the presence of the necessary minimum of salt. The pure $1{\cdot}5N_w$-sodium palmitate is middle soap; it turns into isotropic soap solution upon the addition of the requisite amount of salt, and the viscosity shortly thereafter passes through a maximum as shown in the diagrams. It throws a severe strain upon our explanation (detailed above) to account for these phenomena, because they ended in the production of liquid crystal through excess of salt, with the elimination as a separate phase of most of the water and salt, whereas here the $1{\cdot}5N_w$-sodium palmitate begins as liquid crystal, although retaining all the water with it in one homogeneous phase.

The existence of middle soap as liquid crystal is quite evidently due to mere contiguity of the particles on account of the very high concentration of soap. We have to suppose that this orientation is almost tantamount to coalescence, because no negative ions, other than a trace of hydroxyl ion (and of course the ionic micelles), are present to keep the particles apart. Addition of a small amount of salt supplies this defect, and the tracts of parallel orientation are disbanded with the formation of isotropic solution, although the apparent viscosity is already extremely high and aggregation or linkage is already at an advanced stage. Thereafter, but little salt is required to produce the maximum and the other specified effects.

Comparison of the effects due to the three salts is interesting, but in view of the explanations above it cannot be expected to be of direct significance. The two univalent salts, chloride and acetate, are fairly similar in the position and value of the maximum viscosity,

that for sodium acetate being slightly higher and requiring rather more acetate, sodium acetate being a weaker electrolyte than sodium chloride. The bivalent sodium carbonate gives twice as high a maximum viscosity as the chloride and twice as much of it is required for salting out the palmitate into two layers. However, the acetate is exceptionally effective in salting out, $0{\cdot}57N_w$ being sufficient as compared with $0{\cdot}88N_w$ for the chloride and $1{\cdot}7N_w$ for the carbonate. McBain and Pitter (J., 1926, 893), in comparing a large number of salts, pointed out that apparently the single factor most effective in salting out is the concentration of the sodium ion. We suspect that the high viscosity in the presence of the carbonate may be due to its alkalinity, because we have found with various other samples of sodium palmitate that a slight excess of alkalinity very greatly increases the viscosity. Thus, if the sodium palmitate contains about one equiv. per cent. excess of sodium hydroxide, all the maxima of viscosity are roughly 1·7 times greater.

The futility of attempting to apply any of the usual empirical formulæ to our results is evident from the shape of the curves and also from the fact that the right-hand descending portions of the viscosity curves approximately coincide, *i.e.*, the viscosities are there nearly independent of the amount of soap present.

All the work here described was carried out at the University of Bristol.

Summary.

1. The viscosity of solutions of sodium palmitate has been studied over most of the range of existence of isotropic soap solutions in the presence of sodium chloride, acetate, and carbonate.

2. Addition of electrolytes increases the viscosity to a maximum value many hundred times greater than that of the original soap solution. Further salt decreases the viscosity almost equally rapidly until the salting out concentration is reached.

3. The results are discussed on the basis of the general explanation put forward by McBain for the high apparent viscosity of reversible sols and jellies. The rise in viscosity is in the opposite direction to that predicted by the Donnan equilibrium, and exceeds by a hundredfold the viscosity effects observed by Loeb, although the Donnan equilibrium may well be one of the factors involved.

STANFORD UNIVERSITY, CALIFORNIA. [*Received, August 18th*, 1927.]

CCCLVIII.—*The Composition of Bleaching Powder. Part I.*

By EDMUND ARTHUR O'CONNOR.

THE exact composition of the substances contained in bleaching powder has long been a subject for discussion (see Lunge, "Sulphuric Acid and Alkali," 3rd edn., III, pp. 577—587; Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," II, pp. 262—265), which has centred chiefly around the question of the existence of a definite compound of calcium hypochlorite and calcium chloride in equimolecular proportion, to which was usually assigned the constitution CaCl·OCl. Basic compounds containing hypochlorite and chloride have also been postulated by several authors. Lunge (*op. cit.*, p. 585) expressed the following opinion: "It is certain that no calcium chloride is present as such in ordinary bleaching powder." Similar views were held by O'Shea (J., 1883, **43**, 410) and by Orton and Jones (J., 1909, **95**, 751).

A study of the literature led to the conclusion that there is no positive evidence for the existence of a compound of calcium hypochlorite and chloride. Such a compound has never been isolated, and the evaporation at low temperature of solutions obtained by extraction of bleaching powder with water led to a separation of crystals of hydrated calcium hypochlorite, reported as $Ca(ClO)_2,4H_2O$ (Kingzett, J., 1875, **28**, 404; Orton and Jones, *loc. cit.*). At the same time, Orton and Jones obtained three crystalline preparations, containing calcium hypochlorite and chloride together with calcium oxide and water, which on analysis yielded a molecular ratio of hypochlorite to chloride of 1 : 1. These substances, which could not be recrystallised from water, were only approximately analysed, owing to the small quantities available and to the difficulty of complete separation from mother-liquor. There is, therefore, no certainty that any of them was a single definite compound, although it appears likely that one or more basic double salts may exist.

The preparation of calcium hypochlorite comparatively free from calcium chloride, and in some cases free from calcium oxide, has been exploited in recent years by the Chemische Fabrik Griesheim-Elektron (B.PP. 17859, 182927, 188662; D.R.-PP. 188524, 195896, 282746). Calcium hypochlorite, prepared by chlorinating a paste of calcium hydroxide and water and removing as much as possible of the mother-liquor, is stated to be a very stable compound when thoroughly dry, and superior in this respect, as well as in available chlorine, to the best ordinary bleaching powder. Basic compounds

containing 1—4 mols. of calcium hydroxide to one of hypochlorite, prepared by a similar process, are claimed to have the same advantages. Two of these compounds, $Ca(ClO)_2,2CaO,2H_2O$ and $Ca(ClO)_2,4CaO,4H_2O$, were isolated, but not in crystalline condition.

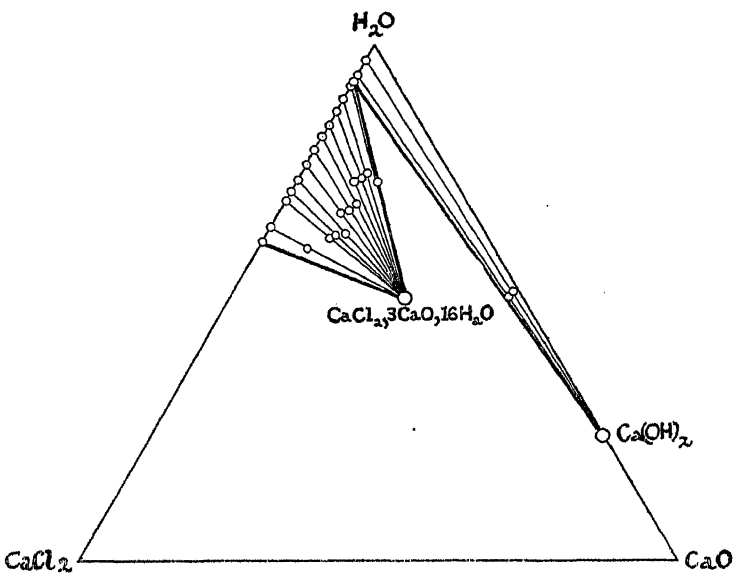
The problem of the exact nature and proportions of the substances composing any particular sample of bleaching powder cannot be expected to be capable of solution, for there is no certainty that equilibrium has been established. The equilibrium composition of a bleaching powder giving any particular ultimate analysis (neglecting formation of chlorate) could be determined if data for equilibria in the quaternary system $Ca(ClO)_2$–$CaCl_2$–CaO–H_2O at the same temperature were available. Consequently, it was decided to attempt at a suitable temperature a preliminary investigation of the three ternary systems in which water is a component.

Solutions of hypochlorites decompose rapidly at the ordinary temperature only in the presence of hypochlorous acid, and if this be removed by addition of a slight excess of alkali, the solutions are comparatively stable, forming chloride and chlorate and evolving oxygen very slowly (Foerster and Jorre, *J. pr. Chem.*, 1899, **59**, 53; Foerster, *ibid.*, 1901, **63**, 141). Solutions of calcium hypochlorite which can contain only small concentrations of free hydroxide rapidly increase in stability as the temperature falls, partly because of the usual diminution of reaction rate and partly because less hypochlorous acid is formed by hydrolysis. The whole of the experimental work was therefore carried out at 0°, and in the system $Ca(ClO)_2$–$CaCl_2$–H_2O a minute amount of calcium hydroxide was allowed to be present in the solutions.

Experimental.

A. *Analytical Methods.*—Hypochlorite was estimated by the usual iodometric method, and chloride by the Volhard process if hypochlorite was absent. In the presence of hypochlorite, chloride was estimated by first determining the former, and then finding the total chloride present after the hypochlorite had been reduced by neutral hydrogen peroxide. The same method of reduction was employed when it was necessary to estimate hydroxide in the presence of hypochlorite. The accuracy of these methods was checked by a determination of total calcium by the oxalate–permanganate process in a few control experiments.

B. *The Preparation and Properties of Calcium Hypochlorite.*—The following procedure, based upon the process of the Chemische Fabrik Griesheim-Elektron (*loc. cit.*), was adopted. About 224 g. (4 g.-mols.) of calcium oxide, prepared by ignition of the pure



precipitated carbonate, were treated with 650 c.c. of water, whereby a thin paste resulted, quite free from lumps. The cooled paste was introduced into a cylindrical gas-jar provided with a rubber stopper with holes for an inlet tube and a stirrer. The inlet tube reached well down into the jar, and the stirrer, which was of anchor-shape, was made long and wide enough to agitate the whole contents of the cylinder when rotated rapidly by a motor. Chlorine, washed with water, was supplied from a small battery of diaphragm cells, with hydrochloric acid as electrolyte, at an initial rate of about 105 g. per hour. The temperature was allowed to rise to about 40°, external cooling being used when necessary. Under these conditions, there was no visible indication of basic salts, the calcium hydroxide progressively disappearing. After about 70% of the theoretical quantity of chlorine had been admitted, a sudden separation of calcium hypochlorite occurred, and the contents of the flask became pasty once more. The temperature was then reduced to about 25°, and more chlorine was passed in at one-third of the above rate, until from 90% to 95% of the theoretical quantity had been supplied. (After the separation of calcium hypochlorite, chlorine is not absorbed so readily, and a more rapid stream of the gas is partly wasted.) It was not found practicable to chlorinate beyond the limit given, as any further quantity of chlorine caused the complete loss of the preparation by production of free hypochlorous acid.

The paste containing calcium hypochlorite was collected in a Buchner funnel on asbestos-paper, since ordinary filter-paper was rapidly destroyed. The filtration was somewhat slow, but when the characteristically soft mass was covered with asbestos-paper and well pressed, a fair separation from mother-liquor was effected. Comparatively little hypochlorite remained in solution. Further separation of mother-liquor was brought about by pressing the cake of hypochlorite between very thick plates of porous earthenware, specially made for the purpose. After a few hours, the apparently dry substance was desiccated in a vacuum over caustic soda. It formed pale greenish-yellow, almost odourless, apparently non-crystalline lumps, which developed a strong smell of hypochlorous acid on exposure to air.

Pure calcium hypochlorite was prepared by making a saturated solution of the crude product in water and filtering off the insoluble residue of calcium hydroxide or basic salt. The solution was evaporated under the diminished pressure afforded by a water-pump. Concentration progressed until the liquid was considerably supersaturated, and short, needle-shaped crystals finally appeared, at first slowly, then more rapidly. At this stage it was found best

to stop the evaporation, and allow the crystals to be produced without agitation. A more granular product, easily filtered and dried as described above, then resulted. A repetition of the process yielded calcium hypochlorite free from chloride, and therefore free from chlorate. About ½% of calcium hydroxide (or an equivalent quantity of basic salt) was present, rendering unfiltered solutions slightly turbid. Analysis of the final product gave results for hypochlorite and total chlorine which agreed with one another within the limits of experimental error. When thoroughly desiccated, calcium hypochlorite shows no appreciable decomposition

FIG. 1.

after several days, if kept out of contact with air. Concentrated aqueous solutions are greenish-yellow, and decompose at 25—35° at the rate of about 1% per day, evolving a very slow stream of oxygen in minute bubbles. At 0°, there is no decomposition or evolution of oxygen during the period of the experiments.

C. *The System* $CaCl_2$–CaO–H_2O.—This system has already been examined at 10°, 25°, 40°, 48°, and 50° (Milikan, *Z. physikal. Chem.*, 1917, 92, 59), basic compounds $CaCl_2,3CaO,16H_2O$; $CaCl_2,CaO,2H_2O$; and $CaCl_2,CaO.5(?4)H_2O$ being reported. The third was obtained only at 48° and 50°, whilst the range of existence of the first increases and that of the second diminishes as the temperature falls. The results (Table I and Fig. 1) obtained at 0° show that $CaCl_2,3CaO,16H_2O$

is the only basic salt obtainable at that temperature It forms well-defined, transparent, needle-shaped crystals, which may attain a length of several mm. if the mother-liquor does not contain too much calcium chloride.

Suitable complexes were rotated in a thermostat for about 24 hours, which was found to be a sufficient time for establishment of equilibrium, and the composition of the solid phases was deduced by the residue method. The separation of residues from solutions was achieved in the following manner. The disc of a Gooch crucible was placed in the bottom of a small cylindrical funnel and covered with a pad of asbestos well pressed down, which was then thoroughly dried. The funnel was stoppered loosely, fitted to the neck of a filter-flask connected to the water pump, and immersed in the ice and water of the thermostat, only the top projecting. The filtration could then be carried out at 0°, no matter how slowly the solution drained through the asbestos pad. The same process was adopted in the examination of the two systems about to be described.

D. *The System* $Ca(ClO)_2$–$CaCl_2$–H_2O.—The investigation of this system presented no special difficulty. When calcium hypochlorite was intended to be present as solid phase, it was added in excess to suitable solutions of calcium chloride. It was necessary to have these solutions, particularly when concentrated, free from calcium hydroxide, otherwise the hydroxide, always present in small amount in solid calcium hypochlorite, was converted into basic chloride, and did not pass entirely into solution. A corresponding error in the composition of the residues, which became slightly too rich in calcium chloride, was then produced.

The experimental figures, reproduced in Table II and Fig. 2,

show definitely that no compound of calcium hypochlorite and calcium chloride can be formed in aqueous solution at 0°, and that the composition of the hydrate of the former salt is $Ca(ClO)_2,3H_2O$, and not $Ca(ClO)_2,4H_2O$ as reported by Kingzett and by Orton and Jones (*loc. cit.*). The solubility of this hydrate in water at 0° is 21·8%.

E. *The System* $Ca(ClO)_2$–CaO–H_2O.—An extended series of measurements was undertaken, the procedure being in all cases

to add solid calcium hypochlorite to milk of lime, and to agitate the resulting complexes for periods varying from 1 to 5 days before analysis. In order to avoid the presence of lumps, freshly burned calcium oxide was slaked in boiling water. Since accurate adjustment of the inital compositions of the complexes was sometimes necessary, the percentage of anhydrous substance in the calcium hypochlorite was determined immediately before use. Two basic salts were found (see Table III and Fig. 3) of formulæ $Ca(ClO)_2,2CaO,2H_2O$ and $Ca(ClO)_2,3CaO,3H_2O$. These are referred to as B 1.2.2 and B 1.3.3, respectively.

FIG. 3.

The salt B 1.2.2 was formed in a few hours from complexes containing from 21·8% to about 16% of calcium hypochlorite, but subsequent investigation showed that its range of stable existence at 0° extends only from 21·8% to 18·0%. Prepared as described above, it was rather voluminous and not visibly crystalline. In consequence, residues containing B 1.2.2 consisted chiefly of solution, although an apparently good filtration had been achieved. Nevertheless, the residue method was quite capable of giving the composition of the solid phase with certainty. The range of stable existence of B 1.2.2 is probably greater above 0°, as it was observed that preparations of B 1.3.3 decomposed on being allowed to warm to room temperature, producing minute crystals. When the rise

* Metastable equilibria.

of temperature was slow, these were larger, taking the form of thin plates, 1—2 mm. in diameter, of great transparency and high lustre, entirely free from the greenish-yellow tint of the normal hypochlorite. They were transformed once more into B 1.3.3 on cooling to 0°. An excellent separation of residue from solution was possible, and the subsequent analyses proved conclusively that the crystalline substance was B 1.2.2.

The compound B 1.3.3 was formed after a few hours when calcium hydroxide was agitated at 0° with a solution containing not less than 15% of hypochlorite. It is definitely different in appearance from B 1.2.2, excessively voluminous, and not visibly crystalline. In consequence, the compositions of solutions and corresponding residues were quite close together. A complex consisting of 50 c.c. of the above solution with about 1 g. of calcium hydroxide became of the consistency of cream, and larger amounts of calcium hydroxide produced a semi-solid mass—a fact which suggests that the basic salt may be highly hydrated; but all the evidence (see Fig. 3) is against this supposition. Over a range of solutions containing from 18·0% to 9·9% of calcium hypochlorite, the tie-lines converge fairly well upon the point representing B 1.3.3. They converge better on a point slightly to the right of this along a line joining the points representing B 1.3.3 and calcium hydroxide. This would indicate a basic salt of approximate composition B 2.7.7,

but the discrepancy may be due to experimental error or to the peculiarities of the system itself.

Introduction of a suspension of B 1.3.3. into preparations in which B 1.2.2 had been formed as solid phase revealed the metastable existence of the latter in contact with solutions containing from 18·0% to about 16% of hypochlorite, the change of solid phase occurring after a few hours' rotation. Owing to the relatively small quantities of calcium hydroxide which could be used, and the correspondingly small amounts of hypochlorite taken up in forming B 1.2.2 or B 1.3.3, it was not easy to obtain a residue containing both basic salts. This was finally produced by inoculating with B 1.3.3 a series of preparations which differed only very slightly from one another in initial composition, and in which B 1.2.2 had already been formed. The difference in appearance of the two basic salts confirmed the analytical results.

The equilibrium of B 1.3.3 and calcium hydroxide with solution could not be determined satisfactorily in spite of many attempts. The separation of B 1.3.3 did not always occur spontaneously when calcium hydroxide was agitated with solutions containing less than about 14% of calcium hypochlorite. Inoculation from another preparation caused it to separate, less and less readily, however, as the concentration of the solution fell. Below a concentration of 10% the appearance of the suspended solid and of the residues was entirely that of calcium hydroxide, even after inoculation and subsequent rotation for several days, but analysis revealed a small proportion of hypochlorite in the solid phase. The best available approximation to the conditions of the equilibrium in question was obtained as follows. About 40 c.c. of a solution containing some 13% of calcium hypochlorite in contact with 2·5 g. of calcium hydroxide were seeded with B 1.3.3 and rotated for several days. A large quantity of B 1.3.3 separated, but, owing probably to its slow formation, did not make the preparation unmanageable. The solution contained 9·9% hypochlorite, and the residue was practically free from hydroxide. Similar treatment of preparations in which the initial concentrations of the solutions varied from 12% to 10% yielded final solutions more concentrated than the above and residues of B 1.3.3 and calcium hydroxide. Reproducible results could not be obtained, and after a number of experiments the figure 9·9% was taken as a provisional lower limit to the range of stable existence of B 1.3.3 in contact with solution.

The concentration of calcium hydroxide in the solutions was small and its variation smaller, furnishing no guide to the establishment of equilibrium. In some cases, it was not determined.

When agitated with solutions containing from 14% to 10% of calcium hypochlorite, calcium hydroxide took up varying small quantities of hypochlorite, which increased with both the concentration of the solution and the time of agitation. Below 10%, the quantity was negligible. The appearance of the solid phase and residues was that of calcium hydroxide. This effect points to adsorption, mixed crystal formation, or production of some basic salt in variable amounts; but no decision between these possibilities could be made. Some of the analytical results are included in Table III, marked with an asterisk to indicate that they represent metastable conditions. Only equilibria believed to be stable are shown in Fig. 3.

Of the basic salts reported by the Chemische Fabrik Griesheim-Elektron (*loc. cit.*), only two (B 1.2.2 and B 1.3.3) have been found to exist at 0° in contact with solutions containing hypochlorite and hydroxide. There is no definite evidence at this temperature of any other basic salt.

Conclusions.

Although equilibria in the appropriate quaternary system have not been investigated, it is possible to discuss at the present stage the probable composition of bleaching powder. A fresh sample, prepared by chlorinating nearly dry calcium hydroxide and containing about 35% of available chlorine, is roughly of the composition $2Ca(ClO)_2 + 2CaCl_2 + 3Ca(OH)_2 + 4H_2O$. No compound of calcium hypochlorite and chloride exists at 0°, and the same is probably true at higher temperatures, as indicated by the method given for the preparation of the former salt. If present separately, the hypochlorite and chloride cannot be wholly in the form of trihydrate and hexahydrate, respectively, because the amount of water present is too small. Lower degrees of hydration, at least of the calcium chloride, are possible. Further, in ordinary good bleaching powder, the proportion of calcium hydroxide is too small to convert completely either the hypochlorite or the chloride present into any of the known basic salts, except $CaCl_2,CaO,2H_2O$. The extent to which these substances are present in dry bleaching powder prepared in the usual way is necessarily problematical, and is further limited in the case of $CaCl_2,3CaO,16H_2O$ by the amount of water available. The equilibrium distribution of the water and calcium hydroxide present, and the possibility of formation of a basic double salt cannot be discussed on the basis of the data at present available, but it appears likely that, in a solid preparation, basic salt formation, if it occurs at all, would be slow, and that fresh bleaching powder is therefore simply a mixture of calcium hydroxide with more or less hydrated hypochlorite and chloride.

Summary.

1. A method was developed for the isolation of relatively pure calcium hypochlorite.

2. The ternary systems $CaCl_2$–CaO–H_2O, $Ca(ClO)_2$–$CaCl_2$–H_2O, and $Ca(ClO)_2$–CaO–H_2O have been investigated at 0°.

3. Basic salts $CaCl_2,3CaO,16H_2O$; $Ca(ClO)_2,CaO,2H_2O$; and $Ca(ClO)_2,3CaO,3H_2O$ were identified.

4. No double salt was formed by calcium hypochlorite and calcium chloride.

5. The probable composition of bleaching powder has been discussed in the light of these results.

It is proposed to extend this investigation, and to attempt the isolation of the hypochlorites of metals other than calcium.

THE UNIVERSITY OF QUEENSLAND,
BRISBANE. [*Received, June 22nd,* 1927.]

CCCLIX.—*Some Effects of the Uneven Distribution of Current Density over an Electrode.*

By ERNEST SYDNEY HEDGES.

IN the ordinary course of electrolysis, the current density is not evenly distributed over a rectangular electrode, but tends to concentrate at the corners and edges. (Possibly, this is related to the well-known tendency of an electric charge to escape from a point.) Thus, whenever film formation takes place at such an electrode, the film first forms at the lowest part of the electrode and travels up the metal in the form of a U of diminishing concavity. This is not due to a concentration gradient in the solution, for the phenomenon occurs however vigorously the liquid is stirred, and is independent of the direction of flow of liquid over the electrode. For the same reason, the inside of an anode (*i.e.*, the side facing the cathode) is more readily attacked than the outside. At a cathode, more metal is deposited on the inside than on the outer side, and the deposit is thicker at the corners and edges.

In experiments with the easily passivated metals, some curious effects were observed through this behaviour. Anodes of iron were often found to be passive on the inside and active on the outside, where no oxygen was evolved; or, at somewhat higher *C.D.*'s, the lower portion of the outside of the electrode became passive, leaving the upper portion active, with the characteristic U-shaped boundary of separation. In certain cases, a small active

area was left near the liquid line, where rapid corrosion took place (compare Evans, J., 1927, 1035; Hedges, J., 1926, 831). It may be necessary to consider this factor in the type of liquid-line corrosion which is characterised by the presence of passivating media. In other cases, the main electrode remained active, whilst just the corners and edges of the electrode became passive. The most striking effects were observed with anodes of cobalt, which readily become passive, with evolution of oxygen, in moderately concentrated solutions of sulphuric acid. In 50% (by vol.) sulphuric acid cobalt dissolves at low *C.D.*'s as a pink, cobaltous ion, but at higher *C.D.*'s it goes into solution as a green cobaltic compound. It was frequently observed that the inside of the electrode was dissolving to give a green solution, whilst the outside dissolved simultaneously to form a red solution.

An interesting conclusion may be drawn from these observations in connexion with Adler's theory (*Z. physikal. Chem.*, 1912, **80**, 385) of the cause of the periodic anodic dissolution of passive metals, according to which the periodic phenomenon is to be traced to alternations of polarity in local elements composing the electrode. In the experiments described above, periodic phenomena were observed, but they did not consist of an alternation of the active and passive regions. The phenomena did not differ in any respect from those observed at higher *C.D.*'s, when the whole surface of the electrode became alternately active and passive. Moreover, electrodes have been observed which, although clearly differentiated into active and passive zones, did not dissolve periodically.

CCCLX.—*The Sulphonation of Glyoxalines. Part III.*

By GEORGE REGINALD BARNES AND FRANK LEE PYMAN.

SULPHONATION of glyoxalines leads to a monosulphonic acid, which was assumed to be glyoxaline-4(5)-sulphonic acid (I) (Pyman and Ravald, J., 1920, **117**, 1429), but attempts to prove the orientation of the sulpho-group failed (Forsyth, Moore, and Pyman, J., 1924, **125**, 919). Recently, Balaban and King (this vol., p. 1858) have shown that 2-thiol-4(5)-methylglyoxaline can be oxidised to 4(5)-methylglyoxaline-2-sulphonic acid by means of hydrogen peroxide, and with the consent of these authors we have oxidised 2-thiolglyoxaline (II) to *glyoxaline-2-sulphonic acid* (III) by their method. It proves to be different from the sulphonation product of glyoxaline,

which is thus shown to be glyoxaline-4(5)-sulphonic acid, as previously supposed.

(I.) (II.) (III.)

4(5)-Methylglyoxaline has now been sulphonated, and yields a sulphonic acid which must be 4(5)-*methylglyoxaline*-5(4)-*sulphonic acid* (IV), since it is not identical with Balaban and King's 4(5)-methylglyoxaline-2-sulphonic acid (V).

(IV.) (V.)

It resembles glyoxaline-4(5)-sulphonic acid and 2-methylglyoxaline-4(5)-sulphonic acid in being readily decomposed by cold bromine water and in failing to yield an acid chloride on treatment with phosphorus pentachloride. Like glyoxaline-4(5)-sulphonic acid, it is hydrolysed almost quantitatively by heating for 3 hours at 170° with concentrated hydrochloric acid, but glyoxaline-2-sulphonic acid is hydrolysed only to the extent of 12% under these conditions. It may be noted that all the many sulphonation and nitration products of glyoxalines which have been oriented hitherto contain the sulpho- or nitro-group in the 4- or 5-position, and there is no evidence at present that glyoxalines can be sulphonated or nitrated in the 2-position.

Experimental.

Glyoxaline-2-sulphonic Acid (III).—2-Thiolglyoxaline (3·21 g.) was added to Merck's perhydrol (10·92 g.) diluted with water (21·8 c.c.) at — 5° to 0°. The solution was basified with sodium hydroxide, kept at 0° for 12 hours, and acidified to Congo-red with hydrochloric acid. When the solution was concentrated, *glyoxaline-2-sulphonic acid* (2·46 g.; yield 46·2%) separated. The mother-liquor was basified with potassium carbonate, evaporated to dryness, and extracted with alcohol. This extract gave with picric acid glyoxaline picrate (0·8 g.; yield 8·4%).

Glyoxaline-2-sulphonic acid crystallises from water in colourless prisms containing $1H_2O$, which is lost in a vacuum over sulphuric acid. The dried acid softens and darkens from 285° and melts at about 303° (corr.), whilst a mixture of this acid with the monosulphonic acid formed by the sulphonation of glyoxaline—glyoxaline-4(5)-sulphonic acid, m. p. 307°—melted at 272—275°. (The latter crystallises from water in anhydrous cubes; Pyman and Ravald, *loc. cit.*) (Found: loss in a vacuum over H_2SO_4, 11·0, 11·1.

$C_3H_4O_3N_2S,H_2O$ requires H_2O, 10·8%. Found in dried acid: C, 24·3; H, 3·1; S, 21·7. $C_3H_4O_3N_2S$ requires C, 24·2; H, 2·7; S, 21·6%).

Glyoxaline-2-sulphonic acid is soluble in about 8 parts of cold water, more readily soluble in hot water, but insoluble in absolute alcohol.

The *barium* salt crystallises from water in feathery needles containing $2H_2O$, and is soluble in about 3 parts of cold water, more readily soluble in hot water, but insoluble in alcohol [Found: loss at 120°, 7·2. $(C_3H_3O_3N_2S)_2Ba,2H_2O$ requires H_2O, 7·7%. Found in dried salt: Ba, 31·3, 31·4. $(C_3H_3O_3N_2S)_2Ba$ requires Ba, 31·8%]. [Barium glyoxaline-4(5)-sulphonate crystallises from water in anhydrous octahedra; Pyman and Ravald, *loc. cit.*].

Hydrolysis. Glyoxaline-2-sulphonic acid (0·83 g.) and concentrated hydrochloric acid (8·3 c.c.) were heated for 3 hours at 170°, and the product was mixed with aqueous barium chloride; barium sulphate was then precipitated in quantity (0·14 g.) corresponding to the hydrolysis of 12% of the acid. After removal of the excess of barium by means of sulphuric acid, and of hydrochloric acid by means of silver hydroxide, 0·45 g. (54%) of glyoxaline-2-sulphonic acid was recovered unchanged, whilst the mother-liquor gave with picric acid glyoxaline picrate (0·1 g.; yield 6·7%). This melted at 205°, and did not depress the m. p. of an authentic specimen of glyoxaline picrate.

Sulphonation of 4(5)-*Methylglyoxaline.*—The well-dried and finely powdered sulphate from 16·76 g. of 4(5)-methylglyoxaline was added to 60—70% oleum (67·0 g.) at 0°, and the mixture heated for 6 hours at 160°. The product was diluted with water, and sulphuric acid removed by means of barium hydroxide, excess of the latter being removed by carbon dioxide. The filtered solution was evaporated to dryness, and the residue was extracted with chloroform, which removed no unchanged base, and dried at 120°; 43·44 g. of crude barium salt containing 29·2% Ba were then obtained. These figures correspond to a yield of 90·5% of barium 4(5)-methylglyoxaline-5(4)-sulphonate, but when the salt was treated with the calculated quantity of sulphuric acid pure 4(5)-methylglyoxaline-5(4)-sulphonic acid was obtained in only 60% yield, and was accompanied by small quantities of a by-product more sparingly soluble in water, which was not obtained in a pure state.

4(5)-*Methylglyoxaline*-5(4)-*sulphonic acid* (IV) crystallises from water in colourless, hexagonal plates containing $1H_2O$, which is lost at 100°. The dried acid melts at 278° (corr.) after sintering a few degrees lower. A mixture of this acid with a specimen of 4(5)-methylglyoxaline-2-sulphonic acid (m. p. 280°), for which we

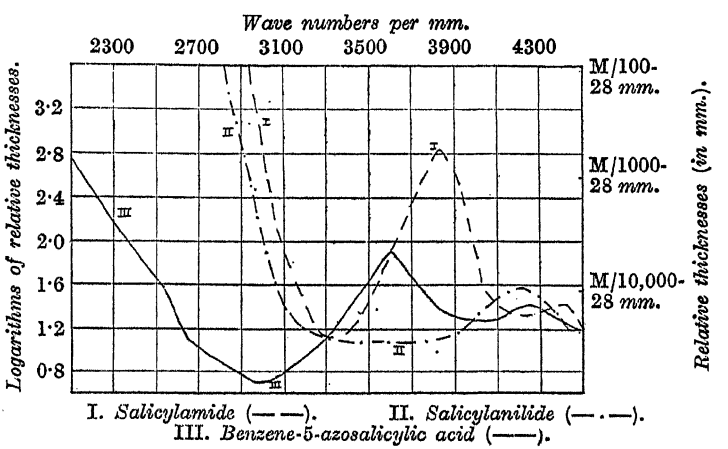
are indebted to Dr. King, melted at 235—240° (Found in air-dried acid: loss at 100°, 9·8, 10·0. $C_4H_6O_3N_2S,H_2O$ requires H_2O, 10·0%. Found in dried acid: C, 29·5; H, 4·1; N, 17·4; S, 20·2. $C_4H_6O_3N_2S$ requires C, 29·6; H, 3·7; N, 17·4; S, 19·8%). The acid is soluble in about 4 parts of cold water, more readily soluble in hot water, but insoluble in alcohol or ether.

The *sodium* salt crystallises from water in long, silky needles, containing $3H_2O$, and is soluble in about 2·5 parts of cold water, but insoluble in alcohol (Found in air-dried salt: H_2O, 21·7, 21·6; Na, 9·5, 9·6. $C_4H_5O_3N_2SNa,3H_2O$ requires H_2O, 22·7; Na, 9·7%). The *ammonium* salt crystallises from water in anhydrous prisms which are soluble in about 4 parts of cold water but insoluble in alcohol (Found: N, 23·3. $C_4H_9O_3N_2S$ requires N, 23·4%). The *barium* salt crystallises from 50% aqueous alcohol in long, opaque needles, containing $3H_2O$. It is soluble in 2 parts of cold water, but insoluble in alcohol [Found in air-dried salt: loss at 120°, 10·2, 10·4. $(C_4H_5O_3N_2S)_2Ba,3H_2O$ requires H_2O, 10·5%. Found in dried salt: Ba, 29·3, 29·5. $(C_4H_5O_3N_2S)_2Ba$ requires Ba, 29·8%].

Hydrolysis. 4(5)-Methylglyoxaline-5(4)-sulphonic acid (0·9 g.) was heated with concentrated hydrochloric acid (10 c.c.) for 3 hours at 170°. The product was mixed with aqueous barium chloride and gave 1·166 g. of barium sulphate corresponding to the hydrolysis of 99·8% of the acid. The filtrate was basified with sodium carbonate, filtered from barium carbonate, and evaporated to dryness. On extraction of the residue with chloroform an oil was obtained which gave with alcoholic picric acid 4(5)-methylglyoxaline picrate (0·89 g.; yield 57%; m. p. 159—160°, alone or mixed with an authentic specimen).

Bromination. To the hydrated sulphonic acid (9·62 g.) in cold water (100 c.c.), bromine (1 mol.; 2·7 c.c.) was added, and the colour of this was immediately discharged. On concentrating the solution and, on occasions, adding alcohol, various crops of crystals were obtained from which the unchanged acid (5·22 g.) and ammonium bromide (1·5 g.) were isolated. The final mother-liquor contained 1·03 g. of sulphuric acid.

Anhydrous 4(5)-methylglyoxaline-5(4)-sulphonic acid did not appear to react with phosphorus pentachloride at 160°.



MUNICIPAL COLLEGE OF TECHNOLOGY,
UNIVERSITY OF MANCHESTER. [*Received, October 5th*, 1927.]

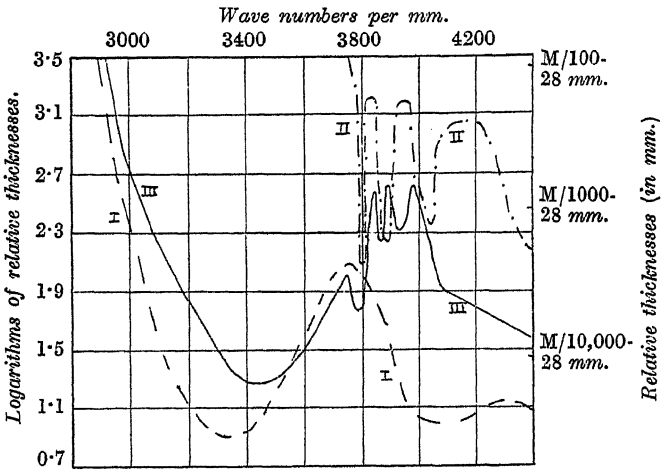
CCCLXI.—*The Absorption Spectra of Various Alkaloids and their Salicylates and of other Derivatives of Salicylic Acid.*

By JOHN EDWARD PURVIS.

IN previous communications (J., 1925, **127**, 2771; 1926, 775; this vol., p. 780), the author has discussed the influence of the basic and acidic constituents of various salts on their absorption spectra. This communication is to describe the results of further investigations on the spectra of various alkaloids and their salicylates, and of other compounds derived from salicylic acid. The substances were dissolved in pure ethyl alcohol and a condensed cadmium spark was the source of radiant energy.

FIG. 1.

I. *Salicylamide* (— —). II. *Salicylanilide* (— · —).
III. *Benzene-5-azosalicylic acid* (——).



Salicylamide (Fig. 1, I) shows two bands. They are not unlike those of salicylic acid, but the more refrangible one is not quite so well marked as that of the acid. Hartley and Hedley (J., 1907, **91**, 319) found that the bands of benzamide and benzoic acid were comparable, except that the benzamide band was not so wide as that of the acid.

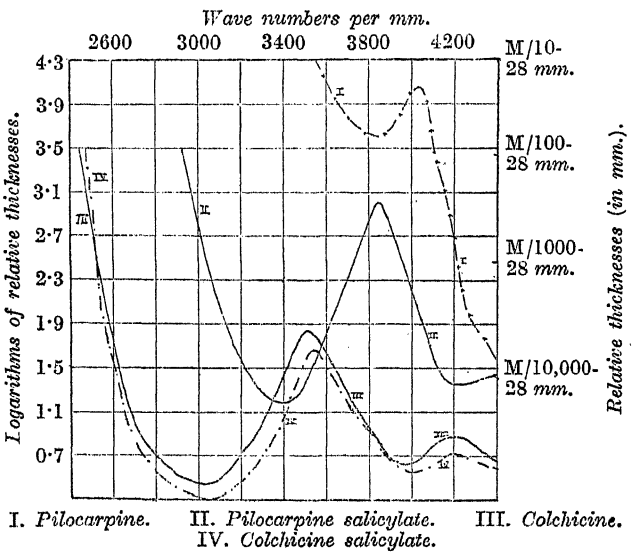
Salicylanilide has one large band (Fig. 1, II). Aniline itself has two large bands, namely, between $1/\lambda$ 3508 and $1/\lambda$ 3648 and between $1/\lambda$ 4165 and $1/\lambda$ 4309, as described by Hartley and Huntingdon (*Phil. Trans.*, 1879, **170**, 257) and by Baly and his colleagues (J., 1905, **87**, 1332; 1915, **107**, 1058). In salicylanilide, therefore, the two bands of aniline and the two bands of salicylic acid have been fused into one large band which covers the positions formerly

occupied by the bands of aniline and salicylic acid. These results are comparable with those obtained with benzanilide, where the bands of benzene and of aniline are replaced by one large band (Crymble, Stewart, Wright, and Glendinning, J., 1911, 99, 451).

Benzene-5-azosalicylic acid shows two bands (Fig. 1, III). The absorption of the less refrangible and very wide one extends into the coloured regions, the group $C_6H_5\cdot N{:}N\cdot$ probably accounting for the colour. The more refrangible band is weaker than the corresponding band of salicylic acid and almost disappears.

FIG. 2.

I. o-*Salicoyloxybenzoic acid* (— —). II. *Atropine* (— . —). III. *Atropine salicylate* (——).



o-*Salicoyloxybenzoic acid* (Fig. 2, I) shows two bands not unlike those of salicylic acid in their general form, but shifted more towards the red end. It has been noticed (*loc. cit.*) that when the hydrogen of the hydroxyl group of salicylic acid is replaced by an acetyl group, as in *o*-acetoxybenzoic acid and other similar compounds, a striking change is produced and the absorption phenomena are not unlike those of benzoic acid. In *o*-salicoyloxybenzoic acid there is no such change, so that the presence of hydrogen of the hydroxyl group of $OH\cdot C_6H_4\cdot CO\cdot$ combined with the other group $-O\cdot C_6H_4\cdot CO_2H$ to produce the acid $OH\cdot C_6H_4\cdot CO\cdot O\cdot C_6H_4\cdot CO_2H$ enables the compound to retain the characteristic absorption of salicylic acid itself.

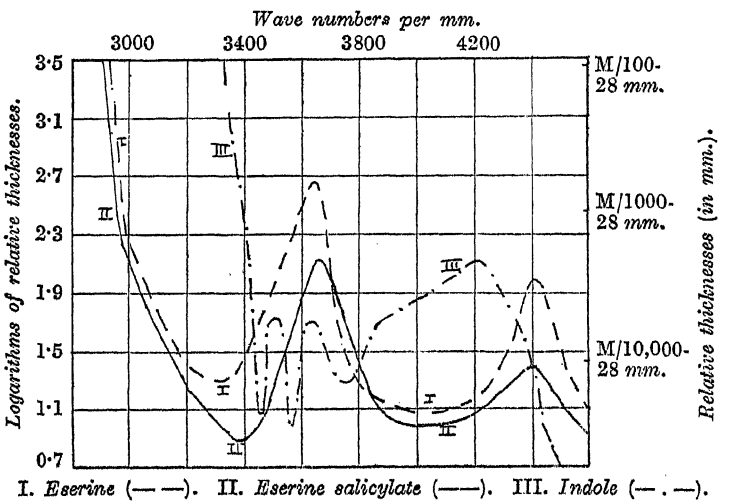
Atropine and Atropine Salicylate.—Dobbie and Fox (J., 1913, **103**, 1193) describe two bands of atropine at about $1/\lambda$ 3770 and $1/\lambda$ 3880. Gompel and Henri (*Compt. rend.*, 1913, **156**, 1541) found a third, weaker, band at $1/\lambda$ 4020. The author has repeated

these experiments and can confirm the presence of three bands (Fig. 2, II).

The curve of atropine salicylate (Fig. 2, III) exhibits a large band like that of salicylic acid, but not quite so strong. Besides that, there are three weak bands on the more refrangible side of this large band, and these are comparable with the three bands of atropine, but a little weaker. The more refrangible band of the acid is represented in the salt by a rapid extension of the rays between about $1/\lambda$ 4100 and $1/\lambda$ 4450. It is obvious, therefore, that the bands of both base and acid are still well marked in the

FIG. 3.

salt, the chief differences being the weaker appearances of the bands of the latter. A sharper differentiation of the separate bands of the basic and acidic parts of the salt could only be made by an instrument of much greater dispersion. This remark applies to the following observations of other alkaloids and their salts.



Pilocarpine and Pilocarpine Salicylate.—In Jowett's investigation of pilocarpine (J., 1903, **83**, 438), Dobbie describes a weak band of pilocarpine nitrate at about $1/\lambda$ 3350. The author has repeated the observations with an alcoholic solution of the base itself and finds a weak band at about $1/\lambda$ 3800 (Fig. 3, I).

Pilocarpine salicylate shows two bands of salicylic acid (Fig. 3, II). As the thickness of the solution increases, the less refrangible band of the salt appears to be slightly wider than that of the acid; and

this is probably caused by the latter impinging on the weak band of the base and covering it up; the absorptive power of the base only becomes visible as the thickness of the solution increases. A saturated solution of pilocarpine salicylate was also examined, but there was no appearance of a separate band of pilocarpine, showing that the bands of the acidic constituent covered up that of the basic part. The more refrangible band of the salt is not so well marked as that of the acid itself.

Colchicine and Colchicine Salicylate.—The curves show (Fig. 3, III and IV) that each substance has two bands. The less refrangible band of the salt is wider on the more refrangible side than that of

FIG. 4.

I. *Eserine* (— —). II. *Eserine salicylate* (——). III. *Indole* (— . —).

the base, and the more refrangible band of the base is stronger than the more refrangible one of the salt. These differences are probably again caused by the overlapping of the separate bands of the basic and acidic constituents. A greater dispersion would be necessary to separate these bands more sharply. The general shift of the absorption towards the red end explains the slight yellow colour of both these substances.

Eserine (Physostigmine) and Eserine Salicylate.—The absorption curves (Fig. 4, I and II) show that each substance has two large bands, and, as in colchicine and its salicylate, the differences are the result of the bands of the acid and basic constituents partly overlapping each other. It was suggested by Stedman and Barger and experimentally confirmed by Späth and Brunner (*Ber.*, 1925, **58**, 518) that physostigmine is a substituted indoline. The author

has investigated the absorption of indole and the curve is compared with that of eserine (Fig. 4, III). This exhibits several bands at 1/λ 3460, 1/λ 3560, and a weaker wider one at 1/λ 3750. There is also a rapid extension of the line of absorption to about 1/λ 4200, and this probably indicates other weaker bands. All the bands of indole disappear in eserine.

These results are to be compared with those described in the previous investigations (*loc. cit.*). In camphor salicylate, for example, the weak band of camphor at 1/λ 3480 would appear to be covered up by the less refrangible strong band of salicylic acid, which widens out with increased thickness of the solution, to 1/λ 3600. Camphor salicylate has again been studied in *M*/10-solutions, and these are stronger than those of the earlier observations, and through thicknesses of from 2 mm. to 28 mm. No camphor band appeared, whereas in camphor itself the band is perfectly clear in such strengths. Similar explanations account for the differences in theobromine and caffeine and their salicylates (*loc. cit.*). In the salicylates of phenazone and quinine (*loc. cit.*), the differences in the absorption are more clearly marked because the specific bands of the bases themselves are fairly strong, and they are not hidden by the bands of the acid nuclei.

The specific absorptive capacity of these compounds, therefore, appears to depend upon the more or less intimate chemical combination of the various centres, as well as upon their chemical type. Where the chemical combination is not so close, as in the salicylates of the alkaloids, both the basic and the acid nuclei largely retain their own specific absorption. On the other hand, where there is a closer chemical combination of the absorbing centres, as, for example, in salicylanilide or benzene-5-azosalicylic acid, the specific absorption of each centre is not so sharply defined. Each centre is influenced by the other centres to a much larger extent than in the salicylates of the alkaloids and other organic bases.

PUBLIC HEALTH CHEMICAL LABORATORY,
CAMBRIDGE. [*Received, July 1st*, 1927.]

CCCLXII.—*Organic Derivatives of Silicon. Part XXXIII. An Amorphous Variety of Octaphenylcyclosilicotetrane.*

By FREDERIC STANLEY KIPPING.

THE glue-like, readily soluble product (E) of the action of sodium on diphenylsilicon dichloride in toluene solution is so strikingly different in physical properties from the four very sparingly soluble

silicohydrocarbons $[SiPh_2]_n$ (A, B, C, and D) by which it is accompanied (Kipping and Sands, J., 1921, **119**, 830) that it could hardly fail to arouse interest; its investigation, continued intermittently since 1921, has led to the conclusion that it consists mainly of an amorphous form of octaphenyl*cyclo*silicotetrane (B), the crystalline variety of which does not melt at 400° and is practically insoluble in cold acetone.

The acetone solution of (E) (*loc. cit.*, p. 836), kept in a closed vessel, continues to deposit crystals, but in gradually diminishing quantities, over periods of more than two years; these deposits consist of octaphenyl*cyclo*silicotetrane (B), but contain, as a rule, a very small proportion of the compound (C) (Kipping, J., 1924, **125**, 2291); octaphenylsilicotetrane (A), which is much more soluble than (C), but much less soluble than (B), in ordinary media, has never been detected. It seems, therefore, that (E) is partly and very slowly transformed into (B), since ordinary supersaturation could hardly continue so long. When the acetone solution is systematically fractionally precipitated with alcohol, a very small proportion of (B) and sometimes traces of (C) are found after each extended set of operations, and this separation or formation of insoluble matter seems to continue almost indefinitely; most of the original preparation, however, is merely resolved into a series of fractions, all miscible with acetone, the more sparingly soluble of which consist of an easily fusible resinous material of the composition $[SiPh_2]_n$, hereafter referred to as (E_1). The more soluble fractions are glue-like or oily, and contain combined oxygen, the origin of which was ultimately traced to the presence of phenoxy- and ethoxy-compounds in the diphenylsilicon dichloride (compare Kipping and Murray, this vol., p. 2734). This discovery and the difficulty of settling the nature of (E_1) made it advisable to hold back the results of its investigation until there was no doubt of its formation from the dichloride.

Even after prolonged fractionation from many different solvents, (E_1) yields no crystalline compound, other than a little (B) and traces of (C); it merely affords a series of graded fractions. Cryoscopic determinations in benzene solution give multiples of $SiPh_2$ ranging from about 7 to 9, and the high molecular complexity of the material is also proved by its non-volatility at high temperatures in a vacuum (p. 2725).

In chemical behaviour, (E_1) resembles octaphenyl*cyclo*silicotetrane (B) and is quite different from the reactive, open-chain isomeride (A); the fact that it does not combine with iodine seems to indicate, but does not prove [compare behaviour of (D), J., 1924, **125**, 2296], that it consists entirely of closed-chain molecules. It

is oxidised by nitric acid, giving a small proportion of the rhomboidal oxide, $Si_4Ph_8O_2$ (J., 1921, **119**, 844), but practically the whole of it seems to be converted into diphenylsilicanediol and condensation products of the latter. It is decomposed by piperidine and aqueous alkali, giving hydrogen and diphenylsilicanediol (or condensation products). The observed hydrogen values (Kipping and Sands, *loc. cit.*, p. 848) are a little lower than that required for $SiPh_2 + 2H_2O = SiPh_2(OH)_2 + H_2$, probably owing to incomplete hydrolysis; the examination of the products (p. 2727) seems to prove, however, that the preparations do not contain any $SiPh_3$-groups, but consist entirely of molecules $[SiPh_2]_n$.

Now when the physical properties of (E_1) are compared with those of octaphenyl*cyclo*silicotetrane (B) and those of (C), which is possibly $[SiPh_2]_6$ or $[SiPh_2]_8$—leaving out of consideration those of the open-chain compounds (A) and (D)—the contrast is so striking that even if (E_1) were regarded as a mixture of several cyclic compounds $[SiPh_2]_n$, the latter could hardly be present as free molecules, capable of forming sparingly soluble crystalline structures of high melting point, like those of (B) and (C). It is therefore suggested that (E_1) consists of molecules of octaphenyl*cyclo*silicotetrane (B) which have got so entangled with one another during their formation that they are inseparable, or nearly so, by physical means at moderate temperatures. It is not assumed that the cyclic structures are joined together like the links of a chain, but that the molecules of (B) are held together by the interlocking of their phenyl groups, forming aggregates of irregular shape, which do not themselves pack into crystals and hinder the orderly arrangement of the whole; if some of these molecules were comparatively loosely attached, and the proportion of irregular aggregates was diminished, a slow deposition of ordinary crystals of (B) from solutions of (E_1) might be expected to take place to a certain extent, as actually occurs. It is possible that octaphenyl*cyclo*silicotetrane and its higher analogues might assume configurations in which the silicon atoms do not all lie in one plane, and that such configurations might be rendered stable by the steric effects of their phenyl groups. Such assumptions, however, would not account adequately for the properties of (E_1), which seems to be a complex mixture of molecules, incapable of crystallisation.

The view that (E_1) is merely a physically different form of (B) is borne out by the following: In one experiment, when (E) was heated under 5—0 mm., small quantities of oily "distillate," apparently decomposition products, were collected as the temperature of the liquid rose from about 300° to 400° and at the same time a very considerable proportion of crystalline matter separated

from the residue, and did not all redissolve; this crystalline deposit consisted of octaphenyl*cyclo*silicotetrane (B) with a small proportion of octaphenylsilicotetrane (A). As it was hardly possible that so large a proportion of free (B) molecules could have been present in the crude (E), it must be concluded that these molecules had been set free by the action of heat.

Unfortunately, attempts to repeat this conversion of (E_1) into (B) have been unsuccessful, but the reverse operation is easily accomplished. When pure (B) is very rapidly heated above 400° until it is partly melted, and then immediately cooled, the glue-like melted portion is very readily soluble in cold acetone; the solution begins to deposit crystals of (B) after a variable interval and continues to do so during several days or weeks; it then gives with alcohol a flocculent precipitate, $[SiPh_2]_n$, melting indefinitely below 150°, and having a molecular weight of about 1500.

These results, the chemical similarity of (E_1) and (B), and all other facts seem to be best accounted for by the assumption that these two substances are physically different forms of octaphenyl-*cyclo*silicotetrane.

The distillate referred to above, and a similar product from other samples of (E), consisted mainly of an oil which gave triphenylsilicol on oxidation, or, with evolution of hydrogen, on treatment with acetone and alkali; from these facts, it would appear that this oil contained triphenylsilicyl, pentaphenylsilicoethyl, or heptaphenylsilicopropyl. It is only formed from (E) very slowly and at high temperatures, but it is clear that the decomposition of the $[SiPh_2]_n$ molecules is accompanied by a transference of phenyl groups from one silicon atom to another.

Experimental.

The crystalline deposit which is formed when an acetone or ethereal solution of (E) is kept in a closed vessel does not redissolve when the supernatant solution is warmed; separated by filtration and treated with cold benzene, it often leaves a very small proportion of a residue which can be identified as (C) by crystallisation from benzene, etc. (compare J., 1924, **125**, 2294). The main portion of the deposit, soluble in cold benzene, was identified as octaphenyl*cyclo*silicotetrane (B) by direct comparison; it did not decolorise a very dilute benzene solution of iodine and was therefore free from octaphenylsilicotetrane (A).

As the formation of deposits in acetone solutions of (E) might conceivably be due to the action of alkali from the glass vessels, an acetone solution which had been kept some 3 months was filtered and acidified with a drop of hydrochloric acid; the solution (in a

closed vessel, gave in the course of 6 months a deposit of (B), and the flask became coated with a very thin layer of some material insoluble in boiling benzene and other solvents, which could be detached in transparent, elastic films. Similar gelatinous films are often formed on the beakers used in fractionating (E) with acetone and alcohol; they char at a very high temperature but without melting and appear to be unchanged when boiled with acetone and potash. This material may be already contained in (E) and if so may be partly accountable for the low hydrogen values of (E_1), or it may be a very complex condensation product of diphenylsilicanediol (which will be described in a future paper), produced by the hydrolysis of (E_1). Crude (E) does not react appreciably with iodine, but it reduces silver nitrate in acetone solution very distinctly.

Separation of Silicohydrocarbons (E_1).—Treated with alcohol, the acetone solution of (E) gives at first a white, plastic precipitate which can be pulled out into long, silk-like threads; the latter change into a very brittle solid when the solvents evaporate. By systematic fractional precipitation in this way, or with water, continued until each of the original fractions (say 8) has been redissolved and reprecipitated several times, the most sparingly soluble portion, now precipitated in a flocculent form, if again treated with cold acetone, usually gives a very small separation of (B) with traces of (C). Another systematic series of operations with the whole set of fractions, starting from the most soluble portion, yields a similar result, and it seems that this very sparingly soluble matter is being continually produced.

Many different preparations of the less soluble fractions (but miscible with acetone) have been analysed; most of them retained solvent very tenaciously and lost in weight during more than 30 days in a vacuum * (Found: Si, 15·3, 15·7, 15·5, 15·6, 15·4, 15·6; C, 77·6, 78·2, 77·9, 78·3; H, 5·9, 5·8, 5·9, 5·8; *M*, cryoscopic in benzene, 1558, 1395, 1456, 1225, 1410; hydrogen values, 110, 108, 113, 116. $SiPh_2$ requires Si, 15·5; C, 79·0; H, 5·5%; *M*, 182; hydrogen value, 122) (compare J., 1921, **119**, 848).

The somewhat low combustion results are partly due to the difficulty of burning the last traces of carbon in the silica residue;

* The best way of obtaining a sample ready for analysis is to dissolve it (2—3 g.) in a very little dry ether in a 300 c.c. beaker, evaporate the solvent on the water-bath to a "glue," and then, while the "glue" is still warm, evaporate the rest of the solvent quickly under reduced pressure; the residue froths and fills the beaker with a white foam, which after 10—15 minutes becomes very brittle and can be easily broken up. Even such preparations do not become constant in weight in less than 3 to 5 days in a vacuum; to the unaided eye they appear to be beautifully crystalline.

the silicon determinations are trustworthy, since the residue obtained on ignition with sulphuric acid containing a little nitric acid is colourless.* The low hydrogen values have not been accounted for satisfactorily; they are partly due to the presence of some non-hydrolysable matter, possibly an amorphous form of (C).

When (E) has been prepared from diphenylsilicon dichloride of about 95—97% purity (compare Kipping and Murray, *loc. cit.*),† the product after two precipitations contains about 15·1% of silicon, consists mainly of (E_1), and does not give phenol on hydrolysis; the isolation of (E_1) then presents no very great difficulty. The earlier crude preparations of (E), however, contained only 12·5—14% of silicon, and the isolation of (E_1) required a prolonged series of fractional precipitations whereby a large proportion of rather more soluble glue-like matter was gradually separated; this material gave phenol and ethyl alcohol on hydrolysis.

The Silicohydrocarbon (E_1).—Many preparations of the composition $[SiPh_2]_n$ were fractionally extracted with boiling alcohol or boiling light petroleum, precipitated from hot phenol with alcohol, etc., but their properties underwent but little change, and no crystalline product, except perhaps traces of (B), could be isolated. The fractional diffusion of an acetone solution through unglazed earthenware also failed to afford crystals.

The preparations have no definite melting point but gradually liquefy over a range of 20° or 30° or so, beginning to sinter from about 110° to 130°; they are miscible with cold ether, benzene, chloroform and many other solvents, from all of which they separate as "glues," which very gradually become brittle, but they are only sparingly soluble in boiling light petroleum and very sparingly in boiling alcohol or glacial acetic acid. Preparations kept in the solid state during 4—5 years are still miscible with cold acetone.

(E_1) does not react appreciably with iodine in cold benzene

* The silica is very hygroscopic and may absorb as much as 28·4% of water on exposure to the air.

† It is no easy matter to ascertain whether—or when—the reaction with sodium is at an end. The toluene solutions of the product, which give no sign of a green flame with copper, afford an aqueous extract containing halogen. This seems to be partly present as sodium chloride, which is slightly soluble in toluene solutions of (E). The heating was usually stopped when an aqueous extract gave a neutral reaction to litmus, but even this test seems to be untrustworthy, and (E) may still contain halogen. If the heating with sodium is continued beyond a certain point, the filtered toluene solution gives an alkaline reaction, and the crude (E), obtained by evaporation, effervesces when treated with (undried) acetone; if this occurs, the fractional precipitation of the acetone solution with alcohol (after removing B) yields a large proportion of trianhydrotrisdiphenylsilicanediol, and the isolation of (E_1) is difficult or impossible.

solution; in carbon tetrachloride solution, a little bromine is absorbed, but many hours elapse before the proportion reaches $Br_2 : [SiPh_2]_2$. In some cases traces of a crystalline bromo-compound were obtained, but the principal solid product was a very little rhomboidal oxide, probably formed by the hydrolysis of a dibromide, $SiPh_2Br{\cdot}SiPh_2Br$, and subsequent condensation of the diol; the reaction seemed also to involve the partial separation of phenyl groups as bromobenzene without precipitation of silica.

When (E_1), partly dissolved and partly suspended in glacial acetic acid, is cautiously oxidised with nitric acid, it yields the rhomboidal oxide, but is almost entirely converted into crystalline and oily condensation products of diphenylsilicanediol.

Formation of (B) and (A) from (E).—A solution of (E) (30—35 g.) in undried commercial ether, which had been kept about 3 weeks in a closed vessel and then filtered from the deposit of (B), was evaporated and the residue heated in a very short-necked (2″) flask under 6 mm. pressure. At first a little (0·2 g.) diphenyl came over; the temperature then rose rapidly to about 300° (thermometer in liquid) and a very slow "distillation" commenced, fractions, each of about 1½ c.c., being collected at 300—330°, 330—350° and 350—360°. The temperature then rose slowly to 400° (5 mm.), but no further distillation occurred and crystals which had been splashed on to the sides of the flask had not liquefied when the heating was stopped.

When cold, the glue-like mass was treated with acetone and left over-night; most of it dissolved, leaving some crystalline matter (about 2 g.), which was washed with acetone. This product was almost completely soluble in cold chloroform, and was reprecipitated by acetone in short, rectangular prisms which were identified as those of octaphenyl*cyclo*silicotetrane (B) by a direct comparison. The portion insoluble in cold chloroform (about 0·1 g.) crystallised from benzene in short, flat prisms and was proved to be octaphenylsilicotetrane (A) by its behaviour towards iodine and in other ways.

In order to prove that the cyclic silicohydrocarbon (B) had not been held in solution by the liquid "distillate" of (E), some of it was dissolved in a portion of this distillate; the solution, diluted with ether or with acetone, gave an immediate precipitate and apparently the whole of the dissolved (B) was deposited.

Of the three fractions referred to above, the two more volatile ones fumed very slightly in the air and contained halogen.* All three fractions deposited traces of trianhydrotrisdiphenylsilicanediol, reduced an aqueous solution of silver nitrate in a marked manner, and gave hydrogen very readily with acetone and aqueous

* The heating with sodium had been continued during at least 6 hours.

alkali. The whole of this thick, oily " distillate " was poured into glacial acetic acid (about 4 vols.)—in which it was only very sparingly soluble—and then a few drops of concentrated nitric acid were added; oxidation set in very readily and after the non-homogeneous mixture had been warmed on the water-bath during some 2 hours and then cooled, a considerable quantity of crystalline matter separated very slowly from the oily layer. This crystalline product, purified by recrystallisation from alcoholic chloroform, was conclusively proved to be triphenylsilicol by analysis, mixed melting-point determinations, etc., and by converting it into triphenylsilicyl oxide (m. p. 222—223°).

The fact that this oil gave a large proportion (at least 25%) of triphenylsilicol on oxidation, whereas undistilled (E) gives no such product, seemed to prove that a migration of phenyl groups had occurred without separation of silicon or silica. The acetone solution of the residue from the distillation, fractionally treated with alcohol, gave precipitates of much the same character as (E_1); they were, however, less readily soluble in acetone, and contained 16—17% of silicon ($SiPh_2$ requires 15·4%), the percentage increasing with the duration of the " distillation."

In the hope of confirming these results, another preparation of (E), which had been kept in dry ethereal solution during 19 days, was separated from the usual deposit, and the crude (E) (12 g.) obtained on evaporation of the solvent was heated under 1—1·5 mm. (thermometer in the liquid) in a very short-necked flask. From about 283° to 310°, about 1½ c.c. of a thick oil very slowly collected in the receiver, but there was no separation of crystals from the distillate or from the residue, even when the latter was treated with acetone.

The distillate contained only traces of halogen, reduced an aqueous acetone solution of silver nitrate, and gave triphenylsilicol on oxidation with a glacial acetic acid solution of nitric acid; when treated with alkali in acetone solution, it gave hydrogen readily at the ordinary temperature, and, after some of the solvent had been expelled, crystals of triphenylsilicol were deposited; these, left on porous earthenware, without having been freed from alkali, passed into crystals of the silicyl oxide. The mother-liquor from the silicol, warmed again with alcohol and alkali, gave further deposits of triphenylsilicyl oxide, and finally at least 80% of a portion of the original distillate was transformed into this compound.

All attempts to isolate triphenylsilicol or the oxide from other portions of this distillate without using nitric acid or alkali were unsuccessful; the oil certainly did not contain the oxide, nor did it give any crystals of the latter after it had been heated for a long

time with alcohol and hydrochloric acid. The residue from this "distillation" solidified to a very brittle resin, which behaved on hydrolysis quite differently from ordinary samples of (E), inasmuch as it gave, in addition to diphenylsilicanediol, a considerable proportion of triphenylsilicyl oxide. A direct comparison of two samples of the same preparation of (E), one of which had been heated at about 350° for some time, proved that only the latter gave triphenylsilicyl oxide on hydrolysis; from 3·7 g. of the unheated material, only about 0·25 g. was not ultimately convertible into diphenylsilicanediol or other products soluble in aqueous alkali.

It must be concluded from these results that at high temperatures some of the molecules composed entirely of $SiPh_2$ groups are decomposed, giving triphenylsilicyl, $SiPh_3$·, or some other compound containing a $SiPh_3$-group.

Conversion of Octaphenylcyclosilicotetrane into an Amorphous Form.—When pure (B) is very rapidly heated in a test-tube over a free flame in an inert atmosphere, it can be partly melted, and when the cooled product is treated with cold acetone, the melted portion dissolves, leaving the crystalline matter; by repeating these operations, the whole of any sample of (B) can be obtained in solution in about 1—2% of the volume of solvent which would have been required to dissolve the crystals, but not more than 0·1 g. of (B) should be heated at a time. The acetone solution begins to deposit crystals of pure (B) either within a few minutes or only after some hours, and this deposition may continue during many days: the filtered solution gives with alcohol an apparently amorphous, flocculent precipitate, which, when separated and freed from solvent, melts very indefinitely from 110° to 150° and contains 15·4% of silicon ($SiPh_2$ requires Si, 15·5%); the molecular weight in camphor was found to be 1500, whereas under the same conditions crystalline (B) gives the normal results for $[SiPh_2]_4$ (J., 1924, **125**, 2291). The alcoholic acetone filtrate from the amorphous precipitate gives on evaporation a little more of an apparently identical product.

As there is no charring, or evolution of vapour, or separation of insoluble matter when (B) is thus heated, and as the whole of the product seems to be silicohydrocarbon $[SiPh_2]_n$, it is concluded that the soluble amorphous product is merely a form of octaphenyl-*cyclo*silicotetrane in which the molecules have become entangled with one another. It is not suggested that this form, produced by melting (B), is identical with (E_1); it seems to differ from (E_1) in being more readily and more completely transformed into the crystalline variety, and may be regarded rather as a mixture of (B) molecules analogous to that which is contained in the original

toluene solution of (E) and from which a considerable proportion of (B) is rapidly precipitated on the addition of acetone.

The author has been assisted in this investigation by J. E. Sands and R. Vyle, M.Sc., and has also received financial help for the purchase of diphenylsilicon dichloride (kindly supplied by Boots' Pure Drug Company) from the Government Grant Committee of the Royal Society: for all such assistance he wishes to record his indebtedness.

UNIVERSITY COLLEGE, NOTTINGHAM. [*Received, August 9th*, 1927.]

CCCLXIII.—*Organic Derivatives of Silicon. Part XXXIV. The Action of Sodium on Phenoxydiphenylsilicyl Chloride.*

By FREDERIC STANLEY KIPPING.

SINCE the product (E) of the action of sodium on diphenylsilicon dichloride may give on hydrolysis appreciable quantities of phenol (this vol., p. 2724), it was inferred that the dichloride, in spite of its constant boiling point, might be contaminated with phenoxyphenylsilicon dichloride, phenoxydiphenylsilicyl chloride, or diphenoxydiphenylsilicane. It is known that atmospheric oxidation may occur during the preparation of magnesium phenyl bromide (Porter and Steel, *J. Amer. Chem. Soc.*, 1920, **42**, 2650) and the resulting Grignard reagent, containing magnesium phenoxy-bromide, might give rise to phenoxy-derivatives if used for the preparation of diphenylsilicon dichloride from silicon tetrachloride.

The action of phenol on diphenylsilicon dichloride was therefore studied, partly in order to observe the boiling points of two of the phenoxy-derivatives just mentioned, but mainly in the hope that by the fractional distillation of the product some other unknown impurity in the dichloride might be isolated and identified.

The results gave no support to the inference that the dichloride formed a constant-boiling mixture with either of these phenoxy-derivatives, and the product—consisting of phenoxydiphenylsilicyl chloride, diphenoxydiphenylsilicane, and unchanged diphenylsilicon dichloride—could be separated into its components by fractional distillation; no fraction representing the long sought-for impurity in the dichloride (compare Kipping and Murray, this vol., p. 2734) was obtained.

The action of sodium on phenoxydiphenylsilicyl chloride was then examined in the hope that symmetrical diphenoxytetraphenyl-

silicoethane would be produced, just as hexaphenylsilicoethane is formed from triphenylsilicyl chloride (Kipping, P., 1911, **27**, 144); the results were quite unforeseen. The products, isolated with the aid of anhydrous solvents, were octaphenylsilicotetrane,

$$-SiPh_2\cdot SiPh_2\cdot SiPh_2\cdot SiPh_2-$$

(Kipping and Sands, J., 1921, **119**, 830; Kipping, J., 1923, **123**, 2590), diphenoxyoctaphenylsilicotetrane, $PhO\cdot[SiPh_2]_4\cdot OPh$, and diphenoxydiphenylsilicane; from the remaining material, with the use of other solvents not free from water, phenol, diphenylsilicanediol, a considerable proportion of an apparently amorphous solid, which is possibly $PhO\cdot[SiPh_2]_4\cdot OH$, and a very viscous oil, possibly $PhO\cdot SiPh_2\cdot SiPh_2\cdot OPh$, were obtained.

The formation of octaphenylsilicotetrane suggested that the phenoxy-chloride was contaminated with diphenylsilicon dichloride; but in subsequent preparations, using only material which, from its boiling point and from analyses, was the pure phenoxy-derivative, the three products named above were again obtained, apparently in the same yields as before; moreover, that of the silicohydrocarbon seemed to be about as large as if diphenylsilicon dichloride had been used instead of the phenoxy-chloride.

Now the supposed phenoxy-chloride cannot be a mixture of equal quantities of diphenylsilicon dichloride and diphenoxydiphenylsilicane. The product of the action of phenol (1 mol.) on the dichloride is not a liquid of constant boiling point, but distils over a range of about 100°. Further, the phenoxy-chloride is immediately and completely soluble in a cold 5% solution of potassium hydroxide, whereas the diphenoxy-derivative is practically insoluble in, and is only slowly hydrolysed by, such a solution; a prepared solution of the diphenoxy-compound in the dichloride gives crystals of the former when it is added to cold aqueous alkali. Another important fact, which seems to show that the phenoxy-chloride is not converted into a mixture of the dichloride and the diphenoxy-derivative at any stage of the reaction, is that, so far as can be ascertained, the other products of the action of sodium on diphenylsilicon dichloride, namely, octaphenyl*cyclo*silicotetrane (B) and the complex silicohydrocarbons (C) and (D) (Kipping, J., 1924, **125**, 2291), are not formed from the phenoxy-chloride. Finally, the production of diphenoxyoctaphenylsilicotetrane proves that a phenoxy-derivative takes part in the reaction, but apparently diphenoxydiphenylsilicane is not attacked by sodium even at temperatures above 110°.

Although, therefore, it must be concluded that octaphenylsilicotetrane and its diphenoxy-derivative are obtained from the phenoxy-chloride, the mechanism of their formation is obscure. The pro-

duction of diphenoxydiphenylsilicane seems to prove that at one stage sodium phenoxide is formed, and reacts with unchanged phenoxy-chloride to give the diphenoxy-derivative; this view is confirmed by the fact that sodium phenoxide is present in the blue insoluble residue (p. 2731). It does not seem likely, however, that symmetrical diphenoxytetraphenylsilicoethane is produced and then reacts with sodium to give sodium phenoxide, because, although some ethers are attacked by the metal (Schorigin, *Ber.*, 1926, **59**, 2510), diphenoxydiphenylsilicane and diethoxydiphenylsilicane (Kipping and Murray, this vol., p. 2736) appear to be unacted on. It may be suggested, therefore, that the phenoxy-chloride is decomposed by sodium, giving first $SiPh_2Cl{\cdot}SiPh_2Cl$ and then

$$SiPh_2Cl{\cdot}[SiPh_2]_2{\cdot}SiPh_2Cl,$$

and that a part of the latter is transformed into octaphenylsilicotetrane, whilst some of it reacts with sodium phenoxide to form diphenoxyoctaphenylsilicotetrane. The absence from the reaction product of (B), (C), and (D), however, does not accord with these assumptions, since it would seem to be highly probable that (B) at any rate would also be formed from such dichlorides.

Experimental.

Interaction of Phenol and Diphenylsilicon Dichloride.—Phenol (1 mol.), dissolved in a little benzene, is dropped slowly into diphenylsilicon dichloride * at about 150°, hydrogen chloride being immediately evolved; the liquid is then heated at about 200° until the evolution ceases (about 3 hours). The product deposits crystals of diphenoxydiphenylsilicon when it is kept at 0°, but it is more convenient to separate the latter by distillation (40 mm.). The first fraction (15—20%) is collected at about 200—240°, a large fraction (about 45%) at 250—260°, and a second large fraction at 280—310°, leaving a small residue. The liquid collected from 200—240°, when again treated with about one-half of its weight of phenol, gave further quantities of the two phenoxy-derivatives, but no fraction having the boiling point of diethoxydiphenylsilicane, a possible impurity in the diphenylsilicon dichloride, could be isolated.

Phenoxydiphenylsilicyl chloride, $SiPh_2Cl{\cdot}OPh$, obtained by the further fractionation of the liquid, b. p. about 250—260°, is a thick oil which barely fumes in the air and is miscible with light petroleum and other anhydrous solvents; it boils at 252—254°/40 mm. [Found: Cl, 11·0, 10·9, 11·2, 11·1 (four different preparations);

* Three samples of the dichloride (b. p. 224—226°/100 mm.) were used, containing 25·2, 24·8, and 25·7% of chlorine, respectively. (Calc. for $SiPh_2Cl_2$: Cl, 27·9%.) Compare Kipping and Murray, *loc. cit.*

Si, 9·0. $C_{18}H_{15}OClSi$ requires Cl, 11·4; Si, 9·1%]. It is immediately and completely soluble in a 5% solution of potassium hydroxide, giving the potassium derivatives of phenol and of diphenylsilicanediol. When left exposed to moist air, it is gradually converted into a solid, smelling strongly of phenol, which after recrystallisation from benzene consists of trianhydrotrisdiphenylsilicanediol.

Diphenoxydiphenylsilicane, $SiPh_2(OPh)_2$, separates in crystals from the fraction collected above 280°, but as it is always mixed with a considerable proportion of the oily phenoxy-chloride the crude product is fractionated again; it then crystallises from light petroleum in massive, colourless prisms and octahedra, m. p. 70—71° (Found: Si, 7·7, 7·8. $C_{24}H_{20}O_2Si$ requires Si, 7·7%). It is very readily soluble in ether, chloroform, benzene, or acetone, but only moderately soluble in cold alcohol. It can be recrystallised from the last-named solvent, but the crystals seem rather sticky and melt at 65—69°, doubtless owing to some very slight hydrolysis having occurred; if attempts are made to recrystallise the impure substance, containing phenoxy-chloride, from alcohol, complete decomposition results, and trianhydrotrisdiphenylsilicanediol may separate. When boiled with water for a short time, the diphenoxy-derivative is not appreciably hydrolysed, owing to its insolubility; it is also relatively stable towards a 5% solution of sodium hydroxide, but it is very readily hydrolysed in presence of acetone or alcohol with separation of trianhydrotrisdiphenylsilicanediol, whilst sodium phenoxide remains in solution. The fact that diphenoxydiphenylsilicane is present in a toluene solution which has been boiled during several hours with excess of sodium, is conclusive evidence of its stability under such conditions, and yet when an apparently pure specimen, recrystallised from light petroleum and melting sharply at 70—71°, is heated with sodium and a little toluene a distinct effervescence occurs and the metal is coated with a white powder. The reaction, however, soon ceases and the rest of the phenoxy-compound is unaltered. It would seem from these observations, repeated several times, that the recrystallised substance contains a small proportion of diphenylsilicanediol or phenoxyhydroxydiphenylsilicane.

Action of Sodium on Phenoxydiphenylsilicyl Chloride.—Freshly distilled phenoxy-chloride is dissolved in dry toluene (about 4 vols.), excess of sodium added, and the whole heated; an exothermic reaction soon sets in and the metal becomes coated with a blue crust similar to that obtained with diphenylsilicon dichloride under the same conditions. After the solution has boiled during 2—3 hours it contains some colourless crystals and seems to be free from phenoxy-chloride when tested with a copper wire. The hot solution

is filtered, the blue residue (I) washed with toluene, and the combined filtrate and washings are evaporated under reduced pressure. The almost colourless, oily product, when mixed with a little light petroleum (b. p. 50—60°), gives a crystalline precipitate (II), and the filtered solution, diluted with more petroleum, gives an oily separation (III); the clear petroleum solution, decanted from the oil, gives a further oily deposit (IV) when it is kept at 0°, but even then it contains a considerable quantity of product (V).

Isolation of octaphenylsilicotetrane. The blue residue (I) of sodium, sodium chloride, and sodium phenoxide is added in small portions to alcohol–acetic acid, the solution being kept acid; the insoluble matter, after being well washed with water, consists of almost pure octaphenylsilicotetrane, which was fully identified by a mixed melting-point determination, by its characteristic action with nitrobenzene and with iodine (compare Kipping and Sands, *loc. cit.*), and in other ways. So far as could be ascertained, the silicohydrocarbons (C) and (D) which are formed together with octaphenylsilicotetrane by the action of sodium on diphenylsilicon dichloride are not produced from the phenoxy-chloride; all the organic matter from the blue residue is soluble in boiling benzene, and although the final mother-liquors and the deposits were carefully examined, not a single crystal of (C) could be detected (compare Kipping, J., 1924, **125**, 2294).

Diphenoxyoctaphenylsilicotetrane, $PhO\cdot[SiPh_2]_4\cdot OPh$. The precipitate (II) consists of diphenoxyoctaphenylsilicotetrane and octaphenylsilicotetrane. The former is extracted with boiling benzene, in which it is much the more soluble, and is then recrystallised from boiling chloroform and again from benzene, from which it separates in well-defined, rhomboidal pyramids and in prisms, m. p. 215—216° (Found: Si, 12·3; C, 78·1; H, 5·2; *M*, in camphor, 1083, 1040. $C_{60}H_{50}O_2Si_4$ requires Si, 12·3; C, 78·7; H, 5·5%; *M*, 915). The diphenoxy-compound is decomposed when it is heated with piperidine and a concentrated solution of sodium hydroxide, giving the sodium derivatives of phenol and diphenylsilicanediol, with evolution of hydrogen. [Hydrogen value (compare Kipping and Sands, J., 1921, **119**, 848) found, 69·0, 67·4, 70·5; calc. for $PhO\cdot[SiPh_2]_4\cdot OPh + 10NaOH = 2PhONa + 4SiPh_2(ONa)_2 + 2H_2O + 3H_2$, 73·1].

Diphenoxyoctaphenylsilicotetrane is practically insoluble in ether, acetone, alcohol, and glacial acetic acid, and is far less soluble in cold benzene and chloroform than octaphenyl*cyclo*silicotetrane (B): it is so like the rhomboidal oxide (Kipping and Sands, J., 1921, **119**, 844) in crystalline form, solubilities, and melting point that it might well be mistaken for the latter, but its mixture with the rhomboidal

oxide melts at 208—211°. It is very readily soluble in boiling aniline, from which it separates on cooling in small prisms. It seems to be unchanged when it is heated during 1—2 hours with a glacial acetic acid solution of nitric acid, and it is so slowly hydrolysed when it is boiled with an alcoholic solution of hydrochloric acid that after about 20 hours' heating most of the substance remains undissolved and unchanged; the presence of phenol in the resulting pink solution can, however, be proved. The stability of the compound may be attributed to steric hindrance; its formation from the phenoxy-chloride under the above-described conditions is all the more noteworthy in view of the non-production of decaphenylsilicotetrane by the action of magnesium phenyl bromide on octaphenylsilicotetrane di-iodide (Kipping, J., 1923, **123**, 2602).

Other products from the phenoxy-chloride. From the combined oily separations (III) and (IV), by fractional extraction with light petroleum, diphenoxydiphenylsilicane was isolated and then, with the aid of a mixture of acetone and light petroleum, some diphenylsilicanediol, which had no doubt been formed by the hydrolysis of the diphenoxy-derivative during the prolonged fractionation with undried solvents. The mother-liquors from the diol gave on evaporation a glue-like mass, smelling strongly of phenol, which did not crystallise in the course of some weeks; after being washed with water and dissolved in acetone, this glue was precipitated by alcohol as a white curd, very similar in properties to the precipitates of (E_1) obtained in like manner (this vol., p. 2723). This product was redissolved and reprecipitated many times and then repeatedly extracted with warm alcohol, in which it was only very sparingly soluble; the warm glue was then drawn into threads and when cold the brittle mass was powdered and freed from solvent. Two different preparations gave Si, 13·3 and 13·6%, respectively; when hydrolysed with piperidine and sodium hydroxide, they gave hydrogen, sodium phenoxide, and the sodium derivative of diphenylsilicanediol, and the following hydrogen values: 82·7, 80·3, 81·1. These results agree with those required for

$$HO{\cdot}SiPh_2{\cdot}SiPh_2{\cdot}SiPh_2{\cdot}SiPh_2{\cdot}OPh,$$

but the physical properties of the material do not seem to correspond with such a formula; possibly the substance is an oxide, $(PhO{\cdot}SiPh_2{\cdot}SiPh_2{\cdot}SiPh_2{\cdot}SiPh_2{\cdot})_2O$.

The light petroleum solution of the product (V) gave on evaporation a very thick, colourless oil, which in the course of some months deposited a considerable proportion of diphenoxydiphenylsilicane; this was removed by repeated extraction with warm alcohol. The residue was then completely and readily soluble in cold light petroleum (b. p. 40—50°), from which it separated as an oil. This product

contained 10·9% of silicon and is possibly impure symmetrical diphenoxytetraphenylsilicoethane, $PhO{\cdot}SiPh_2{\cdot}SiPh_2{\cdot}OPh$, which requires Si, 10·3%; it gave hydrogen with acetone and sodium hydroxide, and the alkaline solution then contained sodium phenoxide and the sodium derivative of diphenylsilicanediol.

The author wishes to express his indebtedness to Mr. R. Vyle, M.Sc., who rendered very efficient assistance during this work, and to the Government Grant Committee of The Royal Society for funds from which to buy diphenylsilicon dichloride from Boots' Pure Drug Co.

CCCLXIV.—*Organic Derivatives of Silicon. Part XXXV. The Preparation of Diphenylsilicon Dichloride: "Grignard" Ether and its Action on Silicon Tetrachloride.*

By FREDERIC STANLEY KIPPING and ARTHUR GEORGE MURRAY.

THE analysis of the first sample of diphenylsilicon dichloride gave 28·0% of chlorine (Calc. for $SiPh_2Cl_2$: Cl, 27·9%).* Large quantities of this compound were used later for the preparation of diphenylsilicanediol, and during a very careful examination of the latter and of its condensation products (J., 1912, **101**, 2108, 2125) there was no indication of unknown impurity in the dichloride. When, however, it was discovered that the product (E) contained phenoxy-compounds (this vol., p. 2720), several samples of the dichloride were examined and found to contain only 23—24% of chlorine; † they also gave 3—4% of phenol on hydrolysis.

The preparation of the magnesium phenyl bromide used in making the silicon compound was then carried out in an atmosphere of nitrogen (compare this vol., p. 2728), as was also, later on, the actual preparation of the dichloride; the samples thus obtained (b. p. 223—224° or 224—225°/100 mm.) gave inappreciable quantities of phenol, but still contained only 25·5—26% of chlorine, a proportion which could not be altered by further fractionation under various pressures. The silicon percentages in such samples agreed very closely with that required for $SiPh_2Cl_2$, an indication that the

* J., 1912, **101**, 2114. The sample was prepared and purified by one of us (F. S. K.), but was analysed under direction by a senior student, ignorant of the nature of the substance.

† The purchased samples were invoiced as having a purity of 80–90%.

impurity might be $SiPh_2(OEt)_2$ or $SiPh_2(OEt)Cl$, formed from traces of alcohol in the large volume of ether used in their preparation; but no matter how thoroughly the Grignard ether was freed from alcohol, the purity of the dichloride could not be increased and all samples gave alcohol on hydrolysis.

The behaviour of silicon tetrachloride towards ether was then studied (the tetraiodide is known to react; Friedel, *Ber.*, 1872, **5**, 27) and it was found that even at the ordinary temperature a slight action occurs, probably as follows: $SiCl_4 + Et_2O = SiCl_3 \cdot OEt + EtCl$. The difficulty of preparing pure diphenylsilicon dichloride is therefore almost certainly due to the formation of ethoxydiphenylsilicyl chloride, which cannot be separated by distillation (p. 2736).

As a solution of magnesium phenyl bromide could not be obtained without the use of ether, the method of preparation of the dichloride was modified so as to limit the interaction of the ether and the tetrachloride. The results were fairly satisfactory, but the product still contained a small proportion of some ethoxy-compound.

The fact that ether reacts with silicon tetrachloride probably accounts for previous difficulties in preparing various organic derivatives of silicon. Thus from the product of the interaction of magnesium ethyl bromide and the tetrachloride, it may not be hard to obtain ethylsilicon trichloride, but the isolation of the di- and the tri-ethyl derivatives by fractional distillation is a very troublesome task (J., 1909, **95**, 311); the difficulty of preparing a pure sample of phenylethylsilicon dichloride (J., 1907, **91**, 217) is also possibly due to the contamination of the product with ethoxyphenylethylsilicyl chloride. In the case of a crystalline product, the formation of some ethoxy-compound would not matter so much, as the impurity would doubtless remain in the mother-liquor; this has been proved to be so in the case of dibenzylsilicon dichloride, since the liquid fractions from the crude preparation give ethyl alcohol on hydrolysis.

EXPERIMENTAL.

For the detection of phenoxy- and ethoxy-groups in an ordinary sample of diphenylsilicon dichloride, the latter is dropped into excess of a 5% solution of sodium hydroxide, and a small proportion of the liquid is then distilled and tested for alcohol; the residue is acidified and again distilled and the distillate is treated with bromine water. Samples of the dichloride prepared by the method described later do not give a recognisable quantity of tribromophenol.

Interaction of Ether and Silicon Tetrachloride.—Very carefully

purified ether was heated under reflux during about 4 hours with an equal volume of silicon tetrachloride; about one-half of the liquid was then distilled and the residue was treated with an excess of sodium hydroxide solution and again distilled; the first small portion of the aqueous distillate gave a distinct but very slight iodoform reaction. By heating the recovered ether (20 c.c.) with about 5% of silicon tetrachloride in a sealed tube during about 8 hours at 100° and then proceeding as before, about four times as much iodoform was obtained, but even under these conditions the quantity was only about 5 mg. The interaction also occurs at the ordinary temperature; after 30 c.c. of ether had been left with about 5 c.c. of silicon tetrachloride during 3 days and most of the ether then distilled off, the residue, on hydrolysis, gave enough alcohol to afford a very slight precipitate of iodoform, and the ether which had been distilled from the mixture, treated again with the tetrachloride, gave a further quantity of the product which yielded alcohol; these processes were repeated four times, with the ether recovered from each previous treatment, and iodoform was obtained, apparently in much the same quantity, after each set of operations.* As the precipitate of iodoform was not appreciably larger than usual when the mixture had been kept during several weeks, it would seem that the reaction is reversible.

Diethoxydiphenylsilicane, $SiPh_2(OEt)_2$, was prepared in order to compare its boiling point with that of diphenylsilicon dichloride. Carefully dehydrated alcohol, in slight excess, was added to the dichloride; only a feeble evolution of hydrogen chloride occurred and two layers were formed, but after having been heated under reflux during 6—8 hours the liquid became homogeneous and was then distilled (100 mm.). The product still contained a little chlorine, and was therefore heated again with a small proportion of alcohol and then fractionated; practically the whole passed over at 217—218°, and a considerable quantity of the preparation gave only an insignificant reaction with an aqueous solution of silver nitrate [Found: Si, 10·4. $SiPh_2(OEt)_2$ requires Si, 10·4%]. The b. p. of the diethoxy-compound differs only very little from that of the dichloride,

$SiPh_2(OEt)_2$	197—198°/50 mm.	217—218°/100 mm.	302—304°/767 mm.
$SiPh_2Cl_2$	199—202°/50 mm.	222—224°/100 mm.	302—305°/757 mm.

* A blank experiment in which ether alone was heated under reflux with a solution of sodium hydroxide during 4 hours, and the alkaline solution was then tested for alcohol, gave a negative result and did not confirm the statement in Allen's "Commercial Organic Analysis" (vol. I, p. 179) that ether kept in presence of moisture generates traces of alcohol.

and it may therefore be deduced that that of the ethoxy-chloride, $SiPh_2Cl{\cdot}OEt$, would differ even less, so that its separation from the dichloride by distillation would be impossible.

Diethoxydiphenylsilicane is specifically heavier than water and is miscible with the common solvents; it seems to be unchanged when it is left during some hours with a 5% solution of potassium hydroxide, but it is quickly hydrolysed by an alcoholic solution and when only a little alkali is present trianhydrotrisdiphenylsilicanediol may separate in crystals; it is also slowly hydrolysed by dilute sulphuric acid. It appears to be unchanged by sodium at 100°.

Preparation of Diphenylsilicon Dichloride.—Silicon tetrachloride (170 g.), diluted with benzene (3 vols.), is placed in a bulb provided with three tubulures, which is fitted with a stirrer and a reflux condenser and is connected through a dropping-funnel with the apparatus for the preparation of magnesium phenyl bromide ($2\frac{1}{4}$ mols.). The air in the whole apparatus is displaced with dry nitrogen and the Grignard reagent is then prepared at 0°, the minimum quantity of ether being used. When about one-half of the magnesium has been dissolved, the ethereal solution is drawn into the exhausted dropping-funnel and is then slowly added to the well-cooled and stirred tetrachloride while the remainder of the Grignard reagent is being made. This portion is then drawn into the funnel as before and added to the tetrachloride, so that at no stage is there any possibility of oxidation. After the product has been stirred during a further period of about 30 minutes, as much ether as possible is distilled off on a water-bath, the operation lasting about 3 hours. More benzene (2 vols.) is then added and the magnesium salts are separated in the usual apparatus (J., 1907, **91**, 216) and well washed with benzene. The combined filtrate and washings give on evaporation such a small deposit of magnesium salt that a second filtration is unnecessary (J., 1912, **101**, 2114) and the product can be directly fractionated. Samples thus obtained contain 27·2—27·3% of chlorine.

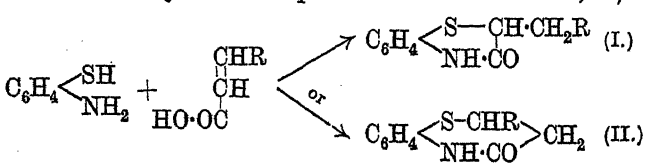
The authors wish to express their thanks to the Government Grant Committee of the Royal Society for funds which enabled them to purchase supplies of diphenylsilicon dichloride from Boots' Pure Drug Co., Ltd.

UNIVERSITY COLLEGE, NOTTINGHAM. [*Received, August 9th,* 1927.]

CCCLXV.—*The Condensation of* o-*Aminothiophenol with* αβ-*Unsaturated Acids.*

By WILLIAM HOBSON MILLS and JAMES BELL WHITWORTH.

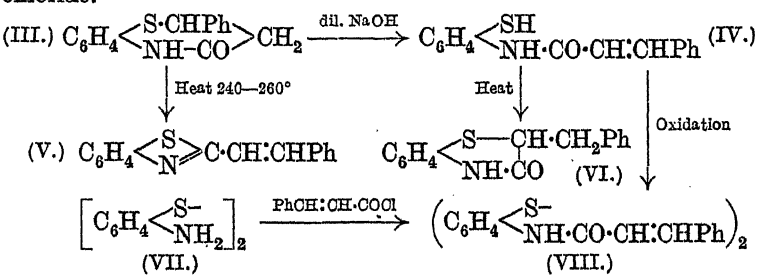
IN the course of some experiments carried out with *o*-aminothiophenol with the view of synthesising a carbothiocyanine dye (J., 1922, **121**, 455), we found that this base reacted in an unexpected manner with glutaconic acid. The two substances interacted very readily when heated together, but the product of the reaction was not the anticipated benzthiazole derivative; it was a new compound formed by the condensation of one molecule of glutaconic acid and one molecule of aminothiophenol, with the elimination of one molecule of water, as shown in the equation



$$C_6H_7NS + C_5H_6O_4 = C_{11}H_{11}O_3NS + H_2O.$$

It was a monobasic acid and it showed none of the reactions characteristic either of the ethylenic linking, the thiol group, or the amino-group. In the interaction, therefore, both the thiol group and the amino-group of the aminothiophenol and the ethylenic linking and one of the carboxyl groups of the glutaconic acid are concerned. That addition of some group to the ethylenic linking had occurred was further indicated by the fact that the new compound was resolvable into antimeric optically active forms, for it would seem that the only way in which an asymmetric carbon atom could be produced in its molecule would be through addition to this linking.

The behaviour of the following αβ-unsaturated acids towards *o*-aminothiophenol was then examined: acrylic, crotonic, and cinnamic acids, and they were all found to react with it similarly to glutaconic acid.



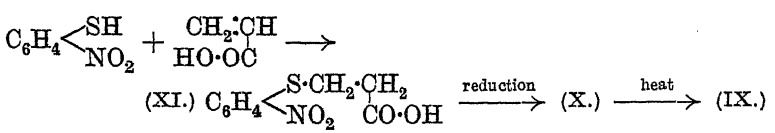
There are four ways in which the observed condensations might occur:

In the first place, *addition of the thiol group* of the aminothiophenol to the ethylenic linking of the acid might take place, accompanied by condensation between the amino- and carboxyl groups. This would give two possible formulæ, according as the sulphur was attached (1) to the α-carbon atom (formation of a ketodihydro-1 : 4-benzthiazine derivative, I), or (2) to the β-carbon atom (formation of a ketotetrahydro-1 : 5-heptabenzthiazine derivative, II).

Alternatively, *addition of the amino-group* of the aminothiophenol to the ethylenic linking of the acid might occur, with condensation between the carboxyl and thiol groups. This would give two further possible constitutions—(3) and (4)—according to whether the nitrogen was attached to the α- or the β-carbon atom.

We found that actually condensation of the amino-group of the aminothiophenol with the carboxyl group of the acid had occurred and that therefore addition of the thiol group to the ethylenic linking had taken place. This was established by examining the compound obtained from cinnamic acid and aminothiophenol. The resulting compound was an indifferent substance, but on being heated with dilute alkalis it dissolved gradually, forming a yellow solution from which carbon dioxide precipitated an isomeric compound, which could be proved to have the constitution (IV); for it had all the properties of a thiophenol, being soluble in alkalis, giving a mercuric derivative with mercuric chloride, and being converted by atmospheric oxygen and various other oxidising agents—iodine, ferric chloride, or hydrogen peroxide—with loss of one atom of hydrogen into a compound insoluble in alkalis, which was shown to be the disulphide (VIII), since it could be synthesised by introducing a cinnamoyl group into each of the two amino-groups of *oo'*-diaminodiphenyl disulphide (VII), by treatment with cinnamoyl chloride.

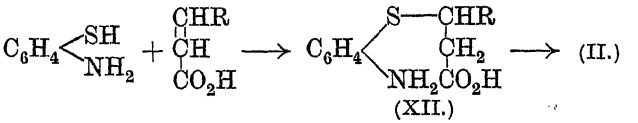
These observations limit the possible formulæ for the compound to (I), the ketodihydrobenzthiazine, or (II), the ketotetrahydroheptabenzthiazine (R = Ph). The behaviour towards alkalis, however, is different from that recorded for the ketodihydrobenzthiazines, which, according to Unger and Graff (*Ber.*, 1897, **30**, 2387), undergo, on boiling with potash, fission of the heterocyclic ring between the -NH- and -CO- groups. Further, the compound could be shown definitely not to be a ketodihydrobenzthiazine, since it was different from the *keto-2-benzyldihydrobenzthiazine* (VI) we obtained, according to the general method described by Unger and Graff (*loc. cit.*) for preparing these compounds, by heating *o*-aminothiophenol with α-bromo-β-phenylpropionic acid.



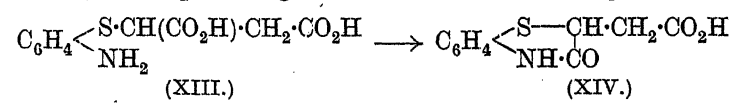
Similarly, our products from acrylic acid and crotonic acid and aminothiophenol are different from the keto-2-methyldihydrobenzthiazine and the keto-2-ethyldihydrobenzthiazine obtained by Unger and Graff from α-bromopropionic acid and α-bromobutyric acid and aminothiophenol; also we found that α-bromoglutaric acid (employed in the form of its ester) gave a different product from that obtained with glutaconic acid.

The compounds in question are therefore ketotetrahydroheptabenzthiazines of the general formula (II).

A final confirmation of the correctness of this conclusion was secured by showing that the compound got by heating aminothiophenol with acrylic acid is identical with the ε-lactam (IX) obtained by Mayer and Horst (*Ber.*, 1923, **56**, 1415) by heating β-2-aminophenylthiolpropionic acid (X), and further by the synthesis of this



compound from *o*-nitrothiophenol and acrylic acid, as follows, the initial condensation evidently consisting in β-addition of the thiol group of the nitrothiophenol to the ethylenic linkage of the acrylic acid:



When *cinnamamidothiophenol* (IV) (see scheme on p. 2739) is heated, it is not converted into 1-styrylbenzthiazole (V) as perhaps might have been expected, but ring closure takes place through addition of the thiol group to the ethylenic linkage. The product is, however, not the original ε-lactam (III) (*keto-2-phenyltetrahydroheptabenzthiazine*), but the isomeric δ-lactam (VI) (keto-2-benzyldihydrobenzthiazine), the sulphur becoming attached to the α-carbon atom of the ethylenic linking. The tendency to the formation of a six- rather than of a seven-membered ring thus over-rides the natural tendency of the sulphur atom of the thiol group to attach itself to the β-carbon atom of the ethylenic linking (Posner, *Ber.*, 1907, **40**, 4788). It follows from this fact that, in the interaction of the αβ-unsaturated acids with *o*-aminothiophenol, of the various reactions possible that which takes place with the greatest velocity (excluding of course salt formation between the acid and base) is the addition of the thiol group to the ethylenic linking, the sulphur becoming attached to the β-carbon atom, the resulting aminophenyl-

thiolpropionic acid (XII) passing, at the temperature employed, with loss of water into its ε-lactam :

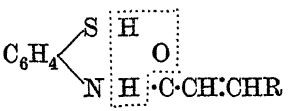
(XII.)

To test this conclusion, the interactions of *o*-aminothiophenol with maleic acid and with monobromosuccinic acid were studied. In all the other cases investigated, we have seen that a different product was obtained according as *o*-aminothiophenol was heated with a given αβ-unsaturated acid or with the corresponding α-bromo-saturated acid. In this one case, however, identical products should be formed, since in the intermediate product (XIII) arising from maleic acid there is, besides the carboxyl group to which, as in the other cases, the amino-group is in the ε-position, a second carboxyl group to which it is in the δ-position and with which it can consequently react, producing a normal six-membered ring :

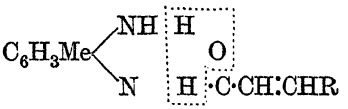
(XIII.) (XIV.)

The result was as expected, the same product (3-*ketodihydrobenzthiazine*-2-*acetic acid*, XIV) being obtained by heating either maleic acid or monobromosuccinic acid with *o*-aminothiophenol.

If the ε-lactam (keto-2-phenyltetrahydroheptabenzthiazine, III obtained by heating *o*-aminothiophenol with cinnamic acid is heated to 240—260°, water is eliminated and there is formed, although not very smoothly, 1-styrylbenzthiazole (V). This explains why Hofmann (*Ber.*, 1880, **13**, 1235) had obtained from *o*-aminothiophenol and cinnamic acid this benzthiazole derivative, whilst we had found the product of the reaction to be the ε-lactam; we had worked at 160—170°, whereas Hofmann had heated the mixture on a sand-bath. Hofmann's procedure does not, however, provide an advantageous method for preparing the benzthiazole base : it can be much more readily prepared by treating *o*-aminothiophenol (or, better, its sodium salt) with cinnamoyl chloride in the cold. On the other hand, we found that the corresponding saturated acid, β-phenylpropionic acid, reacted readily with *o*-aminothiophenol to give phenylethylbenzthiazole.



If *o*-aminothiophenol is heated with ethyl cinnamate instead of with cinnamic acid, a higher temperature has to be employed to bring about reaction, and the product is then the δ-lactam (keto-2-benzyldihydrobenzthiazine, VI).



Thus, according as *o*-aminothiophenol is heated with cinnamic

acid, its ester, or its chloride, three different heterocyclic compounds are obtained.

o-Aminothiophenol —(cinnamic acid)→ Ketophenyltetrahydroheptabenzthiazine (III).
o-Aminothiophenol —(ethyl cinnamate)→ Ketobenzyldihydrobenzthiazine (VI).
o-Aminothiophenol —(cinnamoyl chloride)→ Styrylbenzthiazole (V).

The non-formation of a benzthiazole base when *o*-cinnamamidothiophenol (IV) is heated, or when ethyl cinnamate is heated with *o*-aminothiophenol, shows that the attachment of a $-CH{:}CHR$ group, instead of a saturated system, to the carbon of the $-CO{\cdot}NH-$ group in *N*-acyl derivatives of *o*-aminothiophenol makes the elimination of water in the manner shown more difficult.

The corresponding phenomenon was observed by Fichter (*J. pr. Chem.*, 1906, **74**, 316) with the crotonyl and dimethylacrylyl derivatives of 1 : 3 : 4-tolylenediamine.

The ketotetrahydroheptabenzthiazines are readily acetylated when boiled with acetic anhydride. This was also observed by Mayer and Horst, who found (*loc. cit.*) that their ε-lactam reacted easily with acetic anhydride. However, they assigned to the product the formula (XV), which is at variance with the composition we find for it and for the two corresponding derivatives which we have obtained from our analogous ε-lactams; the molecule is actually less by the elements of a molecule of water than this formula indicates. It is also at variance with the chemical character of the compounds: they are neutral and unaffected by cold

(XV.) $C_6H_4\langle^{S{\cdot}CH_2{\cdot}CH_2{\cdot}CO_2H}_{NHAc}$ $\quad$ $C_6H_4\langle^{S-\!-CHR}_{NAc{\cdot}CO}\rangle CH_2$ (XVI.)

$C_6H_4\langle^{S{\cdot}CH_3}_{NH{\cdot}CO}\rangle CH_3$ (XVII.)

sodium carbonate solution. Since, moreover, the acetyl group is readily eliminated on warming with dilute hydrochloric acid or sodium carbonate with regeneration of the original lactam, the constitution of these acetyl derivatives is clearly that represented by (XVI). Their ready formation is in accordance with the fact observed by Ulffers and von Janson (*Ber.*, 1894, **27**, 93) and by Sudborough (J., 1901, **79**, 533) that diacetylation of a primary aromatic amine is particularly easy when there is another substituent group in the ortho-position to the amino-group. These ε-lactams are closely related in constitution to *o*-acetamidothio-

anisole (XVII) (linking of the two methyl groups in which, with removal of two atoms of hydrogen, would yield the ε-lactam of Mayer and Horst), and Mr. G. E. Watts, working in this laboratory, found that *o*-aminothioanisole is readily converted into a diacetyl derivative when heated with acetic anhydride.

An interesting alternation in properties exists between the γ-, δ-, and ε-lactams, benzthiazolone (XVIII), ketodihydrobenzthiazine (XIX), and ketotetrahydroheptabenzthiazine (IX), with respect to

(XVIII.) $C_6H_4\langle^{S-}_{NH}\rangle CO$ $\qquad\qquad$ $C_6H_4\langle^{S—CH_2}_{NH\cdot CO}$ (XIX.)

acetylation. Benzthiazolone (for which a new method of preparation is described in the experimental part) and, as has been stated, the ε-lactam (IX) are readily acetylated when boiled with acetic anhydride, whilst ketodihydrobenzthiazine is not (Unger and Graff, *loc. cit.*).

EXPERIMENTAL.

I. *Glutaconic Acid and* o-*Aminothiophenol.*

4-Ketotetrahydro-1 : 5-heptabenzthiazine-2-acetic Acid (II; R = $CH_2\cdot CO_2H$).—A mixture of glutaconic acid (2·5 g.) and *o*-aminothiophenol (2·5 g.; 1 mol.) was heated in an atmosphere of carbon dioxide at 120—130° for 20 minutes. A vigorous reaction occurred and after a few minutes the whole had set to a crystalline mass, which, recrystallised from dilute alcohol or water, yielded the pure product as thin, colourless, silky needles, m. p. 235—236° (decomp.). Yield, 4 g. (84·4%) (Found : C, 55·5; H, 4·6. $C_{11}H_{11}O_3NS$ requires C, 55·7; H, 4·6%).

The compound dissolves readily in dilute aqueous sodium carbonate and can be sharply titrated against sodium hydroxide and phenolphthalein [0·2607 g. required 11·1 c.c. *N*/10-NaOH. Found : *M*, 234·8 (monobasic). $C_{11}H_{11}O_3NS$ requires *M*, 237]. It has no marked basic properties, dissolving in hot, concentrated hydrochloric acid and crystallising unchanged on cooling. It is soluble in acetone or glacial acetic acid, sparingly soluble in ether, and practically insoluble in benzene, ligroin, or chloroform.

The *ethyl* ester was prepared by keeping the acid (1 g.) in excess of cold, absolute alcohol, containing dry hydrogen chloride, for 24 hours; when the resulting solution was diluted, and neutralised with sodium carbonate, the *ester* separated in small, lustrous, colourless needles (0·8 g.), which, after recrystallisation from benzene–ligroin, melted at 139—140° (Found : C, 58·7; H, 5·7. $C_{13}H_{15}O_3NS$ requires C, 58·9; H, 5·7%). It is readily soluble in alcohol, ether, or benzene, and sparingly soluble in ligroin.

The ester was also obtained directly from ethyl glutaconate: A mixture of ethyl glutaconate (1 mol.) and *o*-aminothiophenol (1 mol.) was heated under reflux, in an atmosphere of carbon dioxide, at 160—180° for 3 hours; a brown gum was then obtained, from which some crystals separated on standing. The crystalline product was extracted from the gum with hot ligroin, from which it separated on cooling in small, colourless, glistening needles, m. p. 138—140°. A mixture with the ester prepared as described above melted at 139—140°.

Resolution of 4-*Ketotetrahydro*-1 : 5-*heptabenzthiazine*-2-*acetic Acid into Optically Active Components.*—d-4-*Ketotetrahydro*-1 : 5-*heptabenzthiazine*-2-*acetic acid.* From a solution of the *dl*-acid (4·7 g.) and anhydrous brucine (7·9 g.) in warm alcohol (60 c.c.) the brucine salt was rapidly deposited in small, soft, colourless needles. After cooling, the salt was collected and recrystallised three times from alcohol; its specific rotation then became constant. The l-*brucine* d-4-*ketotetrahydro*-1 : 5-*heptabenzthiazine*-2-*acetate* so obtained gave m. p. 164—165° (softening at 155°) and $[\alpha]_{5461}^{20°}$ +154·7° in aqueous solution ($l = 2$; $c = 0{\cdot}527$). On decomposition of this salt with cold, dilute hydrochloric acid, the d-*acid* was deposited in fine, colourless needles, which on recrystallisation from alcohol gave the pure *d*-acid (1 g.), m. p. 230° and $[\alpha]_{5780}^{20°}$ +436·9°, $[\alpha]_{5461}^{20°}$ +506°, $[\alpha]_{4359}^{20°}$ +981° in absolute ethyl alcohol ($l = 2$; $c = 0{\cdot}6008$) (Found: C, 56·0; H, 4·7. $C_{11}H_{11}O_3NS$ requires C, 55·7; H, 4·6%).

Ethyl d-4-*ketotetrahydro*-1 : 5-*heptabenzthiazine*-2-*acetate* was obtained by treating the pure *d*-acid with cold alcoholic hydrogen chloride. It separated from benzene–ligroin in short, thin, colourless needles, m. p. 145—146° and $[\alpha]_{5780}^{20°}$ +424·5°, $[\alpha]_{5461}^{20°}$ +491·7°, $[\alpha]_{4359}^{20°}$ +948·8° in absolute alcohol ($l = 2$; $c = 0{\cdot}5512$).

l-4-*Ketotetrahydro*-1 : 5-*heptabenzthiazine*-2-*acetic acid.* The crude *l*-acid (1·7 g.), recovered from the mother-liquor of the above described brucine salt, and cinchonine (2·2 g.), were dissolved in alcohol (12 c.c.). After the addition of ether, the cinchonine salt gradually separated in small, colourless prisms, which were recrystallised twice from aqueous alcohol; m. p. 193—195° (softening at 175—180°). This salt, decomposed with cold, dilute hydrochloric acid, gave the pure l-*acid* (0·5 g.) in microscopic, colourless needles, m. p. 229—230° and $[\alpha]_{5780}^{20°}$ −435·5°, $[\alpha]_{5461}^{20°}$ −505°, $[\alpha]_{4359}^{20°}$ −976° in absolute ethyl alcohol ($l = 2$; $c = 0{\cdot}6004$).

Ethyl 3-*Keto*-2 : 3-*dihydro*-1 : 4-*benzthiazine*-2-*propionate* (I; R = $CH_2{\cdot}CO_2Et$).—This compound was synthesised for comparison with the compound obtained from *o*-aminothiophenol and glutaconic acid. It melts at 91°, whilst the isomeric ethyl ketotetrahydro-1 : 5-heptabenzthiazine-2-acetate melts at 139—140°.

o-Aminothiophenol (3·4 g.; 2 mols.) and ethyl α-bromoglutarate (3·2 g.) were heated together under reflux, in an atmosphere of carbon dioxide, at 120—130° for an hour; a brisk reaction then occurred with elimination of alcohol and formation of a crystalline material (hydrobromide). The crude product was extracted with hot ligroin, from which *ethyl* 3-*keto*-2 : 3-*dihydro*-1 : 4-*benzthiazine*-2-*propionate* separated in small, colourless, silky needles; these, after recrystallisation from ligroin, melted at 91° (Found: C, 58·8; H, 5·6. $C_{13}H_{15}O_3NS$ requires C, 58·9; H, 5·7%). The residue remaining after the extraction of the ester consisted of the hydrobromide of *oo'*-diaminodiphenyl disulphide. On hydrolysis of the ester, 3-keto-2 : 3-dihydro-1 : 4-benzthiazine-2-propionic acid was obtained in colourless needles, m. p. 174—175°.

II. *Cinnamic Acid and* o-*Aminothiophenol.*

4-*Keto*-2-*phenyltetrahydro*-1 : 5-*heptabenzthiazine* (III).—A mixture of o-aminothiophenol (8 g.) and cinnamic acid (10 g.) was heated for 2 hours under reflux, in an atmosphere of carbon dioxide, at 160—170°; a vigorous reaction then set in with elimination of water. On cooling, the product set to a hard, reddish-brown mass which, on crystallisation from alcohol, yielded 4-*keto*-2-*phenyltetrahydro*-1 : 5-*heptabenzthiazine* in short, colourless, silky needles, m. p. 177°. Yield 11 g. (Found: C, 70·5; H, 5·0. $C_{15}H_{13}ONS$ requires C, 70·6; H, 5·1%).

The compound is soluble in chloroform, acetone, or glacial acetic acid, sparingly soluble in ether or benzene, and insoluble in water. It dissolves in hot concentrated hydrochloric acid and separates from the solution unchanged on cooling.

The *acetyl* derivative (XVI; R = Ph) was obtained by boiling the substance with excess of acetic anhydride for 15 minutes. It crystallised from alcohol in short, glistening, colourless needles, m. p. 155—156° (Found: C, 68·2; H, 5·0. $C_{17}H_{15}O_2NS$ requires C, 68·7; H, 5·0%). It is readily hydrolysed by warming on the water-bath with dilute hydrochloric acid, giving the original material.

The Sulphoxide, $C_6H_4\langle^{SO\cdot CHPh}_{NH-\!-CO}\rangle CH_2$.—To a solution of the heptabenzthiazine (0·6 g.) in warm acetone (15 c.c.), a 4% solution of potassium permanganate in aqueous acetone was added until in slight excess, together with a little dilute sulphuric acid. The mixture was then boiled and filtered hot and the residue was extracted with hot acetone. The almost pure *sulphoxide* separated from the filtrate and was collected after dilution with water and cooling. It separated from acetone–alcohol or from dilute acetic

acid in clusters of thin, silky needles, m. p. 210° (Found: C, 66·4; H, 4·8. $C_{15}H_{13}O_2NS$ requires C, 66·4; H, 4·8%).

The sulphoxide is soluble in glacial acetic acid, sparingly soluble in alcohol or ether, and insoluble in water. It can also be obtained, in an almost pure condition, by treating the heptabenzthiazine with hydrogen peroxide (30%) in cold glacial acetic acid solution and diluting the mixture with water after several hours.

The Sulphone.—To a solution of the heptabenzthiazine (0·7 g.) in glacial acetic acid (10 c.c.), excess of 5% aqueous potassium permanganate (20 c.c.) was slowly added at room temperature, with stirring. The *sulphone* soon began to separate from the solution and after an hour the product was collected and recrystallised from dilute acetic acid, the solution being decolorised by charcoal. It was thus obtained in short, colourless, glistening needles, m. p. 234—235° (Found: C, 62·6; H, 4·6. $C_{15}H_{13}O_3NS$ requires C, 62·7; H, 4·5%).

The sulphone is moderately easily soluble in glacial acetic acid, sparingly soluble in alcohol or benzene, and insoluble in light petroleum, chloroform, or water. It is also formed when the heptabenzthiazine is oxidised by chromic acid in boiling glacial acetic acid solution.

Action of Alkali on 4-Keto-2-phenyltetrahydro-1 : 5-heptabenzthiazine: Formation of o-Cinnamamidothiophenol (IV).—When the heptabenzthiazine is heated for some time with excess of dilute caustic alkali solution, complete hydrolysis takes place into cinnamic acid and *o*-aminothiophenol. When, however, it is carefully heated with a small excess of caustic alkali, the product is *o-cinnamamidothiophenol.*

4-Keto-2-phenyltetrahydro-1 : 5-heptabenzthiazine (4 g.) was heated with 10% caustic potash solution (40 c.c.) and a little alcohol (8 c.c.) under reflux for 20—30 minutes, a deep yellow solution being obtained. After cooling, this was diluted with water and treated with carbon dioxide; *o*-cinnamamidothiophenol was then precipitated as a faintly yellowish-white, pasty mass. It crystallised from alcohol in clusters of small, almost colourless needles, m. p. 147—148°. Yield, 2 g. (Found: C, 70·6; H, 5·2. $C_{15}H_{13}ONS$ requires C, 70·6; H, 5·1%).

o-Cinnamamidothiophenol is readily soluble in acetone, chloroform, or benzene, and moderately easily soluble in ether or ligroin. It dissolves in caustic soda and slowly in sodium carbonate, giving yellow solutions, from which it is precipitated on acidification. It is readily oxidised to the corresponding disulphide by means of iodine, hydrogen peroxide or ferric chloride, or by exposure to the air.

The *mercurichloride* is precipitated when an alcoholic solution of the cinnamamidothiophenol is treated with aqueous mercuric chloride. It crystallises from alcohol, in which it is only sparingly soluble, in fine, colourless needles, m. p. 211—212°.

Conversion of o-*Cinnamamidothiophenol into* 3-*Keto*-2-*benzyl*-2 : 3-*dihydro*-1 : 4-*benzthiazine* (VI).—*o*-Cinnamamidothiophenol was heated in an atmosphere of dry carbon dioxide at 165—170° for 4—6 hours. The resulting dark, viscous liquid set, on cooling, to a hard, glassy mass, which was powdered and extracted with ether. The colourless, crystalline residue separated from alcohol in clusters of small, yellowish-white, silky needles. It proved to be 3-keto-2-benzyldihydro-1 : 4-benzthiazine and melted, alone or mixed with a specimen synthesised from α-bromo-β-phenylpropionic acid and *o*-aminothiophenol (see below), at 159—160°.

oo′-*Dicinnamamidodiphenyl Disulphide* (VIII).—(a) *From* o-*cinnamamidothiophenol.* From a solution of *o*-cinnamamidothiophenol (1 g.) in cold acetone (30 c.c.) to which excess of 30% hydrogen peroxide (2—3 c.c.) had been added, the *disulphide* soon separated as a mass of colourless, silky needles, which, after recrystallisation from acetone or glacial acetic acid, and when mixed with the pure disulphide synthesised as described below, melted at 163—164° (Found: C, 70·9; H, 4·8. $C_{30}H_{24}O_2N_2S_2$ requires C, 70·9; H, 4·7%).

(b) *From* oo′-*diaminodiphenyl disulphide* (VII). A solution of cinnamoyl chloride (2·6 g.) in dry benzene was gradually added to a solution of *oo′*-diaminodiphenyl disulphide (3·9 g.) in the same solvent. After 30 minutes, the pasty product was collected and treated with warm alcohol to remove the hydrochloride of the diaminodiphenyl disulphide, and the residue was crystallised from glacial acetic acid; pure *oo′*-dicinnamamidodiphenyl disulphide then separated in colourless, silky needles, m. p. 163—164° (Found: C, 71·0; H, 4·8%).

The disulphide is readily soluble in chloroform or hot benzene, sparingly soluble in alcohol, and insoluble in light petroleum.

Bromo-derivative. To a solution of *oo′*-dicinnamamidodiphenyl disulphide (0·5 g.) in dry chloroform (12 c.c.), a 10% solution of bromine in dry chloroform (6 c.c.) was gradually added; a colourless, pasty solid was then precipitated. After being washed with chloroform, this crystallised from acetone in small, glistening, colourless plates (0·4 g.), which darkened at 205° and melted at 213° (decomp.) (Found: C, 54·2; H, 3·6; Br, 23·8.

$$C_{30}H_{24}O_2N_2Br_2S_2$$

requires C, 53·9; H, 3·6; Br, 24·0%).

3-*Keto*-2-*benzyl*-2 : 3-*dihydro*-1 : 4-*benzthiazine* (VI).—(a) *From* α-*bromo*-β-*phenylpropionic acid.* A mixture of α-bromo-β-phenyl-

propionic acid (2·5 g.) and *o*-aminothiophenol (2 g.) was heated in an atmosphere of carbon dioxide at 125—130°; a vigorous reaction then set in and was complete after about 20 minutes. The crude product was crystallised twice from alcohol, pure *3-keto-2-benzyl-2 : 3-dihydro-1 : 4-benzthiazine* being obtained in short, colourless, silky needles, m. p. 159—160° (1·6 g.) (Found: C, 70·3; H, 5·1. $C_{13}H_{15}ONS$ requires C, 70·6; H, 5·1%). This substance is readily soluble in acetone, chloroform, benzene, or glacial acetic acid and moderately easily soluble in ligroin or ether. It is insoluble in concentrated hydrochloric acid and in dilute caustic soda solution, but it dissolves in cold, concentrated sulphuric acid to a yellow solution, from which it is precipitated unchanged by water. It does not form an acetyl derivative.

(b) *From ethyl cinnamate.* A mixture of ethyl cinnamate (3 g.) and *o*-aminothiophenol (2 g.) was heated under reflux in an atmosphere of carbon dioxide at 230—240° for 4—5 hours. The crude product was a deep red, oily liquid, which, on treatment with ether, yielded a pale yellow, crystalline solid. Recrystallised from alcohol, this separated in small, faintly yellow, silky needles, m. p. and "mixed m. p." with pure 3-keto-2-benzyldihydro-1 : 4-benzthiazine synthesised as above, 159—160° (Found: C, 70·5; H, 5·0%).

1-Styrylbenzthiazole (V).—(a) *From cinnamoyl chloride.* The condensation of cinnamoyl chloride with *o*-aminothiophenol takes place readily in cold benzene solution, but the following method, using the sodium salt of the aminothiophenol, is more satisfactory.

To a solution of *o*-aminothiophenol (1·3 g.) and sodium (0·23 g.) in absolute alcohol (12 c.c.), cinnamoyl chloride (1·6 g.) was gradually added, the mixture warmed on the water-bath for a few minutes, and the solution filtered from the precipitated sodium chloride and concentrated. On cooling, *1-styrylbenzthiazole* was deposited from the solution and on recrystallisation from alcohol it separated in short, thick, colourless prisms (1 g.), m. p. 112—113° (Found: C, 75·7; H, 4·8. $C_{15}H_{11}NS$ requires C, 75·9; H, 4·6%).

The *picrate* crystallised from alcohol, in which it is only sparingly soluble, in bright yellow platelets, m. p. 195—196°.

(b) *From 4-keto-2-phenyltetrahydro-1 : 5-heptabenzthiazine.* The thiazine was heated at 240—260° for about an hour; water was evolved and the fused mass changed to a dark brown gum, which set to a hard solid. This was crystallised twice from alcohol (charcoal) and 1-styrylbenzthiazole was then obtained in short, colourless prisms. These, alone or mixed with the pure base obtained by method (a), melted at 112—113°. The yield was poor.

(c) *From cinnamic acid* (compare Hofmann, *Ber.*, 1880, **13**, 1235).

Cinnamic acid (2 g.) and *o*-aminothiophenol (1·8 g.) were heated together at 210—220° for about 2 hours; a dark-coloured gum was obtained which was difficult to purify. On treatment with picric acid in alcoholic solution, however, the picrate of the benzthiazole base was precipitated, and after crystallisation from alcohol (charcoal), this was obtained in bright yellow platelets (1 g.), m. p. 195—196° (Found: C, 54·3; H, 2·9. $C_{21}H_{14}O_7N_4S$ requires C, 54·1; H, 3·0%).

The base was also obtained in small yield by heating together cinnamic acid and aminothiophenol at a higher temperature and treating the crude product with alkali, according to Hofmann's method. Its formation did not readily take place below about 220°.

β-*Phenylpropionic Acid and* o-*Aminothiophenol:* 1-β-*Phenylethylbenzthiazole.*—A mixture of β-phenylpropionic acid (1 mol.) and *o*-aminothiophenol (1 mol.) was heated under reflux in an atmosphere of carbon dioxide at 160—170° for 2 hours. The crude product was heated for a short time on the water-bath with 10% caustic soda solution; the yellow oil obtained solidified on cooling, and on crystallisation from dilute alcohol it yielded 1-β-*phenylethylbenzthiazole* in lustrous, colourless platelets, m. p. 60—61° (Found: C, 75·4; H, 5·5. $C_{15}H_{13}NS$ requires C, 75·3; H, 5·4%). The base is moderately easily soluble in cold alcohol and readily soluble in ether.

The *picrate* separates from alcohol in small, bright yellow plates, m. p. 132—133°.

III. *Crotonic Acid and* o-*Aminothiophenol.*

4-*Keto*-2-*methyltetrahydro*-1 : 5-*heptabenzthiazine* (II; R = Me).—A mixture of crotonic acid (1·3 g.) and *o*-aminothiophenol (1·8 g.) was heated in an atmosphere of carbon dioxide at 165—170° for 20 minutes. A vigorous reaction then occurred and the whole set to a crystalline mass, which, recrystallised from alcohol, yielded pure 4-*keto*-2-*methyltetrahydro*-1 : 5-*heptabenzthiazine* in small, granular, colourless plates (2 g.), m. p. 205—206° (Found: C, 61·9; H, 5·6. $C_{10}H_{11}ONS$ requires C, 62·2; H, 5·7%).

The compound is soluble in glacial acetic acid, benzene, or ligroin, and sparingly soluble in ether. It crystallises from chloroform in thin needles.

The *acetyl* derivative (XVI; R = Me) was obtained by boiling the substance with excess of acetic anhydride for 10 minutes, and separated from dilute alcohol in thin, colourless, glistening needles, m. p. 93° (Found: C, 60·9; H, 5·5. $C_{12}H_{13}O_2NS$ requires C, 61·3; H, 5·5%). It is readily hydrolysed by warming on the water-bath with dilute hydrochloric acid or sodium carbonate for a short time,

giving the original material (m. p. 205—206°). It is moderately easily soluble in alcohol and readily soluble in ether.

IV. *Acrylic Acid and* o-*Aminothiophenol.*

4-Ketotetrahydro-1 : 5-heptabenzthiazine (IX).—Acrylic acid (2 g.) and *o*-aminothiophenol (3·5 g.) were heated together in an atmosphere of carbon dioxide at 125—130° for about an hour. The crystalline product was washed with ether and recrystallised from dilute alcohol, from which *4-ketotetrahydro-1 : 5-heptabenzthiazine* separated in small, lustrous, colourless needles (1·3 g.), m. p. 215—216° (Found: C, 60·5; H, 5·1. C_9H_9ONS requires C, 60·3; H, 5·0%). The compound is readily soluble in acetone or glacial acetic acid, sparingly soluble in benzene, and practically insoluble in ether, chloroform, or light petroleum.

The *acetyl* derivative (XVI; R = H) was obtained by boiling the compound with excess of acetic anhydride for 15 minutes. It crystallised from alcohol in small, colourless needles, m. p. 96—97° (Found: C, 59·8; H, 5·0; N, 6·3; S, 14·4. $C_{11}H_{11}O_2NS$ requires C, 59·7; H, 5·0; N, 6·3; S, 14·5%). It is hydrolysed by warm dilute hydrochloric acid, yielding the original material.

Synthesis of 4-Ketotetrahydro-1 : 5-heptabenzthiazine (IX) *from Acrylic Acid and* o-*Nitrothiophenol.*—The *o*-nitrothiophenol was obtained by reduction of *oo'*-dinitrodiphenyl disulphide by means of sodium sulphide (Claasz, *Ber.*, 1912, **45**, 747) and isolated from the solution by means of dilute acetic acid. It crystallised from light petroleum in pale yellow needles, m. p. 61°.

Addition of o-*nitrothiophenol to acrylic acid:* o-*Nitrophenylthiolpropionic acid* (XI). *o*-Nitrothiophenol (5·2 g.) and acrylic acid (2·4 g.) were together dissolved in dry benzene (25 c.c.) with the addition of 2—3 drops of piperidine, and the solution kept for 48 hours (compare Ruhemann, J., 1905, **87**, 17); o-*nitrophenylthiolpropionic acid* gradually separated in yellow crystals. Recrystallised from glacial acetic acid, it formed short, yellow needles (4 g.), m. p. 148—149° (Found: C, 47·7; H, 4·0. $C_9H_9O_4NS$ requires C, 47·6; H, 4·0%).

o-*Aminophenylthiolpropionic acid* (X). A mixture of *o*-nitrophenylthiolpropionic acid (4·5 g.), concentrated hydrochloric acid (15 g.), and tin (7·1 g.) was heated on the water-bath until the reduction was complete. The solution was then largely diluted with water, treated with hydrogen sulphide to precipitate the tin, and concentrated by evaporation in a vacuum. On cooling, the hydrochloride of *o*-aminophenylthiolpropionic acid separated in short, colourless needles, m. p. 173—174°, which soon became coloured on standing.

On treating the hydrochloride (1·2 g.) in concentrated aqueous solution with *N*-sodium hydroxide (5 c.c.), the *amino-acid* was obtained in colourless crystals (0·8 g.), which separated from dilute alcohol in short, thick needles, m. p. 87—88° (Found: C, 54·8; H, 5·7. $C_9H_{11}O_2NS$ requires C, 54·8; H, 5·6%) (compare Mayer and Horst, *loc. cit.*).

4-*Ketotetrahydro*-1 : 5-*heptabenzthiazine.* The hydrochloride of *o*-aminophenylthiolpropionic acid (1·5 g.) was heated at 180—190° for ½ hour, hydrogen chloride and water being eliminated. On cooling, the product set to a reddish-brown solid, which, crystallised from alcohol, yielded pure ketotetrahydro-1 : 5-heptabenzthiazine (0·2 g.) in lustrous, colourless needles, m. p. and "mixed m. p." with the lactam synthesised from acrylic acid and *o*-aminothiophenol, 215—216°.

The acetyl derivative of the lactam was obtained on heating the above hydrochloride with excess of acetic anhydride for 30 minutes.

V. *Maleic Acid and* o-*Aminothiophenol.*

3-*Keto*-2 : 3-*dihydro*-1 : 4-*benzthiazine*-2-*acetic Acid* (XIV).—Maleic acid (3·5 g.) and *o*-aminothiophenol (3 g.), when mixed, reacted readily with considerable development of heat and the whole soon set to a hard mass. After being heated for a few minutes at 100—110°, the product was crystallised from dilute alcohol, from which it separated in small, colourless needles, melting at 195—196°, and at the same temperature after mixture with pure 3-*keto*-2 : 3-*dihydro*-1 : 4-*benzthiazine*-2-*acetic acid* synthesised from *o*-aminothiophenol and monobromosuccinic acid (see below). Yield 5 g. (93·5%) (Found: C, 53·6; H, 4·0. $C_{10}H_9O_3NS$ requires C, 53·8; H, 4·0%).

The compound is soluble in alcohol, sparingly soluble in ether, and practically insoluble in benzene, chloroform, or ligroin. It crystallises from water in thin, silky needles. It dissolves readily in cold, dilute sodium carbonate solution and is precipitated on acidification. After boiling for some time with 10% caustic potash solution it was precipitated unchanged on acidification.

The same product was obtained from fumaric acid and *o*-aminothiophenol. In this case no reaction appeared to take place in the cold, but the compound was readily formed on heating the two substances together at 150—160° for 15 minutes.

3-*Keto*-2 : 3-*dihydro*-1 : 4-*benzthiazine*-2-*acetic Acid from Monobromosuccinic Acid.*—Monobromosuccinic acid (1 g.) and *o*-aminothiophenol (0·6 g.) were heated together in an atmosphere of carbon dioxide at 120—125° for 15 minutes; a vigorous reaction then occurred and the mixture soon set to a solid mass. The product

was crystallised twice from dilute alcohol (charcoal) and pure keto-dihydrobenzthiazineacetic acid was thus obtained in small, colourless needles (0·6 g.), m. p. 195—196° (Found: C, 54·2; H, 4·0%).

The following work was kindly carried out by Mr. G. E. WATTS:

Diacetyl Derivative of o-*Aminothioanisole.*—*o*-Aminothioanisole (10 g.) was boiled with acetic anhydride (30 g.; 4 mols.) for an hour. The resulting solution was distilled in a vacuum to remove acetic acid and anhydride, and the residual gum crystallised from alcohol, from which the *diacetyl* derivative separated in colourless, transparent prisms, m. p. 69—70°. Yield, 13 g. (82%) (Found: C, 59·1; H, 5·9; N, 6·1. $C_{11}H_{13}O_2NS$ requires C, 59·2; H, 5·8; N, 6·3%).

Preparation of Benzthiazolone (XVIII).—*Ethyl* o-*nitrophenylthiolformate*, $NO_2{\cdot}C_6H_4{\cdot}S{\cdot}CO_2Et$. To a solution (deep red) of *o*-nitrothiophenol (31 g.) in alcoholic sodium hydroxide (8 g. of NaOH in 30 c.c. of alcohol) a solution of ethyl chloroformate (21·7 g.) in alcohol (20 c.c.) was added, with shaking; the red colour of the nitrothiophenol soon disappeared, considerable heat was evolved, and sodium chloride was precipitated. The mixture was poured into water (500 c.c.) and the ethyl nitrophenylthiolformate, which separated as a yellow oil, was extracted with ether. It decomposed when heated in a vacuum.

Ethyl o-*aminophenylthiolformate.* Crude ethyl nitrophenylthiolformate (35 g.), mixed with alcohol (20 c.c.), was shaken with a solution of stannous chloride (115 g.) in concentrated hydrochloric acid (50 c.c.) for an hour, the mixture being cooled in ice from time to time. The solution was diluted, freed from tin by means of hydrogen sulphide, made alkaline with sodium bicarbonate, and extracted with ether. On removal of the ether the amino-ester remained as a colourless oil. Yield, 20 g. (67%).

The *hydrochloride* of the amino-ester was prepared by treating an alcoholic solution of the ester with hydrogen chloride and precipitated by the addition of ether. It crystallised from alcohol–ether in fine, colourless needles, m. p. 120—122° (Found: Cl, 15·2. $C_9H_{12}O_2NClS$ requires Cl, 15·2%).

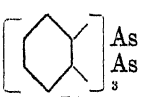
Benzthiazolone. Ethyl *o*-aminophenylthiolformate, mixed with a little of its hydrochloride, was heated at 115° for 2 hours; it then changed to a crystalline mass. This, recrystallised from aqueous alcohol, gave colourless needles of benzthiazolone; they melted at 128° and were readily soluble in strong alkalis and in strong mineral acids (compare Claasz, *Ber.*, 1912, **45**, 1029).

The acetyl derivative was obtained by boiling the substance with excess of acetic anhydride for 15 minutes. It separated from aqueous alcohol in fine, colourless needles, m. p. 50° (compare Claasz,

loc. cit.), and was readily hydrolysed by warm 10% sodium hydroxide solution, giving the original material.

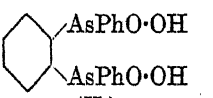
One of us (J. B. W.) wishes to express his indebtedness to the Chemical Society for a grant which defrayed part of the cost of this investigation.

UNIVERSITY CHEMICAL LABORATORY,
CAMBRIDGE. [*Received, August 25th*, 1927.]



CCCLXVI.—*Organic Compounds of Arsenic. Part III. Tri-o-phenylenediarsine.*

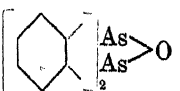
By NIAL PATRICK MCCLELAND and JAMES BELL WHITWORTH.



TRI-*o*-PHENYLENEDIARSINE (I) appears to be the first compound in which it is established that a pair of atoms is linked to each of three benzene rings in the ortho-position in such a way that, a symmetrical grouping being assumed, the planes of the rings are inclined at 120° to one another.

A substance, $C_{18}H_{12}N_2$, described in the literature as triphenylenediamine was obtained by von Dechend and Wichelhaus (*Ber.*, 1875, **8**, 1609) by the action of nitrobenzene on aniline or diphenylamine, but its constitution is unknown.

The new substance (I) was obtained as follows: Diazotised *o*-aminodiphenylarsinic acid coupled with phenylarsine oxide to give *phenylene*-1 : 2-*diphenylarsinic acid* (II), which was then reduced with phosphorus trichloride, presumably to phenylene-1 : 2-diphenylchloroarsine; this was not obtained in the pure state and on distillation it gave *tri*-o-*phenylenediarsine* (I), evidently by the loss of two molecules of hydrogen chloride and consequent double ring closure.



(I.)

(II.)

(III.)

(IV.)

The constitution of the substance (I) is supported by the following observations, which show that triphenylenediarsine bears the same relation to the derivatives of arsanthrene (Kalb, *Annalen*, 1921, **423**, 39) as the triarylarsines do to those of the diarylarsines: (1) as triphenylarsine dichloride decomposes on distillation into diphenylchloroarsine and chlorobenzene (La Coste and Michaelis, *Annalen*, 1880, **201**, 242; Michaelis, *ibid.*, 1902, **321**, 142, 160; Winmill, J., 1912, **101**, 720), so triphenylenediarsine tetrabromide (III) on

heating gives (in addition to bromine and triphenylenediarsine) *o*-dibromobenzene and arsanthrene bromide; (2) as di-*p*-tolylarsenious oxide on heating gives tri-*p*-tolylarsine (La Coste, *Annalen*, 1881, **208**, 20), so arsanthrene oxide (IV) on distillation gives triphenylenediarsine and arsenious oxide as indicated by the equation 3 (IV) = 2 (I) + As_2O_3 (compare the decomposition of phenylarsine oxide into triphenylarsine and arsenious oxide on heating; La Coste and Michaelis, *ibid.*, p. 239).

Moreover, the substance behaves as a tertiary arsine, being converted into the oxide by nitric acid and forming a tetrabromide and a mercurichloride.

Triphenylenediarsine is formed in the preparation of arsanthrene chloride by Kalb's method (*loc. cit.*) and probably accounts for the sparingly soluble impurity which he found in arsanthrene oxide.

The stereochemistry of the new system is under investigation, and it is hoped to prepare corresponding compounds with other elements in place of arsenic.

EXPERIMENTAL.

Phenylene-1 : 2-*diphenylarsinic Acid* (II).—Into a well-stirred, diazotised solution of *o*-aminodiphenylarsinic acid (20 g.; concentrated hydrochloric acid, 58 c.c.; water, 700 c.c.; ice, 500 g.) was run a solution of phenyldichloroarsine (18 g.) in 5*N*-caustic soda (64 c.c.) to which sodium acetate (58 g.), dissolved in ice-water (450 c.c.), had been added just previously. The mixture was made alkaline with caustic soda, boiled with charcoal, and filtered. On acidification, the filtrate gave a yellowish-brown, pasty precipitate. This was boiled with alcohol, which removed most of the coloured impurity, the residue was dissolved in a large volume of dilute aqueous ammonia, the solution neutralised with acetic acid and boiled with charcoal, and an excess of dilute acetic acid added to the boiling filtered solution; *phenylene*-1 : 2-*diphenylarsinic acid* (9 g.) then slowly separated in pale yellow, microscopic crystals which did not melt below 310° and were insoluble in water and in the usual organic solvents (Found: C, 49·0; H, 3·5. $C_{18}H_{16}O_4As_2$ requires C, 48·4; H, 3·6%).

Tri-o-*phenylenediarsine* (I).—Phenylene-1 : 2-diphenylarsinic acid (9 g.), suspended in chloroform (100 c.c.), was treated with excess of phosphorus trichloride (25 g.), heat being evolved and most of the acid dissolving. The solution was heated on the water-bath for 3 hours and filtered from a little tar. On distillation of the solvent a dark brown, oily residue was obtained from which no crystalline product could be isolated. It was therefore heated under reduced pressure; vigorous frothing occurred at 120—300°,

and at 320—340°, crystals of *triphenylenediarsine* gradually sublimed on the upper part of the distilling flask, but no distillate was obtained. The crystalline product was collected and a further quantity was obtained on extracting the charred residue in the flask with hot benzene. On recrystallisation from benzene (charcoal), triphenylenediarsine (2·5 g.) was obtained in small, almost colourless plates, m. p. 295—296°. It is soluble in benzene, acetone, or light petroleum, readily soluble in chloroform, sparingly soluble in alcohol or ether, and insoluble in water. It can be sublimed without decomposition (Found: C, 57·4; H, 3·2; As, 40·1; *M*, in camphor by Rast's method, 360, 396, 364. $C_{18}H_{12}As_2$ requires C, 57·1; H, 3·2; As, 39·8%; *M*, 378).

The authors are indebted to Professor Hutchinson for the determination of the crystallographic constants:

System: Monoclinic (holohedral). $a : b : c = 1·589 : 1 : -$; $\beta = 113° 15'$. Forms present: *a*(100), *c*(001), *m*(110). Angles observed: *am* 55° 35′, *ac* 66° 45′.

The crystals are elongated parallel to the axis of the zone [*am*] and are either tabular parallel to *a* with *m* and *c* small or bounded by *m* and *c* planes with *a* small or absent. The face *c* is invariably somewhat rounded. The optic axial plane is perpendicular to the plane of symmetry and lies in the obtuse axial angle. A negative acute bisectrix emerges obliquely from *a*. On viewing the crystal in monochromatic convergent light perpendicular to a pair of *m* faces, the emergence of an optic axis near the edge of the field can be seen. In white light, the dark brush passing through the centre of the ring system is replaced by brilliant red and blue fringes, indicating strong dispersion, and no extinction can be obtained on the *m* face in parallel light. The material available did not lend itself to an accurate determination of the optical constants, but β for sodium light was found to be 1·790 approximately.

The *mercurichloride* was obtained in short, colourless needles from the diarsine and mercuric chloride in cold acetone; after recrystallisation from alcohol, in which it was sparingly soluble, it melted at 285—286°. It was readily decomposed by warm dilute caustic soda solution.

The *oxide* was obtained on boiling the diarsine with concentrated nitric acid and pouring the resulting solution into water. It was readily soluble in alcohol and separated from dilute aqueous alcohol in short, thin, colourless needles, which did not melt below 360° (Found: C, 52·6; H, 3·0. $C_{18}H_{12}O_2As_2$ requires C, 52·7; H, 2·9%).

The *tetrabromide* (III) was precipitated as an orange-red, crystalline substance, m. p. 255—256°, when the diarsine was treated with a small excess of bromine in dry chloroform (Found: Br, 45·7.

$C_{18}H_{12}Br_4As_2$ requires Br, 45·9%). It is readily soluble in acetone or alcohol and in hot glacial acetic acid (with decomp.), sparingly soluble in chloroform, and insoluble in ether, benzene, or light petroleum. It is readily decomposed by dilute caustic soda solution or even by water, giving the colourless oxide (Found: As, 36·4. Calc. for $C_{18}H_{12}O_2As_2$: As, 36·7%).

When the tetrabromide was heated under reduced pressure (15 mm.), decomposition took place at about 260°, much bromine was evolved, and a small quantity of a yellow liquid distilled; the residue set to a crystalline mass on cooling. The liquid product was dissolved in ether, treated with caustic soda to remove free bromine, and distilled in a vacuum, being thus obtained as a colourless oil, b. p. 104—105°/15 mm., 224°/ordinary pressure (Found: Br, 68·2. Calc. for $C_6H_4Br_2$: Br, 67·8%). On intensive cooling, the liquid set to a colourless solid, m. p. 4°. It was concluded that the liquid was *o*-dibromobenzene, which has b. p. 224° and m. p. 5·6°. (The *m*-isomeride has b. p. 220° and m. p. — 7°, and the *p*-isomeride, m. p. 87°.)

As it would probably have been difficult to separate the small amount of arsanthrene bromide from the triphenylenediarsine by recrystallisation, the crystalline residue was treated with alcoholic ammonia to convert the arsanthrene bromide into the oxide. After dilution with water, the product was collected and extracted with hot alcohol, the portion remaining undissolved consisting of triphenylenediarsine, which after recrystallisation from benzene gave m. p. and "mixed m. p." 295—296°. The cooled alcoholic extract was filtered from a small amount of the diarsine which had separated and was then concentrated. Arsanthrene oxide, which separated on cooling, crystallised from alcohol in small, lustrous plates which, alone or mixed with pure arsanthrene oxide, melted at 194—195°.

The presence of bromide in the ammoniacal liquor was verified.

Treatment of triphenylenediarsine with chlorine yielded a light yellow compound, which has not been investigated. Methyl iodide gave no addition compound on prolonged heating with the diarsine in a sealed tube at 50—60°.

Formation of Triphenylenediarsine from Arsanthrene Oxide.—Pure arsanthrene oxide distilled under 15 mm. pressure, without appreciable decomposition, as a yellow liquid, which rapidly solidified. When, however, the pure oxide was distilled in a current of carbon dioxide under only slightly reduced pressure, considerable decomposition took place. Arsenious oxide sublimed into the receiver, and a crystalline substance on the upper part of the distilling flask. The crystalline product was extracted with hot alcohol to remove any unchanged oxide and then recrystallised from

benzene, from which it separated in small, colourless plates, m. p. 295—296°, and at the same temperature after mixture with pure triphenylenediarsine. The dark brown residue in the distilling flask gave a further small quantity of the diarsine on extraction with benzene.

Triphenylenediarsine appears to be formed during the distillation of arsanthrene chloride, for, when arsanthrene chloride prepared by Kalb's method (*loc. cit.*) was converted into the oxide by alcoholic ammonia, and the oxide crystallised from alcohol, a small quantity of triphenylenediarsine remained undissolved. It separated from benzene in small, colourless plates, m. p. and "mixed m. p." with the pure diarsine 295—296° (Found: C, 57·3; H, 3·1%), and on oxidation with nitric acid it gave triphenylenediarsine oxide as fine needles (Found: C, 52·7; H, 2·8%).

CCCLXVII.—*The Halogenation of Phenols. Part II. Iodination.*

By FREDERICK GEORGE SOPER and GILBERT FREEMAN SMITH.

THE relative ionisation constants of chlorine and hypochlorous acid to give a positive halogen ion (Soper and Smith, J., 1926, 1582) express qualitatively the ease with which these substances chlorinate phenols. A study of the chlorination by hypochlorous acid showed, however, that the hypochlorous acid *molecule* was the chlorinating agent, so that the parallelism between the ease of chlorination and the ionisation constant of the chlorinating molecule is not due to preliminary ionisation into a reactive positive halogen ion. The ionisation constant of the halogenating agent may be regarded as a measure of the number of polarised molecules present and collisions between these and other molecules may be effective. It was of interest to extend this line of argument to iodination by iodine and by hypoiodous acid, the relative ionisation constants of which, given by the ratio K_h/K_w (K_h being the hydrolysis constant, $C_H.C_I C_{HOI}/C_{I_2} = 3 \times 10^{-13}$, of iodine in water; Bray and Connolly, *J. Amer. Chem. Soc.*, 1911, **33**, 1485), are as 30 to 1. It might be expected from this ratio that the ease of halogenation by iodine would be comparable with that by hypoiodous acid.

The mechanism of the iodination of phenols was investigated by Cofman (J., 1919, **115**, 1040), who showed that in acid solution iodine does not iodinate, whilst the active iodine in an alkaline

solution was equal to the concentration of hypoiodous acid, as calculated from the known kinetics of iodate formation (Skrabal, *Monatsh.*, 1911, **32**, 171). It might appear from these facts that iodine is incapable of iodination and that hypoiodous acid or (as Cofman suggests as an alternative) the positive iodine ion is the halogenating agent. As, however, in acid solution the phenol would be mainly un-ionised, whilst in alkaline solution the very much more highly reactive phenoxide ions would be present, the mechanism has been further examined in order to determine whether iodine is capable of reacting with phenoxide ions.

Examination of the speed of iodination of phenol was carried out by the use of a solution of iodine in potassium iodide in the presence of a neutral phosphate buffer. If molecular iodine is involved in the interaction, then the speed will be proportional, on the classical reaction-velocity equation, to the concentration of free iodine in the mixture. The equilibrium concentration of free iodine can be calculated from the expression $C_{I_2}C_{I'}/C_{I_3'} = K_1$ (Bray and MacKay, *J. Amer. Chem. Soc.*, 1910, **32**, 914), using the appropriate value for K_1 which depends on the iodide concentration. The speed of iodination at constant phenol concentration will thus be given by $v = k_{I_2}K_1C_{I_3'}/C_{I'}$, and since, in the presence of excess of iodide ions, $C_{I_3'}$ is represented sufficiently accurately by the thiosulphate titre of the solution, the velocity coefficient, k_1, of the reaction calculated from the equation

$$v = k_1 \times \text{thiosulphate titre} \quad . \quad . \quad . \quad . \quad (1)$$

should vary inversely as the iodide-ion concentration.

If the iodination is caused by hypoiodous acid, the velocity coefficient k_1 should vary approximately as the inverse of the square of the concentration of the iodide ion at constant hydrogen-ion concentration, for $C_{HOI}a_{H^+}.a_{I'}/C_{I_3} = K_h = 3 \times 10^{-13}$, a denoting the appropriate activity * of the ion, and hence

$$v = k_{HOI} \cdot C_{HOI} = k_{HOI}K_hK_1C_{I_3'}/a_{H^+}.a_{I'}C_{I'} \quad . \quad . \quad . \quad (2)$$

The results obtained are given in Table I. The values of the activity of the iodide ion, $a_{I'}$, have been interpolated for the appropriate ionic strength, μ, from a table of the activities of the chloride ion (Lewis and Randall, " Thermodynamics," 1924, p. 351). The concentrations of iodine and of hypoiodous acid given in cols. 4 and 6, respectively, are the initial equilibrium concentrations of these substances in the reaction mixture. The unimolecular coefficient k_1 (the mean of two experiments agreeing to within 1%) is seen to

* The activity of a neutral molecule has been equated to its concentration, in the absence of other information.

be proportional to the initial concentration of the hypoiodous acid. Although the concentration of the iodine is between 10^4 and 10^5 times that of the hypoiodous acid, there is no appreciable iodination by iodine.

TABLE I.

Ph·OH = 0·010; I_2 added = 0·001M; Temp. = 25·0°; $a_{H^+} = 10^{-7}$.

μ.	$C_{I'}$.	$K_1 . 10^3$.	$C_{I_2} . 10^5$.	$a_{I'}$.	$C_{HOI} . 10^{10}$.	k_1.	$\frac{10^{-4} . k_1}{C_{I_2}}$.	$\frac{10^{-8} . k_1}{C_{HOI}}$.
0·2092	0·1	1·31	1·295	0·0745	5·231	0·1926	1·486	3·685
0·3092	0·2	1·21	0·605	0·1434	1·287	0·0477	0·788	3·75
0·5092	0·4	1·00	0·250	0·2724	0·2752	0·0102	0·407	3·71

It is now necessary to differentiate between the interaction of hypoiodous acid and that of positive iodine ion with the phenol molecule or with the phenoxide ion. This is possible by an examination of the speed of iodination in solutions containing a constant concentration of iodide ion and various hydrogen-ion concentrations. Since the reaction is examined over the hydrogen-ion concentration range from $0·5 \times 10^{-7}$ to 4×10^{-7}, the phenol exists mainly in the un-ionised condition, its ionisation constant, K_a, being $1·1 \times 10^{-10}$. The concentration of phenoxide ions is thus inversely proportional to the hydrogen-ion concentration.

For a reaction between hypoiodous acid and phenol, the speed will be given by

$$v = k_2 C_{HOI} C_{Ph·OH} = k_2 K_1 K_h C_{Ph·OH} C_{I_3'}/a_{H^+} a_{I'} C_{I'}$$
$$= k_2 K_I K_h C_{Ph·OH} C_{I_3'}/a_{H^+} f_{I'} C_{I'}^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where $f_{I'}$ is the activity coefficient of the iodide ion. The velocity coefficient, k_1, of equation (1) should vary inversely as $f_{I'} a_{H^+}$, or, since the ionic strength is nearly constant in the different mixtures, inversely as the hydrogen-ion activity. If the reaction is between the phenoxide *ion* and hypoiodous acid,

$$v = k_3 C_{HOI} C_{Ph·O'}$$
$$= k_3 K_1 K_h K_a C_{Ph·OH} C_{I_3'}/a_{H^+}^2 f_{Ph·O'} f_{I'} C_{I'}^2 \quad . \quad . \quad (4)$$

and k_1 should vary approximately as the inverse of the square of the hydrogen-ion activity.

For iodination by positive iodine ions, the concentration of which is controlled by the equilibrium constant $K_2 = a_{I^+} a_{I'}/C_{I_2} = a_{I^+} C_{I'} f_{I'}/C_{I_2}$, the velocity equation will be $v = k_4 C_{Ph·OH} C_{I^+} = k_4 K_1 K_2 C_{Ph·OH} C_{I_3'}/C_{I'} a_{I'} f_{I'}$, and k_1 would be independent of the hydrogen-ion concentration, whilst for an interaction of positive iodine ion with the phenoxide ion the constant k_1 would be inversely proportional (approximately) to the hydrogen-ion concentration. Actually, experiments carried out at the hydrogen-ion

activities of 0·5, 1·0, 2·0, and 3·98 × 10^{-7} showed that the velocity coefficient k_1 varied more rapidly than the inverse of the hydrogen-ion activity of the mixture, but less rapidly than its inverse square. The results are summarised in Table II.

TABLE II.

Ph·OH = 0·010; KI = 0·100; temp. = 25·0°.

HPO_4''.	H_2PO_4'.	μ.	$f_{I'}$.	a_{H^+}. 10^7.	k_1 (obs.).	$10^7 \times k_1 a_{H^+}$.	$10^{14} \times k_1 a_{H^+}^2$.	k_1 (calc.).
0·0370	0·0130	0·224	0·741	0·5	0·420	0·210	0·105	0·440
0·0296	0·02037	0·209	0·745	1·0	0·193	0·198	0·193	0·182
0·0205	0·0295	0·191	0·752	2·0	0·083	0·166	0·322	0·081
0·0126	0·0374	0·175	0·759	3·98	0·036	0·143	0·570	0·038

Assigning the values 4·85 × 10^9 and 2·76 × 10^7 to k_3 and k_2 respectively, and taking the value of $f_{Ph\cdot O'}$ as equal to that of $f_{I'}$, k_1 has been calculated from the equation

$$v = k_2 C_{HOI} C_{Ph\cdot OH} + k_3 C_{HOI} C_{Ph\cdot O'}$$
$$= \frac{K_1 K_h C_{Ph\cdot OH} C_{I_2'}}{a_{H^+} \cdot C_{I'}^2 f_{I'}} (k_2 + k_3 K_a / a_{H^+} f_{Ph\cdot O'}) \quad . \quad . \quad . \quad (5)$$

which, in combination with (1), gives

$$k_1 = \frac{K_1 K_h C_{Ph\cdot OH}}{a_{H^+} \cdot C_{I'}^2 f_{I'}} (k_2 + k_3 K_a / a_{H^+} f_{Ph\cdot O'}) \quad . \quad . \quad . \quad (6)$$

Bearing in mind the necessarily approximate values used for the activities of the various ions and neutral molecules, the divergencies between the observed and calculated values of k_1 are not unreasonable.

Conclusions.

It would thus appear that the iodination of phenol is not caused by the positive iodine ion, but that the main reactions are those between the hypoiodous acid and the ionised and un-ionised phenol, the reactivity of the phenoxide ion being 180 times that of the phenol molecule. Molecular iodine is a singularly poor iodinating agent, being at least 10^6 times less active than hypoiodous acid in spite of its greater ease of ionisation and, presumably, its more highly polar condition.

The behaviour of halogens and the hypohalous acids towards phenols (as illustrated by chlorine and iodine) is thus not entirely explained on a theory of reactivity governed by the polar state of the molecules, iodination indicating that some other factor can dominate. This factor may be the affinity of the residual nuclear hydrogen for the residue of the halogenating molecule. The affinity of the hydrogen ion for the hydroxyl ion is so much greater than for the iodide ion that hypoiodous acid becomes very much

more reactive than iodine. In chlorination, however, the large difference in the affinities of Cl· for OH′ and for Cl′ ($4{\cdot}8 \times 10^{10}$ to 1) appears to be the controlling factor.

EXPERIMENTAL.

Buffer Solutions.—The phosphate buffer solutions were prepared from potassium dihydrogen phosphate (B.D.H., A.R.) and sodium hydroxide free from carbonate; the quantities taken (Table II) were interpolated from those given by Clark ("Determination of Hydrogen Ions," N.Y., 1920, p. 76). Conductivity water was used in making up all the solutions.

Measurement of the Speed of Iodination.—The reaction was started by addition of the iodine solution in potassium iodide to the mixture of phenol (m. p. 40·0°) and phosphate buffer solution at 25·0°. 10 C.c. of the reaction mixture were removed at suitable intervals and run into 50 c.c. of 0·5*N*-sulphuric acid, whereby the reaction was stopped. Titration of the residual iodine with *N*/500-thiosulphate was carried out in an atmosphere of nitrogen, which enabled perfectly sharp end-points to be obtained. The results for a typical experiment are given in Table III.

CCCLXVIII.—*The Activity Theory of Reaction Velocity. The Interaction of* N-*Chloroacetanilide and Hydrochloric Acid.*

By FREDERICK GEORGE SOPER and DAVID REGINALD PRYDE.

THE effect of electrolytes on the speed of reactions catalysed by acids is interpreted at the present time along two lines. On one theory, the catalyst is the hydrogen ion, its catalytic activity being proportional either to its thermodynamic activity (Harned, *J. Amer. Chem. Soc.*, 1918, **40**, 1461), which is affected by the presence of salts, or to its concentration (Brönsted and Pedersen, *Z. physikal. Chem.*, 1924, **108**, 185) as calculated from the concentration ionisation constant, which changes with the ionic strength (Arrhenius,

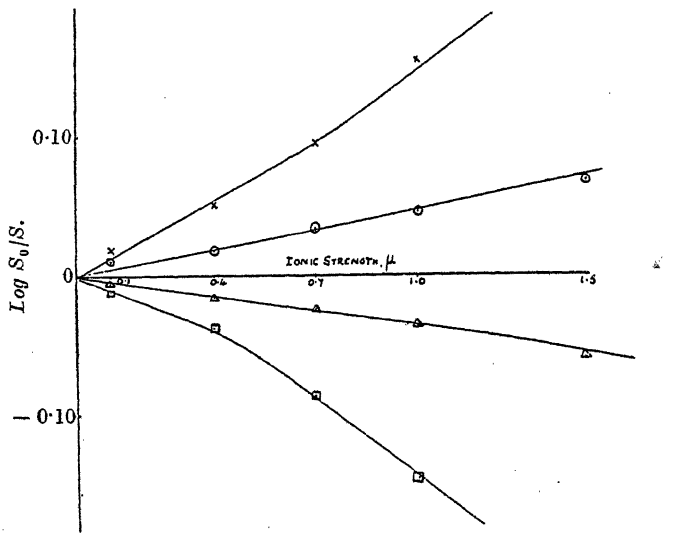
Z. physikal. Chem., 1899, **31**, 197; Brönsted, J., 1921, **119**, 574). The other theory, which has recently been extended by Dawson (Dawson and Carter, J., 1926, 2282 *et seq.*), attributes catalytic activities to the undissociated molecule and to the acid anion, as well as to the hydrogen ion. On the latter theory, the catalytic activities of the various ions are assumed to be proportional to their concentrations. It may be noted, however, that Dawson, in calculating his hydrogen-ion concentrations in acetic acid–acetate mixtures, uses a constant value for the ionisation constant of acetic acid in which he substitutes for the acid and anion concentrations (Dawson and Dean, *ibid.*, p. 2876); no allowance is made for the increase of the concentration ionisation constant (some 200%: Brönsted, *loc. cit.*; compare K_w, Harned, *J. Amer. Chem. Soc.*, 1925, **47**, 930) as the salt concentration is increased from 0 to 1·0*N*.

A factor very generally neglected in the study of acid catalysis is the effect the electrolyte may have on the active mass of the non-electrolyte, as demonstrated by the experiments of Jones and Lapworth (J., 1911, **99**, 1427), who found that the equilibrium constant of the reaction $EtOH + CH_3{\cdot}CO_2H \rightleftharpoons CH_3{\cdot}CO_2Et + H_2O$ changes by more than 100% as the amount of the catalyst, hydrogen chloride, is altered. Since the catalyst does not appear in the equilibrium constant, the velocity coefficients k and k' in the equations, $v = kC_{catalyst}C_{alcohol}C_{acid}$ and $v' = k'C_{catalyst}C_{ester}C_{water}$, must vary as the catalyst concentration changes. The general procedure has been to regard k as strictly constant, and to deduce the effective concentration of the catalyst on this assumption. It is obvious that this procedure may lead to erroneous theories. If deductions are to be made as to the effective concentrations of the catalyst, k, and therefore k/k', must be strictly constant. The equilibrium constant of a system must therefore be expressed in such a way as to be independent of the changes in medium caused by the addition of neutral salts, and the velocity equation must be modified so as to be in harmony with this equilibrium constant. An equilibrium constant of this nature was proposed by van 't Hoff (Lectures, 1898), concentrations being replaced by the ratio of concentration to the limiting solubility in the particular medium. Replacement of concentrations by this ratio in the velocity equation $v = kC$ gives $v = k_0C/S$; Dimroth (*Annalen*, 1910, **377**, 127) used this equation in studying the effects of solvents on the velocity of intramolecular transformation, and found that, whilst the classical velocity coefficient had values which differed as much as 100-fold from each other, the values of k_0 only exhibited a 3-fold variation. It would thus appear that part of the effect of the medium on

reaction speed is connected with solubility. It follows that, if the solubility of a non-electrolyte, such as ethyl acetate, is decreased by the presence of electrolytes, its reactivity may be increased. This is also indicated from a consideration of the kinetic equilibrium of a solid with its saturated solution. If the solubility is decreased, a greater proportion of the solute molecules must possess sufficient translational energy to deposit themselves on the surface of the solid, and the reactivity, which depends on the proportion of molecules having an energy greater than some critical value (Arrhenius, *Z. physikal. Chem.*, 1889, **4**, 226; Hinshelwood, *Phil. Mag.*, 1925, **2**, 360), may be expected to increase (Scatchard, *J. Amer. Chem. Soc.*, 1923, **45**, 1581).

The van 't Hoff equilibrium constant is a partial statement of the activity constant. Defining the activity, a_A, of a substance A by the expression $F_A = C_A + RT \log a_A$, where F_A is the partial free energy and C_A is a constant, and putting $F_A + F_B = F_P + F_Q$ as the condition * of equilibrium in the system $A + B \rightleftharpoons P + Q$, it is seen that $a_A a_B / a_P a_Q$ is constant and independent of the medium. The modified velocity equation corresponding to the classical equation is thus $v = k a_A a_B$, but it is important to note that this equation is only one of a number which, when applied to a balanced reaction, satisfy the activity equilibrium constant. The general velocity equation is of the type

$$v = k_0 a_A a_B F_1 \text{ (activities)}. \quad F_2 \text{ (specific effect of solvent)}. \quad F_3 \ldots F_n, \ldots \ldots \ldots \ldots \ldots \ldots \quad (1)$$



with the stipulation that the functions F_1, F_2 . . ., should be common to both the forward and the reverse reactions of the reversible change.

The object of the present work was to test the equation $v = k a_A a_B$, or, if this was inadequate, some equation of the general type (1), and for this purpose a knowledge of the activities of the reacting substances in the presence of each other is necessary. Whilst the effect of small concentrations of a non-electrolyte on the activity of an electrolyte is negligible, the electrolyte may exert a large effect on that of the non-electrolyte. The determination of the activity of a substance in the presence of those reagents which are causing its decomposition is difficult, and it does not suffice to regard the salting-out effect of all electrolytes as identical at equivalent concentrations. It has been possible to overcome this difficulty in the study of the interaction of hydrochloric acid and *N*-chloroacetanilide (Orton and Jones, *Rep. Brit. Assoc.*, 1910,

* This is permissible if a displacement of the equilibrium is not attended by a change in the ionic strength (Soper, *J. Physical Chem.*, 1927, **31**, Nov.).

85; Rivett, *Z. physikal. Chem.*, 1913, **82**, 301; Harned and Seltz, *J. Amer. Chem. Soc.*, 1922, **44**, 1475), for both hydrogen and chlorine ions must be present before the *N*-chloroacetanilide reacts, and it was therefore possible to measure separately the effects of these ions on the activity of the chloroamine. It was found that the replacement of the chloride ion by the nitrate ion raised the solubility of the chloroamine in a certain ratio, which depended on the salt concentration, but was otherwise independent of the kation present. From the solubility in nitric acid, that in hydrochloric acid could be deduced, and the activity coefficient was found in

FIG. 1.

△ HCl, ⊡ HNO_3, × KCl, ⊙ KNO_3 *solutions.*

this way to change by 13% over the hydrochloric acid range examined (0·1—1·5*M*). The results are given graphically in Fig. 1, where the logarithm of the activity coefficient of the chloroamine (the ratio of the solubility in water to that in the salt solution) has been plotted against the ionic strength.

Measurement of the Rate of Interaction of Hydrochloric Acid and N-*Chloroacetanilide.*—The transformation of *N*-chloroacetanilide to *o*- and *p*-chloroacetanilides was shown by Orton and Jones (*loc. cit.*) to involve two successive stages: first, an interaction of the hydrochloric acid and the chloroamine with the production of chlorine, and secondly, reaction between the chlorine and the acetanilide. It has since been shown by one of us (*J. Physical Chem.*, 1927, **31**, 1192) that the speed of the transformation is

approximately equal to that of the first stage, but that the measurement of the rate of reaction is complicated by simultaneous *N*-chlorination of the chloroanilides which are produced. The effect of this was shown to be that the rates of the transformation as ordinarily measured indicate an apparent reactivity of the hydrochloric acid, which is too great in the more concentrated acid solutions. In order to measure the true rate at which chlorine is being formed, it is necessary to have present excess of some substance which is readily chlorinated and does not itself react with the hydrochloric acid or the chloroamine. Acetanilide, phenol, and *p*-cresol have been used for this purpose, and have given identical results.

It is possible that chlorine may be produced from a chloroamine by two mechanisms: (1) a direct interaction of hydrochloric acid and the chloroamine the rate of which it is desired to measure, and (2) a primary hydrolysis of the chloroamine to hypochlorous acid, followed by the rapid interaction of hydrochloric and hypochlorous acids, giving chlorine (k_2 at $25° = 1{\cdot}0 \times 10^6$; Soper and Smith, J., 1926, 1582). If (2) occurs appreciably, the rate of chlorine formation will be greater than the rate of interaction of the chloroamine and hydrochloric acid. In aqueous solution, the rate of hydrolysis of *N*-chloroacetanilide is very slow, for in the presence of phenols with which hypochlorous acid reacts rapidly, no detectable disappearance of the chloroamine occurred in 7 hours. In acid solution, the rate of hydrolysis becomes measurable. It is unaffected by the amount of phenol present, is proportional to the acid strength, and is practically the same for nitric, sulphuric, and perchloric acids of the same concentration. If the rate of hydrolysis is the same in hydrochloric acid as in other acids, it is approximately 6% of the rate of chlorine formation in 0·1*M*-hydrochloric acid and decreases to 0·4% in 1·5*M*-acid. The rates of chlorine formation corrected for the rate of hydrolysis of the chloroamine give the speeds of direct interaction of the chloroamine and hydrochloric acid.

Activity of the Hydrochloric Acid.—Since the general activity reaction-velocity equation has been developed from the free-energy condition for equilibrium, $F_A + F_B = F_P + F_Q$, which applies strictly only to those equilibria in which a slight displacement does not affect the ionic strength, it is necessary to examine the reaction $(HCl \rightleftharpoons H^{\cdot} + Cl') + {:}NCl \longrightarrow Cl_2 + {:}NH$, more closely. Although the chlorine does not remain in the system, but is immediately taken up by other substances which are present, the velocity equation must satisfy the equilibrium conditions which would be attained were the chlorine to remain free in the system. For a

slight displacement of the above equilibrium such that dn mols. of hydrogen chloride disappear, there is a disappearance of $2dn$ ions, with a consequent decrease in the free electrical energy of the medium (Soper, *loc. cit.*). This change in the free energy of the medium is independent of whether the un-ionised acid or the ions actually react with the chloroamine. The equilibrium condition is therefore

$$-dF_{H^\cdot} - dF_{Cl'} - dF_{:NCl} + dF_{Cl_2} + dF_{:NH} - dF_{\text{medium}} = 0. \quad (2)$$

The interaction of hydrochloric acid and the chloroamine is apparently of the third order, but since it has the normal temperature coefficient (Harned and Seltz, *loc. cit.*), whilst a true termolecular reaction, involving the simultaneous collision of 3 molecules, has a temperature coefficient of nearly unity (Bodenstein, *Z. physikal. Chem.*, 1922, **100**, 68), it is probable that the reaction is one involving the un-ionised hydrogen chloride and the chloroamine. The partial free energy of the un-ionised hydrogen chloride is connected with those of the hydrogen and chlorine ions by the equation

$$-dF_{HCl} + dF_{H^\cdot} + dF_{Cl'} + dF_{\text{medium}} = 0 \quad . \quad . \quad (3)$$

where the dF_{medium} corresponds to the increase in the electrical free energy of the medium due to the formation of $2dn$ ions.

Combining (2) and (3), we have

$$-dF_{HCl} - dF_{:NCl} + dF_{Cl_2} + dF_{:NH} = 0,$$

or

$$F_{HCl} + F_{:NCl} = F_{Cl_2} + F_{:NH} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and substitution for $F_{HCl} = RT \log a_{HCl} + C_{HCl}$ etc., gives

$$a_{HCl}a_{:NCl}/a_{Cl_2}a_{:NH} = \text{constant},$$

corresponding to the simple activity reaction-velocity equation

$$v^* = -dc_{:NCl}/dt = k_0 a_{HCl} a_{:NCl} = k_0 a_{HCl} f_{:NCl} c_{:NCl}. \quad . \quad . \quad . \quad (5)$$

Values of a_{HCl} are given by *E.M.F.* measurements on hydrochloric acid concentration cells without liquid junction, for in a slight displacement of the system in equilibrium the electrical work $dnEF/N$ is balanced by the change in the partial free energy of

* The speed is regarded as the number of g.-mols. of the reagents reacting in unit time *per unit volume*, rather than the number reacting per unit weight of solution, for the activity is connected, as was pointed out by Scatchard (*loc. cit.*), with the number of molecules possessing a certain critical energy which enables them to pass through, or react with, unit area of the boundary surface in unit time. If one imagines a number of planes of unit area immersed in the solution, then those molecules possessing sufficient energy to carry them through the surface will also pass through each of these planes. If the planes are of infinitesimal thickness and are arranged so as to form a solid cube, the activity will measure the number of molecules possessing a certain critical energy in that cube, *i.e.*, in unit volume. The number of molecules reacting should also, therefore, have reference to unit volume.

the hydrochloric acid caused by its transference from cell to cell together with the net change in the electrical energy of the two media, *i.e.*,

$$dnE\mathrm{F}/N = -dF_{\mathrm{H'I}} - dF_{\mathrm{Cl'I}} - dF_{\mathrm{mediumI}} + dF_{\mathrm{H'II}} + dF_{\mathrm{Cl'II}} + dF_{\mathrm{mediumII}}$$

which, on being combined with (3), gives

$$dnE\mathrm{F}/N = -dF_{\mathrm{HClI}} + dF_{\mathrm{HClII}}$$

and $E\mathrm{F} = RT \log (a_{\mathrm{HClII}}/a_{\mathrm{HClI}}) + \text{constant}$.

Comparison of (5) with the equation $v = kc_{\mathrm{:NCl}}$ used in evaluating a velocity coefficient at any one acid concentration indicates that $k/a_{\mathrm{HCl}}f_{\mathrm{:NCl}}$ should be constant at constant temperature, unless the speed is affected by viscosity.

Effect of Viscosity.—Since activities, and therefore activity equilibrium constants, are independent of viscosity, it is possible to show theoretically by consideration of the equilibrium, $\mathrm{A} \rightleftharpoons \mathrm{P} + \mathrm{Q}$, that if the velocity of a unimolecular reaction is unaffected by viscosity, then that of a bimolecular reaction should also be unaffected; for application of the reaction-velocity equation to such an equilibrium gives $K = k_1/k_2$, and if K and k_1 are independent of viscosity, then k_2 must also be independent of it. This argument applies to any reaction-velocity equation of type (1).

In Table I the relative viscosities of the acid media (Green, J., 1908, **93**, 2023) have been included. The molalities (g.-mols. of acid per 1000 g. of water) are given in the first column, k' is the rate of chlorine formation, k'' the rate of hydrolysis of the chloroamine, $k = k' - k''$ is the rate of interaction of the chloroamine and hydrochloric acid, and a_{HCl} the activity measured electrometrically by Scatchard (*J. Amer. Chem. Soc.*, 1925, **47**, 641).

TABLE I.

C_{HCl}.	$10^3 . k'$.	$10^4 . k''$.	$10^3 . k$.	$a_{\mathrm{H}} . a_{\mathrm{Cl}'}$.	$f_{\mathrm{:NCl}}$.	$\frac{k}{a_{\mathrm{HCl}}f_{\mathrm{:NCl}}}$	η.
0·1	0·52	0·32	0·49	0·00642	0·989	0·0767	1·000
0·2	1·88	0·58	1·82	0·02397	0·980	0·0775	1·005
0·3	4·06	0·96	3·95	0·05239	0·972	0·0775	1·011
0·4	7·11	1·25	6·98	0·09242	0·964	0·0783	1·017
0·5	10·8	1·50	10·6	0·1448	0·957	0·0772	1·023
0·6	16·0	1·92	15·8	0·2134	0·951	0·0778	1·029
0·7	21·9	2·24	21·7	0·2966	0·947	0·0779	1·035
0·8	29·1	2·54	28·9	0·3985	0·939	0·0773	1·042
0·9	38·2	2·88	37·9	0·5204	0·932	0·0779	1·043
1·0	48·2	3·24	47·9	0·6675	0·925	0·0776	1·054
1·5	124	4·80	124	1·843	0·877	0·0767	1·083

The values of $k/a_{\mathrm{HCl}}f_{\mathrm{:NCl}}$ are constant to within 1%, which is of the order of the experimental error, whilst the viscosity changes by 8%. The observed rates of reaction may therefore be regarded as supporting the simple activity velocity equation for a reaction

between neutral molecules in aqueous media. They do not necessarily indicate that the reactivity of an ion is proportional to its thermodynamic activity.

On Brönsted's theory (*Z. physikal. Chem.*, 1922, **102**, 169),

$$v = kc_{:NCl}\, c_{HCl} f_{:NCl} f_{HCl} / f_{(:NCl,HCl)}$$
$$= kc_{:NCl}\, a_{HCl} f_{:NCl} / f_{(:NCl,HCl)},$$

and comparison with the simple activity equation shows that, in order to account for the observed facts, the activity coefficient of the critical complex (:NCl, HCl) must be constant to within 0·5% over the acid range examined (0·1—1·5*M*). This is unlikely in view of the solubility changes which apparently almost invariably occur on addition of electrolytes to a solution.

Experimental.

Measurement of the Solubility of N-*Chloroacetanilide in Acid and Salt Solutions.*—Excess of *N*-chloroacetanilide was added to the salt solution and shaken for 15 minutes at 25·0°; 10 c.c. of the clear solution were then removed by a pipette attached to a glass tube, on the lower end of which was mounted a perforated platinum plate covered with filter-paper. The chloroamine present was estimated by running it into acidified potassium iodide solution and titrating the liberated iodine with *N*/100-thiosulphate. The mean of four titrations was taken after saturation was attained (approx. 15 mins.). The measured solubilities of *N*-chloroacetanilide (in g.-mols. per litre) in potassium chloride, potassium nitrate, and nitric acid solutions are given in Table II, together with the calculated solubility in hydrochloric acid.

Table II.

Ionic strength.	0·0.	0·1.	0·4.	0·7.	1·0.	1·5.

,, KNO_3.	(0·01383)	0·01350	0·01325	0·01275	0·01243	0·01178
,, HNO_3.		0·01418	0·01511	0·01680	0·01935	0·02295
,, HCl ...		0·01398	0·01434	0·01461	0·01495	0·01577

Speed of Chlorine Formation from N-*Chloroacetanilide and Hydrochloric Acid.*—The effect of increasing the concentration of acetanilide, phenol, or *p*-cresol on the rate of fall of the iodine titre of a mixture of *N*-chloroacetanilide and hydrochloric acid is shown in Table III :

Table III.

HCl = 0·2*M* :NCl = 0·01*M* ; temp. = 25·0°.

Concentration of phenol, *p*-cresol, or acetanilide, *M*	0·01.	0·02.	0·03.
100*k'* (acetanilide)	0·183	0·188	0·188
100*k'* (phenol)	0·186	0·188	0·188
100*k'* (*p*-cresol)	—	0·188	0·188

The limiting value for k which corresponds to the rate of chlorine formation from 0·01 M-chloroamine and 0·2M-hydrochloric acid is thus 0·00188. The limiting values for other acid concentrations are given in Table I. Care was taken when mixing the aqueous solution of chloroamine with the calculated weight of hydrochloric acid solution to adjust the initial temperatures so as to compensate for the heat of mixing. The speed of the reaction in the presence of 1·5M-hydrochloric acid is too great to allow of pipetting out portions of the mixture, and portions were therefore poured into weighed flasks containing potassium iodide and sodium acetate at 10-sec. intervals, the flasks were reweighed, and the contents titrated.

Speed of Hydrolysis of N-*Chloroacetanilide.*—Determinations of the rate of hydrolysis of the chloroamine were carried out in aqueous sulphuric, nitric, and perchloric acids, *p*-cresol being present in solution to remove the hypochlorous acid as formed. In the absence of acid, there is no detectable disappearance of the chloroamine in 7 hours. The rate of disappearance of chloroamine in the presence of acid follows a unimolecular velocity equation and the results obtained are summarised in Table IV.

TABLE IV.

:NCl = 0·01M; *p*-cresol = 0·1M; temp. = 25·0°.

Concentration of acid.	H_2SO_4.					HNO_3.	$HClO_4$.

$k'' \times 10^4$	0·321	0·584	1·25	2·54	3·24	3·24	3·70

Summary.

1. Since concentration equilibrium constants are affected by the presence of electrolytes, the classical velocity coefficients are not true constants, and the use of an equation, $v = kf_{\text{catalyst}}C_AC_B$, for determining the effective concentration of the catalyst is not justifiable. Attention has therefore been redirected to the general form of a reaction-velocity equation.

2. The simplest type of the generalised equation applying to reactions involving neutral molecules, *viz.*, $v = ka_Aa_B$, is found to be in agreement with observations on the rate of interaction of hydrochloric acid and N-chloroacetanilide. The activities of the reagents used in the velocity equation are those which obtain in the presence of each other. Actually, the activity of the chloroamine was found to be progressively decreased by 13% as the hydrochloric acid concentration was increased from 0·1 to 1·5M.

3. The measurement of reaction speed in mols. transformed in unit time *per unit volume*, rather than per unit weight of solution, is justified on theoretical grounds.

4. A proof is advanced that reaction velocity is independent of viscosity.

The authors' thanks are due to the Department of Scientific and Industrial Research for a grant which enabled one of them (D. R. P.) to take part in the investigation.

CCCLXIX.—*The Orienting Influence of Free and Bound Ionic Charges on Attached Simple or Conjugated Unsaturated Systems. Part II. The Nitration of 1-Benzylpiperidine and of Some Related Substances.*

By ALFRED POLLARD and ROBERT ROBINSON.

ALTHOUGH it is now generally agreed that the *m*-directive effect of the ammonium-salt group in the benzylammonium salts is associated with the positive charge of the ion, there are still many aspects of the subject that call for elucidation. The majority of the constitutive influences that have been observed in this field are susceptible of simple explanations, for example, the somewhat higher *m*-direction in $CH_2Ph{\cdot}NMe_2$ than in $CH_2Ph{\cdot}NEt_2$ (Goss, Ingold, and Wilson, J., 1926, 2440) is the result to be anticipated from the theory of Allan, Oxford, Robinson, and Smith (J., 1926, 401), the terminal methyl groups in the latter compound having a smaller electron affinity than the hydrogen atoms which they may be regarded as displacing. Thus in the benzyldiethylammonium ion the positive charge of the nitrogen atom is neutralised by electron displacement towards it to a larger extent than is the charge of the nitrogen atom in the benzyldimethylammonium ion. Considerations like these, although frequently applicable, cannot be extended, however, to benzylpiperidine, from which the yield of *m*-nitro-derivative is notably higher than that from the closely related tertiary bases already mentioned. Noelting and Kregczy (*Bull. Soc. chim.*, 1916, **19**, 355) found that benzyldiethylamine on nitration in sulphuric acid solution gave from 35—40% of the *m*-nitro-derivative; Flürscheim and Holmes (J., 1926, 1562) found 33—53% under various conditions in sulphuric acid solution. Goss, Ingold, and Wilson (*loc. cit.*), employing nitric acid (*d* 1·5) alone, found that the proportion of the *m*-isomeride formed was 51%, and we have confirmed this. On the other hand, we were aware that the estimate of the proportion of the *m*-nitro-isomeride formed in

the nitration of benzylpiperidine, that was based by Ing and Robinson (J., 1926, 1665) on the separation as hydriodide, namely 60%, was a conservative one. Employing Francis and Hill's bromination method (*J. Amer. Chem. Soc.*, 1924, **46**, 2498), we find that 72% of *m*-nitrobenzylpiperidine is actually formed. Similarly, 1-β-*phenylethylpiperidine*, $C_5H_{10}N{\cdot}CH_2{\cdot}CH_2Ph$, obtained by the interaction of magnesium benzyl chloride and *N-iso*butoxymethylpiperidine in accordance with the general method of Robinson and Robinson (J., 1923, **123**, 532), gave on nitration about 22% of its *m*-nitro-derivative. This figure is higher than that found for the simpler dialkylated β-phenylethylamines (compare Goss, Hanhart, and Ingold, J., 1926, 250) and confirms the benzylpiperidine case. We are aware that this pronounced effect of ring closure may be accounted for merely as the result of a composition difference of two hydrogen atoms, our knowledge being insufficient to enable us to exclude this possibility on *a priori* grounds; we are nevertheless of the opinion that such a simple view is inadequate and, in the sequel, propose an alternative.

Flürscheim and Holmes (*loc. cit.*) showed that the proportion of *m*-nitrobenzyldiethylamine formed in the nitration of the salt of the base in sulphuric acid was diminished by saturation of the solution with ammonium sulphate. We have extended the study of this phenomenon to the nitration of benzylpiperidine in nitric acid solution. The addition of ammonium nitrate reduced the proportion of *m*-isomeride formed to about 56%, but as this salt is not readily soluble in nitric acid we made a further series of experiments on the influence of the addition of trimethylammonium nitrate to the acid, and found that the proportion of *m*-isomeride formed could be reduced to 16%. Addition of rubidium nitrate, which is readily soluble in nitric acid, produced roughly the anticipated effect. Addition of urea also decreased the proportion of the *m*-isomeride formed, and this was due to Flürscheim's effect and not to the removal of nitrous acid, because when nitric acid freed from nitrous acid by means of lead peroxide or by hydrogen peroxide was employed for the nitration of benzylpiperidine the normal proportion of the *m*-isomeride was formed.

These variations in orientation produced by the addition of salts are unexpectedly great and demonstrate that the condition of the kation is of primary importance in determining the nature of the observed results. We attribute the effect to the progressive electrostriction of the kations by the nitrate ions, an explanation which is the equivalent, in the modern theory, of Flürscheim and Holmes's suggestion that the ion undergoes substitution in the *m*-position and the undissociated salt in the *o*- and *p*-positions. On any theory, the

results make it evident that the value obtained in an experiment in which the base is gradually added to the nitric acid represents a mere average, since the ionic concentration is progressively increased during the nitration. This must coincide with a decreasing rate of formation of the *m*-isomeride relative to that of the *p*-isomeride. (Attempts to define and apply standard conditions are being made.) Nevertheless we have found that the results obtained in the nitrations are reproducible and, although the numbers representing the proportions of *m*-isomeride formed have not the character of fundamental constants, some conclusions may be drawn from a consideration of these averages obtained in the case of related bases. It would, for example, appear most probable that the proportion of *m*-isomeride formed is partly related to the existence of constitutive factors that either hinder or assist the operation of electrostriction of the kations. In this connexion stereochemical conceptions are of primary importance (compare Flürscheim's steric factor, *s*, in the correlation of the strengths of bases with their constitutions), because it is clear that the anions or negative ends of polarised complexes can the more effectively modify the field of the positively charged nitrogen atom the closer they can approach it. Other things being equal, we should expect the degree of electrostriction of the kations to be influenced as follows:

(1) *The smaller the number of atoms directly attached to the central charged atom, the greater should be the degree of electrostriction.* The present authors have studied the nitration of a benzyldiethylsulphonium salt and will shortly submit an account of the work. The proportion of *m*-isomeride formed, although still noteworthy, is very much lower than in the nitration of benzyltrimethylammonium nitrate. We attribute the result partly to the fact that the central atom is surrounded by four atoms in the ammonium salt, but by only three in the sulphonium salt. Benzylmethylpiperidinium nitrate, $CH_2Ph{\cdot}NMe{:}[CH_2]_5{}NO_3$, gave more than 90% of the *m*-nitro-derivative on nitration, and the proportion of the *m*-nitro-isomeride formed in the nitration of benzylpyridinium perchlorate was estimated to be about 67%. The nitrogen atom is attached to four atoms in the first case, but to only three in the second. This explanation of the result is adequate, but we do not exclude the possibility that the charge may be distributed over the pyridine nucleus to some extent by induction and may thus be less effective on account of electron displacements towards it.

(2) *The greater the volume of the central charged atom the greater should be the degree of electrostriction.* In this case, the larger radius might be expected to hinder electrostriction, but this effect may be

ignored, since it also places the charge further away from the aromatic nucleus, and this in itself diminishes the intensity of the field. On the other hand, electrostriction should be facilitated in the larger atoms by the smaller electron density near the surface rendering such atoms *softer* and perhaps by the appearance of patches not covered by the surrounding atoms. Thus under comparable conditions we may anticipate diminishing *m*-substitution in ascending a group in the periodic system: *e.g.*, $CH_2Ph{\cdot}NR_3 > CH_2Ph{\cdot}PR_3 > CH_2Ph{\cdot}AsR_3 > CH_2Ph{\cdot}BiR_3$, and $CH_2Ph{\cdot}SR_2 > CH_2Ph{\cdot}SeR_2$.

(3) *The smaller the space occupied by the atoms or groups attached to the central charged atom, the greater should be the degree of electrostriction.* This consideration clearly applies to the case of hydrogen atoms, which have even been regarded as embedded in the electron shells (Thomson, Paneth). The nakedness of the proton is necessarily a most important factor favouring electrostriction in the salts of primary, secondary, and tertiary bases in diminishing degree. In other examples, the electron displacements and distances separating the atomic centres must also be taken into account.

(4) *The greater the mobility of the groups surrounding the central charged atom, the greater should be the degree of electrostriction.* We imagine that closer approach of the anions is possible when the surrounding groups can be pushed aside or when, as the result of their normal vibrations, there are phases in which the nucleus of the central atom is exposed. Herein, we suggest, lies the explanation of the benzylpiperidine case. In benzyldiethylamine, the ethyl groups are not fixed, but may be supposed to be capable of some movement over a limited area of the surface of a sphere. When the ends of the chains are joined together as in benzylpiperidine, this freedom of movement must be lessened and electrostriction would be hindered in consequence. It is proposed to test this hypothesis by instituting further comparisons between open-chain and cyclic bases. The highest proportion of the *m*-derivative should be formed in the nitration of *N*-alpharylquinuclidinium salts, since the molecular framework in this series should be especially rigid.

The course of the nitration of benzylpiperidine was unaffected by the addition of nitromethane or ethyl malonate to the reaction mixture, and the addition of nitrobenzene only lowered the proportion of *m*-isomeride formed to 58%. Evidently these weak bases do not form true ionised salts with nitric acid, and we suggest the following conception of the nature of the solutions. It is generally recognised that, in an acid HX, X has a more or less pronounced affinity for the negative charge and by electron displacement the nucleus of the proton is bared so that HX is polarised. In a base

Be (e = electron) of the type that might form a salt BeH}X, B has a more or less pronounced affinity for the positive charge, and this molecule also is polarised (or there may be a tendency to polarisation consummated by induction). In an acid, therefore, there are an intense local positive field and a diffuse negative field; in a base, the negative field is the more concentrated. The respective complexes thus contain *bound* ions (although the charges are not integral), and the ever-changing interplay of the forces between these is the interpretation we offer of the expression " loose additive complex " which might be applied to the cases considered. This hypothesis gives a very similar picture of the condition of salts and of additive complexes in solution. In both cases, moderately stable molecules containing a limited number of the components may exist for definite periods of time.

EXPERIMENTAL.

Method of Estimation of the Proportion of m-*Isomeride formed.*—In applying the method of Francis and Hill (*loc. cit.*) to the products of nitration of benzylpiperidine, we found that the presence of small quantities of unchanged benzylpiperidine did not affect the results and that the best procedure was to analyse directly the mixture of bases obtained. An important precaution was the avoidance of too large an excess of titanous chloride or of bromine. The nitro-compounds present were first estimated by reduction with titanous chloride and back-titration with ferric alum; reduction with a slight excess of titanous chloride was then effected in a fresh experiment, followed by bromination at 0° with the usual precautions. Within the limits of experimental error, the pure *o*-, *m*-, and *p*-nitrobenzyl-piperidines (Lellmann and Pekrun, *Annalen*, 1890, **259**, 40) (purity estimated by means of titanous chloride, 99—100%) required after reduction 2, 3, and 2 molecular proportions of bromine, respectively. The fact that stoicheiometric rather than empirical relations can be employed in the calculations was confirmed by the analysis of the following mixtures: *ortho*, 48·4% and *meta*, 51·6% (Found: *meta*, 48, 51·4%); *meta*, 48% and *para*, 52% (Found: *meta*, 44, 47, 52%); *meta*, 71% and *para*, 29% (Found: *meta*, 69, 72%).

Nitration of Benzylpiperidine.—The nitration (of 5 g.) was carried out as described by Ing and Robinson (J., 1926, 1664) and the bases were isolated by means of ether. The mononitration was almost theoretical (Found: *meta*, 66, 71, 72, 76, 77; mean, 72%). In subsequent experiments, the conditions of nitration were the same (3 g. of the base and 20 c.c. of nitric acid, d 1·50) and the yields were from 90—98%. When relatively large amounts of ammonium nitrate were added, stirring was rendered difficult by the separation

of solids from the solution when it was cooled to −15°. These may contain $NH_4NO_3,2HNO_3$, but also, in all probability, a similar complex derived from benzylpiperidinium nitrate, because the proportion of the base that was nitrated under the standard conditions was very much lower than in other cases. The results were: addition of ammonium nitrate (5 g.) (Found: nitration, 95%; *meta*, 57, 59, 59%); addition of ammonium nitrate (7 g.) (Found: nitration, 17·8%; *meta*, 54, 58%); addition of ammonium nitrate (8 g.) (Found: nitration, 24·5%; *meta*, 54, 56%).

Lithium, sodium, potassium, and rubidium nitrates form a series in which the solubility in nitric acid increases, lithium nitrate being very sparingly soluble and rubidium nitrate being freely soluble. Addition of rubidium nitrate (3 g.) gave a clear reaction mixture (Found: nitration, 98%; *meta*, 19, 23·4, 25%). From the results tabulated below, it was found that the equivalent amount of trimethylammonium nitrate should reduce the proportion of the *m*-isomeride formed to 24%.

Trimethylammonium nitrate was crystallised from alcohol until its m. p. was 152—153°. The effects of additions of this salt are shown in the following table:

$NHMe_3NO_3$ added (g.).	Nitration (%).	*Meta* (%).	Mean.
0·5	98·3	59, 62, 66, 71	64
1·0	99·3	50, 53	51·5
1·5	96·0	40, 40, 41	40
2·0	98·7	30, 31, 33	31·3
3·5	81·3	15, 16, 17	16
7·0	90·9	21, 21	21

The result with 7·0 g., indicating a rise in *m*-isomeride formation after a minimum value has been reached, will be further investigated when the conditions are more accurately defined. The percentage nitration of the base in this case was confirmed by reducing the product (1·62 g.) with zinc and dilute sulphuric acid, the resulting amines being then benzoylated and the unchanged benzylpiperidine isolated by distillation in steam. The picrate (0·18 g.) was obtained in canary-yellow crystals, m. p. 174—176°; mixed with the picrate of benzylpiperidine, m. p. 175—177°, it melted at 174°. We were thus able to isolate as picrate 67% of the unchanged benzylpiperidine which the titanous chloride estimation indicated to have been present in the nitration product.

Since the rate of predominating *m*-substitution in a monosubstituted benzene derivative is always lower than that of predominating *op*-substitution (Holleman), it seemed possible that the degradation of the reagent might result in a diminution of the proportion of the *m*-isomeride formed. The gradient of the curve representing the relation between reaction velocity and chemical

activity of the reagent should, in other words, be steeper in the case of the formation of the *m*-isomeride. This consideration might have a bearing on the effect of addition of salts to the nitric acid, and we therefore tried another method of degradation, namely, the removal of nitrous acid. Urea (1·0 g.) was added to nitric acid (20 c.c.; *d* ·51), which was then cooled in a freezing mixture and thereafter allowed to warm to the ordinary temperature (the density became 1·52); after cooling again, the mixture was employed in a nitration under the standard conditions (Found: nitration, 99%; *meta*, 45, 45%). Lead peroxide was added to nitric acid (*d* 1·53), mixed with a little acid (*d* 1·54) prepared by distillation of a mixture of nitric acid (*d* 1·51) and phosphoric anhydride; after filtration the acid had *d* 1·51 and was free from lead. The nitration was carried out with this specimen in the presence of a small amount of lead peroxide (Found: nitration, 94%; *meta*, 65, 69, 73%). Another specimen of nitric acid (*d* 1·5) was prepared by the addition of concentrated aqueous hydrogen peroxide to nitric acid (*d* 1·54), and this was employed in the nitration (Found: nitration, 98%; *meta*, 71%).

When the standard nitration conditions were modified by reduction of the volume of nitric acid to 10 c.c., a small diminution in the proportion of *m*-isomeride formed was observed (Found: nitration, 95%; *meta*, 61, 62, 64%), but when the volume of nitric acid employed for the nitration of 3 g. of the base was trebled (60 c.c.) some dinitration occurred.

The following results were obtained under the standard conditions modified as stated: Addition of nitrobenzene (5 g.) (Found: nitration, 98%; *meta*, 57, 59%); addition of nitromethane (2·5 g.) (Found: nitration, 99%; *meta*, 70, 73, 73%); addition of ethyl malonate (6·5 g.) (Found: nitration, 97%; *meta*, 69, 69%).

Benzyldiethylamine was nitrated under the conditions used for benzylpiperidine (Found: nitration, 98%; *meta*, 48, 50, 51%).

Nitration of Benzylmethylpiperidinium Nitrate.—Benzylmethylpiperidinium iodide, prepared from benzylpiperidine and methyl iodide, crystallises from ethyl alcohol in colourless needles, m. p. 147° (Found: I, 40·0. $C_{13}H_{20}NI$ requires I, 40·1%). It is readily soluble in water and in hot alcohol.

This salt was converted into the *nitrate* by exact decomposition with silver nitrate, and the aqueous solution was evaporated to a syrup and then in a vacuum over sulphuric acid for several months. The friable solid was extremely hygroscopic, liquefying in the air in a few seconds; an estimation by means of nitron, combined with a titration showing the amount of free nitric acid present, indicated that the material contained 99—100% of the quaternary nitrate.

The salt (20 g.) was added to nitric acid (80 c.c.; *d* 1·5) at 0° during 15 minutes, and the solution kept at this temperature for 2 hours and at room temperature for 2 hours more. The liquid was then diluted and distilled under diminished pressure, and this process was repeated so as to remove most of the nitric acid. The residue was neutralised with ammonia, and the picrate precipitated by stirring for 1 hour with an excess of picric acid. The mixture of picrate and picric acid was collected, washed with aqueous picric acid, and mechanically shaken with ether and dilute hydrochloric acid until no solid remained. The acid aqueous solution was concentrated under diminished pressure, again extracted with ether, and then neutralised with ammonia and concentrated to about 100 c.c. The iodide was then precipitated by the addition of a large excess of sodium iodide (yield, 94%). The crude nitration product (10 g.) was fractionally crystallised from methyl alcohol; 9·7 g. of the pure *m*-isomeride were obtained (Found: I, 35·0%), and the colour reactions of the last mother-liquor showed that it still contained the *m*-isomeride in preponderating amount, a little of the *p*-isomeride, and a yellow impurity.

The three nitrobenzylmethylpiperidinium iodides were prepared from the nitrobenzylpiperidines and methyl iodide and dried at 100° for analysis. o-*Nitrobenzylmethylpiperidinium iodide* crystallises from methyl alcohol in intensely yellow prisms, m. p. 183—184° (Found: I, 34·9. $C_{13}H_{19}O_2N_2I$ requires I, 35·1%). This salt develops a brownish-yellow colour in boiling methyl-alcoholic potassium hydroxide, and on the addition of a methyl-alcoholic solution to acetone and solid potassium hydroxide a bright brownish-red solution is obtained.

m-*Nitrobenzylmethylpiperidinium iodide* crystallises from methyl or ethyl alcohol in very pale yellow needles which darken at 198° and melt at 204° (Found: I, 35·1%). It gives no coloration in boiling methyl-alcoholic potassium hydroxide, but when a methyl-alcoholic solution is added to acetone and solid potassium hydroxide an intense and characteristic violet colour is developed.

p-*Nitrobenzylmethylpiperidinium iodide* crystallises from water or methyl alcohol in large, well-developed, yellow prisms, and from ethyl alcohol in pale yellow needles, m. p. 188° (decomp.) (Found: I, 34·9%). This salt develops a reddish-brown coloration in boiling methyl-alcoholic potassium hydroxide, and a dull mauve-red one when a methyl-alcoholic solution is added to acetone and solid potassium hydroxide.

These salts exhibit colour reactions under other conditions, but those recorded above were selected, after numerous trials, for the purpose of assisting in the identification of specimens. It will be

observed that under one set of conditions the *m*-isomeride gives no reaction whereas the *o*- and *p*-isomerides develop colorations; under the other set of conditions the *m*-isomeride gives the most characteristic reaction.

Nitration of Benzylpyridinium Perchlorate.—Aqueous perchloric acid was added to a solution of benzylpyridinium chloride; the precipitated oil crystallised in contact with ice-water. The dry salt (20 g.) was added during 45 minutes to nitric acid (100 c.c.; *d* 1·5) at 0°; the mixture was kept at this temperature for 1 hour and then allowed to warm to the temperature of the room during 1·5 hours. The solution was diluted, the greater part of the nitric acid distilled under diminished pressure, an excess of perchloric acid (*d* 1·12) added, and the mixture kept in the ice-chest for 24 hours; the precipitated perchlorates were then collected, washed, and dried (A) (20·5 g.) (Found: C, 45·8; H, 3·6. $C_{12}H_{11}O_6N_2Cl$ requires C, 45·9; H, 3·5%). In another experiment, the nitric acid was not removed and the crystallisation of the perchlorates was carried out fractionally, crops of approximately 12 g., 5 g., and 3 g. being obtained. On recrystallisation, the first fraction gave pure *m*-nitrobenzylpyridinium perchlorate, but the separation could not be carried out in a quantitative manner. Oxidation of the crude nitration product with potassium permanganate gave *m*- and *p*-nitrobenzoic acids, which were separated and identified; the yields, however, were not satisfactory. It was found possible to apply Francis and Hill's bromination method to this case, because the nitrobenzylpyridinium perchlorates may be quantitatively reduced to aminobenzylpyridinium chlorides by means of titanous chloride. This is not effected, however, under the ordinary conditions and the following experiment indicates the modifications required. A solution of *p*-nitrobenzylpyridinium perchlorate (0·1000 g.) in 50% sulphuric acid (25 c.c.) and water (150 c.c.) was boiled with titanous chloride for 20 minutes with the usual precautions, care being taken to avoid undue concentration (Found: titanous chloride solution used, 37·2 c.c. Calc. for complete reduction, 37·3 c.c.). Applying this method of reduction to the product (A), followed by bromination in the usual manner, we found *meta*, 64, 69, 69%. A mixture of *m*-nitrobenzylpyridinium perchlorate (70%) and *p*-nitrobenzylpyridinium perchlorate (30%) was similarly analysed (Found: *meta*, 69, 71%).

The isomeric nitrobenzylpyridinium perchlorates were prepared by addition of perchloric acid to solutions of the corresponding chlorides or bromides.

o-Nitrobenzylpyridinium perchlorate crystallises from alcohol in colourless, elongated, rhombic prisms, m. p. 155—156° (Found: C,

46·1; H, 3·5. $C_{12}H_{11}O_6N_2Cl$ requires C, 45·9; H, 3·5%). The action of boiling aqueous sodium hydroxide on this salt causes a decomposition, one of the products of which is *o*-nitrotoluene.

m-*Nitrobenzylpyridinium perchlorate* crystallises from alcohol in colourless, prismatic needles, m. p. 176—177° (Found: C, 46·0; H, 3·6%).

p-*Nitrobenzylpyridinium perchlorate* crystallises from alcohol in colourless, elongated laminæ, m. p. 181—182° (Found: C, 46·0; H, 3·6%). The long, flat plates have jagged edges and well-formed pointed or square-cut ends and exhibit a strong twinning tendency. On boiling with sodium hydroxide solution, *p*-nitrotoluene is produced.

1-β-*Phenylethylpiperidine.*—The preparation of 1-*iso*butoxymethylpiperidine (McLeod and G. M. Robinson, J., 1921, **119**, 1474) is conveniently carried out on a moderately large scale. A mixture of piperidine (400 g.) and *iso*butyl alcohol (400 g.) was added to 40% aqueous formaldehyde solution (400 g.) with cooling in running water; the mixture was saturated with potassium carbonate and kept over-night and the oil was then dried with fresh potassium carbonate. On distillation, 665 g., b. p. 200—210°, were obtained (yield, 83%). The considerations dictating the use of *iso*butyl alcohol are that the higher alcohols give the better yields, and that some decomposition occurs in the distillation of 1-*n*-butoxymethylpiperidine under ordinary pressure. *iso*Butoxymethylpiperidine (120 g.) was slowly added to an ethereal solution of magnesium benzyl chloride (from 100 g. of benzyl chloride, 20 g. of magnesium, and about 1500 c.c. of ether), a violent reaction ensuing after each addition. Water was then cautiously introduced with shaking until a clear ethereal layer could be decanted from the magnesia sludge; the latter was washed with fresh ether. The base was extracted from the ethereal solution by successive small volumes of dilute hydrochloric acid, and any unchanged *iso*butoxymethylpiperidine decomposed by heating the acid solutions for 15 minutes on the steam-bath. The base was then set free by means of sodium hydroxide, separated, dried with sodium hydroxide, and distilled. 105 G., b. p. 162°/35 mm., of a colourless oil were obtained (yield, 80% calculated on the *iso*butoxymethylpiperidine) (Found: equiv., 189·3. Calc., 189·2). The b. p. /760 mm. was 262—264° with some decomposition. The *picrate* crystallised from alcohol in perfectly straight, canary-yellow needles, m. p. 144—145° (Found: N, 13·4. $C_{19}H_{22}O_6N_4$ requires N, 13·4%). The length of the individual crystals seems to be limited only by the shape of the container and the volume of the solution; those which we obtained were about 8—10 cm. long.

On nitrating the base under the conditions used for benzylpiperidine, and assuming the stoicheiometric relation for the bromination of the *m*- and *p*-amino-derivatives, we found: nitration, 98%; *meta*, 20, 22·7, 24%.

1-*γ*-*Phenylpropylpiperidine*, $CH_2Ph{\cdot}CH_2{\cdot}CH_2{\cdot}N{:}[CH_2]_5$.—The method described in the last section was applied, the initial materials being phenylethyl bromide (98 g.), magnesium (12·5 g.), and *iso*butoxymethylpiperidine (85 g.). 59 G. of a colourless oil, b. p. 150°/15 mm., were obtained (yield, 58%) (Found: equiv., 202. Calc., 203). This base has b. p. 272—274°/760 mm. with decomposition. The *picrate* crystallises from alcohol in bright yellow tablets, m. p. 99—100° with slight previous softening (Found: N, 13·0. $C_{20}H_{24}O_6N_4$ requires N, 13·0%).

In this case, nitration with nitric acid (*d* 1·5) causing some dinitration, the standard conditions were employed with nitric acid having *d* 1·465 (Found: nitration, 99%; *meta*, 5, 6, 8%).

We desire to thank the Department of Scientific and Industrial Research for grants which have enabled one of us to take part in the investigation.

THE UNIVERSITY, MANCHESTER. [*Received, September 2nd,* 1972.]

CCCLXX.—*The Orienting Influence of Free and Bound Ionic Charges on Attached Simple or Conjugated Unsaturated Systems. Part III. The Nitration of* m-*Nitrophenylbenzylsulphone.*

By BIBHUCHARAN CHATTERJEE and ROBERT ROBINSON.

THE hypothesis (Allan, Oxford, Robinson, and Smith, J., 1926, 401) that the positive charge of the dipole in the nitro-group of phenylnitromethane is the cause of the *m*-substitution observed by Holleman, and the related wider theory, can be tested experimentally in many directions, the most obvious of which is the study of the orienting influence in aromatic substitution of polar and dipolar groups situated at various distances from the nucleus. This field of systematic work is too large to be covered by any one group of investigators, but the exploitation of it by Ingold and his co-workers has involved some duplication of research, particularly in connexion with the nitration of phenylethylamine derivatives and of substances of the forms $Ph{\cdot}CO{\cdot}R$ and $Ph{\cdot}CH_2{\cdot}SO_2R$. Some preliminary experiments in the latter group are described in this and the following communication.

The interest of the toluene-ω-sulphonyl compounds resides in their theoretical analogy with the phenylnitromethanes, the double dipole $-\overset{++--}{SO_2}$ being compared with the single dipole $-\overset{+-}{NO_2}$, and in the fact that the effect of varying the group R can be observed. We selected the case of *m*-nitrophenylbenzylsulphone because we thought that the group $-C_6H_4\cdot NO_2(m\text{-})$ should be almost neutral and the results could therefore be ascribed to the influence of the sulphone group. The proportions of the *o*-, *m*-, and *p*-isomerides formed on nitration, estimated by colorimetric methods which are fully described in the experimental section, were approximately 25, 28, and 47%, respectively. The double semi-polar double bond of the sulphone group has thus a smaller *m*-orienting effect than the single semi-polar double bond of the nitro-group. This constitutes a definite argument against the view that the charges in the semi-polar double bonds are integral and effective as such.

As Born (compare *Ann. Reports*, 1926, 261) has shown, kations and anions are distorted and polarised in the neighbourhood of each other, and if this is true of the components of a molecule of sodium chloride, how much more must it be true of the bound ions in a semi-polar double bond. In fact, the intensity of the external fields may be chiefly governed by this atomic polarisation. On this basis, we may conclude that the kationic charge of the sulphur atom in the sulphone group is less effective than that of the nitrogen in the nitro-group and that this is due to the relatively greater degree of polarisation of the oxygen atoms in the sulphone; this again is clearly connected with the larger nuclear charge of the sulphur atom and the smaller electron density of its outer shell.

Ingold, Ingold, and Shaw (this vol., p. 813) found that the nitration of benzylmethylsulphone gave about 30% of the *m*-nitro-isomeride, but these authors attributed the result (comparison with phenylnitromethane) to absorption of the effect of the ionic charge of sulphur in passing through the outer shells of the atom. This suggestion appears to be fallacious owing to the circumstance that in the calculation of the kationic charges, for example, + 1, + 2, or + 6, in various theories respecting sulphur compounds, the electrons of the outer shells are taken into account or assumed to be donated to other atoms. Probably the distance separating the centres of sulphur and carbon atoms in C—S is greater than that separating the centres of carbon and nitrogen atoms in C—N and this must reduce the effectiveness of equivalent charges in accordance with Coulomb's Law; if the charges are not equivalent, the validity of this explanation is greatly impaired.

Our view that the bound oxygen ions are polarised, thus reducing

the net charge of the sulphur atom, is closely connected with the theory of electrostriction of sulphonium kations by free anions; it is, in fact, intramolecular electrostriction. It should be noted that this hypothesis emphasises the importance of the part played by the central atom and can be correlated experimentally with work on the distribution of electrons in crystals. The hypothesis is also connected with the strength of the sulphonic acids, for it is surely the polarisation of the oxygen atoms in the $R{\cdot}SO_3$ ion that loosens the grip of their electrons on the proton (alternatively, increases the repulsion of the proton by the oxygen nucleus).

EXPERIMENTAL.

m-*Nitrophenylbenzylsulphone*, $NO_2{\cdot}C_6H_4{\cdot}SO_2{\cdot}CH_2Ph$.—A mixture of sodium *m*-nitrobenzenesulphinate (20 g.), benzyl chloride (15 g.), and 95% alcohol (60 c.c.) was refluxed for 4 hours, and the product (18 g.) precipitated by the addition of water. The *sulphone* crystallised from alcohol in very pale yellow needles, m. p. 151—152° (Found: C, 56·8; H, 4·5; N, 5·2. $C_{13}H_{11}O_4NS$ requires C, 56·3; H, 4·0; N, 5·1%).

m-*Nitrophenyl*-o-*nitrobenzylsulphone* was similarly prepared from *o*-nitrobenzyl chloride (8 g.), the yield being 14·7 g. It crystallised from acetone in pale yellow plates, m. p. 192—193° (Found: C, 48·6; H, 3·5; N, 9·0. $C_{13}H_{10}O_6N_2S$ requires C, 48·5; H, 3·1; N, 8·7%).

m-*Nitrophenyl*-m-*nitrobenzylsulphone* crystallised from alcohol in almost colourless, microscopic cubes, m. p. 194—195° (Found: C, 48·5; H, 3·0; N, 8·5%).

m-*Nitrophenyl*-p-*nitrobenzylsulphone* crystallised from acetone in very pale yellow needles, m. p. 180—181° (Found: C, 48·8; H, 3·6; N, 9·0%). The three isomerides are very sparingly soluble in most organic solvents and although the *o*-isomeride is the most sparingly soluble in alcohol, neither this nor any other solubility property could be employed for their separation.

Nitration of m-*Nitrophenylbenzylsulphone*.—The finely powdered substance (5·00 g.) was gradually added during 15 minutes to nitric acid (40 c.c.; *d* 1·5) kept at − 5° to 0°. Each addition produced a brownish-red, evanescent coloration. After 1 hour, the mixture was allowed to reach the room temperature and the product was precipitated by water after 3 hours. It was ground under water, washed, and dried (5·63 g. or 97%). In a second similar experiment the yield was 98·5% (Found: C, 48·6; H, 3·4%).

Various attempts to fractionally crystallise this material were made, but no suitable solvent could be found, and after experi-

menting with oxidation methods, which also we were compelled to abandon on account of the sparing solubility of the isomerides, we adopted the following colorimetric method. The *p*-isomeride gives a carmine coloration in alcoholic solution on the addition of 10% aqueous sodium hydroxide, whereas the *o*- and *m*-isomerides give no coloration under these conditions. In dilute solutions, the intensity of this colour was roughly proportional to the concentration of the *p*-isomeride and it was not affected by the presence of the *o*- or *m*-isomeride. A Zeiss "Stufenphotometer" was employed for the measurements and all the comparisons were direct, and not through a standard. The liquids were mixed in the adjustable vessels so that the colours could be compared as quickly as possible, and stirring was necessary before the caps were screwed on. Remarkably consistent results were obtained. Solutions of the nitration product (0·1987 g.), the *o*-isomeride (0·2018 g.), the *m*-isomeride (0·2098 g.), and the *p*-isomeride (0·2023 g.) in absolute alcohol (1000 c.c. each) were prepared. Taking 10 c.c. of the standard solution and adding 2 c.c. of 10% aqueous sodium hydroxide, it was found that the solution of the *p*-isomeride was roughly twice as concentrated (in *p*-isomeride) as the solution of the nitration product, columns of 5·35, 6·0, and 6·9 mm. balancing columns of 10·7, 11·9, and 13·8 mm., respectively. A closer comparison was then made by diluting the solution of the *p*-isomeride with an equal volume of alcohol and producing the colour as before; the solution of the *p*-isomeride was distinctly the stronger, the measurement indicating that the nitration product contained 47% of the *p*-isomeride. A mixture of the solution of the *p*-isomeride (45 c.c.) and alcohol (55 c.c.) gave a perceptibly weaker colour than the solution of the nitration product, the measurement again indicating that the nitration product contained 47% of the *p*-isomeride. The experiment was twice repeated with exactly the same results, so that the determination of the proportion of the *p*-isomeride in the mixture was considered to be sufficiently accurate to be employed in further work.

The estimation of the proportions of the *o*- and *m*-isomerides was much more difficult and the method was not capable of very great accuracy; the experiments were, however, frequently repeated and it is hoped that the results are not seriously in error. The *o*-isomeride gives an intense violet coloration with strong alkalis in alcoholic acetone (or pure acetone) solution, whereas the *m*-isomeride gives no immediate coloration. The following solutions were employed: (1) *o*-isomeride (5 c.c.), *p*-isomeride (20 c.c.), alcohol (17·5 c.c.); (2) *o*-isomeride (10 c.c.), *p*-isomeride (20 c.c.), alcohol (12·5 c.c.); (3) *o*-isomeride (15 c.c.), *p*-isomeride (20 c.c.), alcohol

(7·5 c.c.); (4) *o*-isomeride (20 c.c.), *p*-isomeride (20 c.c.), alcohol (2·5 c.c.); (5) nitration product (42·5 c.c.). Sodium ethoxide solution (10 c.c.) (from 10 g. of sodium in 250 c.c. of alcohol) and then pure acetone (50 c.c.) were added to each mixture. The colour developed by the nitration product was found to lie between those produced by solutions (2) and (3) and was much closer to that of (2). Experiments with solutions of compositions between those of (2) and (3) confirmed this and indicated that the nitration product contained 25—30% of the *o*-isomeride. The colour-tone match was not perfect, however, and it was then noticed that the *m*-isomeride slowly developed a brownish-red coloration in acetone solution in the presence of sodium ethoxide. A fresh series of solutions was therefore made up in which the pure alcohol was replaced by the appropriate volume of the *m*-isomeride solution; a colour-tone match was then obtained and the intensity showed that the proportion of the *o*-isomeride in the nitration product was 23—27%. This was confirmed by a direct estimation of the content of *m*-isomeride.

The three isomerides develop colorations when solid potassium hydroxide is added to their cold solutions in acetone, but if, after a short time, water is added, the colorations due to the *o*- and *p*-isomerides are discharged and the *m*-isomeride gives a brownish-yellow solution. A series of mixtures was prepared as before from the standard alcoholic solutions and, after the alcohol had been removed, acetone (30 c.c.) and potassium hydroxide (2 cm. stick) were added. The mixture was stirred for 5 minutes, water (50 c.c.) was then added, and the colour compared with that obtained from the nitration product under identical conditions. The proportion of the *m*-isomeride in the nitration product was thus found to lie between 25 and 32%. A mixture of the *o*-isomeride (0·250 g.), the *m*-isomeride (0·280 g.), and the *p*-isomeride (0·470 g.) was then made and its colour reactions were compared with those of the nitration product, the substances being weighed on a micro-balance, with the result that no difference could be detected. The mixture after fusion, resolidification, and grinding had m. p. 152—156° and the nitration product had m. p. 153—157°; a mixture of the two had m. p. 152—156°.

The authors wish to express their indebtedness to the Chemical Society for a grant which defrayed a part of the cost of the investigation.

THE UNIVERSITY, MANCHESTER. [*Received, September 9th*, 1927.]

CCCLXXI.—*The Orienting Influence of Free and Bound Ionic Charges on Attached Simple or Conjugated Unsaturated Systems. Part IV. The Nitration of Toluene-ω-sulphonic Acid and of Toluene-ω-sulphonyl Chloride.*

By ARTHUR C. BOTTOMLEY and ROBERT ROBINSON.

THE work of Vorländer (*Ber.*, 1919, **52**, 262) proved that an atom bearing a positive charge when directly attached to the aromatic nucleus has a powerful *m*-directive effect, and on the lines of electronic theories this may be interpreted as meaning that a group having a strong attraction for electrons has a *m*-directive effect. The discovery of the largely predominating *meta*-nitration of benzyltrimethylammonium nitrate (Part I, J., 1926, 1655) justified this view in the most convincing manner. It may be fairly claimed that the connexion between polarity and orientation thus firmly established is less hypothetical in character than any other in organic chemistry. The proof that *m*-substitution in benzene derivatives is *sometimes* due to a general electrical effect of the first substituent suggests that *m*-direction may *always* be initiated in this way.

Among *m*-directive groups the only one which seems to present difficulty from this point of view is the sulphonic acid group. At first sight it is hard to reconcile the net negative charge of the sulphonic ion with an assumed tendency to attract electrons. It must be remembered, however, that sulphuric acid is a powerful dibasic acid and therefore $HS\bar{O}_4$, which may be written $HO{\cdot}S\bar{O}_3$, is evidently able to donate a proton to acceptor molecules, and this means that the $-S\bar{O}_3$ group, in spite of its charge, retains a high electron affinity. The phenomenon is doubtless connected with incomplete neutralisation of the charge of the sulphur atom by the distorted oxygen ions surrounding it (see the preceding communication) and with the partial neutralisation of the field of the oxygen ions by neighbouring kations and kationoid complexes.

The possibility that the sulphonic acid group is *m*-directive for the same reason that the ammonium-salt group is *m*-directive would become a probability if it could be shown that the effect is produced when a saturated carbon atom separates the sulphur atom from the benzene nucleus; we accordingly studied the nitration of toluene-ω-sulphonic acid. This substance is nitrated to a predominating extent in the *op*-positions, but the proportion of the

m-nitro-isomeride produced is much greater than that obtained in the nitration of toluene. This result confirms the view that the sulphonic ion group, $\bar{S}O_3$, has a higher electron affinity than has a hydrogen atom, and we may confidently attribute the *m*-substitution of benzenesulphonic acid to the occurrence of the condition $Ph\longrightarrow\bar{S}O_3$.

Toluene-ω-sulphonyl chloride, $Ph\longrightarrow CH_2\overset{(a)}{\longrightarrow}SO_2\overset{(b)}{\longrightarrow}Cl$, may be regarded as a sulphone in which the normal displacement (a) is reinforced by that (b) due to the chlorine atom. In harmony with our theory, the percentage of the *m*-isomeride formed in the nitration of this substance is much greater than that formed in the nitration of toluene-ω-sulphonic acid and considerably greater than that formed in the nitration of benzyl-*m*-nitrophenylsulphone.

The publication of Ingold, Ingold, and Shaw (this vol., p. 813), dealing with the nitration of substances of the form $CH_2Ph{\cdot}SO_2R$, appeared when our work was at a stage where the determinations of the proportion of *m*-isomeride formed in the nitrations had been completed. In view of it, the experimental section of this communication has been curtailed so that all repetition of description has been avoided. We carried out, for example, identifications of the products as nitrotoluene-ω-sulphonamides (compare Mohr, *Annalen*, 1883, **221**, 218; Purgotti and Monti, *Gazzetta*, 1900, **30**, ii, 254) and no further reference to this part of our work is deemed necessary.

EXPERIMENTAL.

Method of Estimation of the Proportion of m-*Isomeride formed in the Nitrations.*—Francis and Hill's method of bromination after reduction of the nitro-compounds with titanous chloride (*J. Amer. Chem. Soc.*, 1924, **46**, 2498) has been found to be applicable to the sodium nitrotoluene-ω-sulphonates. Small corrections were applied for the deviations from the stoicheiometric relations found for sodium *o*-, *m*-, and *p*-nitrotoluene-ω-sulphonates.

Sodium *o*-nitrotoluene-ω-sulphonate was crystallised from semi-saturated brine and dried at 100—120° (Found: NaCl, 20·3; sodium nitrotoluenesulphonate estimated by titanous chloride, 79·4%). On reduction and bromination, the deviation from the theoretical value (in the volume of potassium bromate solution required for bromination) was − 0·4%. Sodium *m*-nitrotoluene-ω-sulphonate was crystallised from semi-saturated brine and dried at 130—140° (Found: NaCl, 7·1; sodium nitrotoluenesulphonate, 92·4%; deviation from theory on reduction and bromination, + 0·9%). The *o*-isomeride loses $1H_2O$ at 100°, but the *m*- and *p*-isomerides retain their water of crystallisation below 125°. Sodium

p-nitrotoluene-ω-sulphonate was crystallised from brine and dried at 140° (Found: NaCl, 1·9; sodium nitrotoluenesulphonate, 96·6%; deviation from theory on reduction and bromination, + 1·1%).

Some difficulty was experienced in obtaining satisfactory end-points in the final titrations with sodium thiosulphate, and this was overcome by using not too large an excess of bromine and by neutralising part of the acid after the liberation of iodine.

Nitration of Sodium Toluene-ω-sulphonate.—Sodium toluene-ω-sulphonate crystallised from 95% alcohol in lustrous leaflets, and the specimens employed were anhydrous and free from sodium chloride.

In a preliminary experiment, 20 g. of the salt were nitrated and 16·5 g. of washed sodium nitrotoluenesulphonates (dried at 100°) were obtained (Found: loss at 140° or H_2O, 6·0; NaCl, 8·6; sodium nitrotoluenesulphonates, 85·3%; *meta*, 20·2, 19·8, 18·5, 19·4%). The true yield was 57·6% and therefore the minimum value for the proportion of *m*-isomeride formed is 11—12%.

In attempts to improve the yield products were obtained containing sodium nitrate, which interfered seriously with the determinations. In subsequent experiments, the absence of nitrates was always confirmed.

Ultimately, the following nitration conditions were adopted: Sodium toluene-ω-sulphonate (10 g.) was added during 30 minutes to nitric acid (15 c.c.; *d* 1·5) at 0°, a further quantity of the acid (5 c.c.) being used to wash the sides of the container. Three hours from the commencement the ice-bath was removed and 1 hour later the solution was mixed with water (120 c.c.) and neutralised by means of sodium carbonate (20 g.), and after the addition of sodium chloride (30 g.) the liquid was heated until a clear solution resulted. The cooled liquid was kept at 0° for 3 hours and the separated solid was then washed twice with 15% brine (10 c.c.) and dried at 100° (Specimen A, 12·8 g.) (Found: H_2O, 4·9; NaCl, 10·0; sodium nitrotoluenesulphonate, 84·8%; *meta*, 11·7, 11·0, 10·6, 10·3, 9·6, 9·6%). The yield of sodium nitrotoluene-ω-sulphonates was therefore 88% and the minimum value for the proportion of *m*-isomeride formed is 9·2% (maximum, 21·2%). Another specimen (B) was prepared in the same manner (purity, 82%; true yield, 88%).

Nitration of Toluene-ω-sulphonic Acid.—The free acid (9 g.), prepared by Böhler's method (*Annalen*, 1870, **154**, 50), was treated exactly as described above for its sodium salt. The isolated, washed, and dried solids amounted to only 8·0 g. A further amount of sodium chloride (20 g.) was therefore added and 6·0 g. of the

mixed salts were obtained. The products were free from nitrates and were mixed (Found: H_2O, 3·3; NaCl, 39·9; sodium nitrotoluenesulphonates, 56·8%; *meta*, 14·2, 13·7, 14·2%). Here the true yield was 63·6% and the minimum value for the proportion of *m*-isomeride is 8·9%. We are unable to account for the variations in yield which were observed, but since the actual amount of the *m*-isomeride obtained was as great in this experiment (yield, 64%) as in the one previously described (yield, 88%), we may conclude that the proportion formed is greater in the nitration of the acid than in that of the salt. The point is not raised in the introduction, because it is hoped to follow up this indication by fresh experiments before the interesting theoretical implications are discussed.

Nitration of Toluene-ω-sulphonyl Chloride.—Toluene-ω-sulphonyl chloride (10 g.) was added during 30 minutes to nitric acid (15 c.c.; *d* 1·5) at 0°, a further amount of nitric acid (5 c.c.) being employed to wash the sides of the container. After 3 hours, the ice-bath was removed and 1 hour later the product was precipitated by water, collected, and boiled with a solution of sodium carbonate (11 g.) in water (100 c.c.) until no oil remained (about 1 hour). The liquid was filtered hot, sodium chloride (20 g.) introduced, and the mixture kept at 0° for 3 hours; the separated solid was then collected, washed twice with 15% brine (10 c.c.) at 0°, and dried at 100° (yield, 10·2 g.) (Found: H_2O, 5·7; NaCl, 12·3; sodium nitrotoluenesulphonates, 77·6%; *meta*, 44%). The yield was 63% and the minimum value for the proportion of *m*-isomeride formed is 28%. The specimen contained carbonate, and this probably accounts for the fact that the water, sodium chloride, and nitrocompounds determined totalled only 95·6%. Another nitration was carried out in exactly the same manner, but the alkaline solution was neutralised with hydrochloric acid and the sodium nitrotoluenesulphonates were salted out in two crops (mixed, 15·7 g.) (Specimen C) by means of sodium chloride (total, 50 g.) (Found: H_2O, 3·8; NaCl, 40·2; sodium nitrotoluenesulphonates, 55·8%; *meta*, 56, 54, 56, 56%). The true yield was 70·5% and the minimum value for the proportion of *m*-isomeride formed is 39% (maximum, 67·5%).

Comparison of these experiments shows that more efficient salting out increases the percentage of the *m*-isomeride in the product, and hence the true value for the *m*-isomeride content should be considerably greater than the minimum; it must also, of course, be much less than the maximum.

Estimation of the Proportions of the p-*Isomeride in Specimens A, B, and C.*—On heating at 100° with concentrated aqueous potassium hydroxide, the *o*- and *m*-nitrotoluene-ω-sulphonates

develop no coloration, whereas the *p*-isomeride gives a yellowish-orange solution. Attempts to apply this reaction in a colorimetric method gave unintelligible results until it was found that the colour produced by the *p*-isomeride is more intense in the presence of the *o*-isomeride and still more intense in the presence of the *m*-isomeride. The *o*- and *m*-isomerides give no coloration when mixed and heated with aqueous potassium hydroxide.

Solutions were made up to contain 1·0% of the pure *o*-, *m*-, and *p*-isomerides and of the nitro-compounds in specimens A, B, and C. 10 C.c. of one of these solutions or of a mixture of them were mixed with 25 c.c of a solution of potassium hydroxide (100 g.) in water (100 c.c.) and heated in a bath of boiling water for about 2 hours. All the comparisons were direct under identical conditions, and in addition to the determination of the intensity of the colour the rapidity of its appearance afforded valuable guidance. In making up the standards, the ascertained percentage of the *m*-isomeride in the specimen to be tested was introduced and kept constant, the proportions of the *p*- and *o*-isomerides being varied.

In the case of specimen C, the colour was practically identical with that of a standard made from 5·5 c.c. of the *m*-isomeride solution and 4·5 c.c. of the *p*-isomeride solution and was distinctly stronger than that obtained from the standard—*m*-, 5·5; *p*-, 4·0; *o*-, 0·5 c.c. The colours were estimated after dilution of the solutions to 40 c.c. by means of the Zeiss "Stufenphotometer." The specimen C, obtained in 70·5% yield from the nitration of toluene-ω-sulphonyl chloride, does not, therefore, contain an appreciable amount (<5%) of the *o*-isomeride.

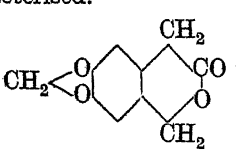
No difference could be detected in the behaviour of the specimens A and B when a direct comparison was made; most of the experiments were therefore made with B, because a larger quantity of this specimen was available. A series of comparisons with standards showed that the colour derived from B was more intense than that from the standard—*m*-, 1·0; *p*-, 4·5; *o*-, 4·5 c.c., and less intense than that from the standard—*m*-, 1·0; *p*-, 5·0; *o*- 4·0 c.c.

The actual intensity measurements of these and four other standards compared with the solution from B were used to construct a graph, by means of which the solution exactly equivalent to the B solution was found to be—*m*-, 1·0; *p*-, 4·8; *o*-, 4·2 c.c. This was experimentally confirmed with solutions made up from quantities weighed on a micro-balance.

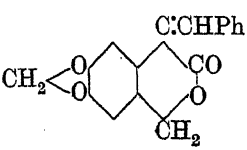
A specimen was made by admixture of the *o*-, *m*-, and *p*-isomerides and sodium chloride that contained 82% of the pure sodium nitrotoluene-ω-sulphonates (*m*-, 10; *o*-, 40; *p*- 50%) and was found

in numerous quantitative trials under different conditions to resemble B closely in behaviour. The colours were developed a very little the more rapidly with the artificial mixture. Finally, the specimen A was reproduced on the same basis and with the same results.

The colour reactions observed with alkaline solutions also guarantee the absence of sodium dinitrotoluene-ω-sulphonates. A specimen of the latter (probably the 2 : 4-dinitro-derivative) was prepared by nitration of sodium *o*-nitrotoluene-ω-sulphonate with a hot mixture of sulphuric and nitric acids. The sodium salt crystallised in colourless leaflets and developed a green colour with cold, dilute aqueous sodium hydroxide; on heating, an intense bluish-green solution was obtained.



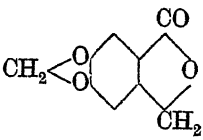
The authors wish to thank the Advisory Council of the Department of Scientific and Industrial Research for a grant that enabled one of them to take part in the investigation.



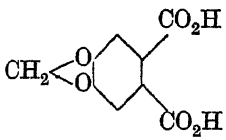
THE UNIVERSITY, MANCHESTER. [*Received, September 12th*, 1927.]

CCCLXXII.—*A New Synthesis of Hydrastic Acid.*

By THOMAS STEVENS STEVENS and MARY CARRICK ROBERTSON.

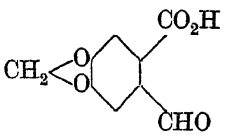


IN the course of recent synthetic work, the lactone (I) was obtained by the action of formaldehyde on homopiperonylic acid, and its structure confirmed by oxidising it to 4 : 5-methylenedioxyhomophthalic acid (Stevens, this vol., p. 178). It was further considered desirable to attempt the conversion of (I) into hydrastic acid, both on account of the interest attaching to a synthesis of that important substance, and also because the homophthalic acid is not readily characterised.

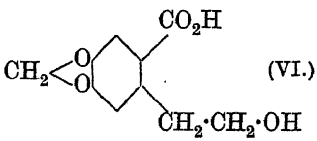


(I.) 

 (II.)



The compound (I) was condensed with benzaldehyde in presence of piperidine to form the lactone (II) of α-(6-*hydroxymethylpiperonyl*)-*cinnamic acid*. Oxidation with neutral permanganate converted this into 4 : 5-*methylenedioxyphthalide* (III), which was further oxidised in alkaline solution to hydrastic acid (IV). The substances



(III) and (IV) are clearly the "methylenedioxy-analogues" of *m*-meconin and *m*-hemipinic acid, and it was hoped that it would

(III.) 

(IV.) 

be possible to complete the series by oxidising (III) to the aldehydo-acid (V), analogous to *m*-opianic acid, but this could not be accomplished.

(V.) 

(VI.) 

The hydroxy-acid derived from the lactone (I) lactonises spontaneously when liberated from its salts, whereas that derived from (III), like many derivatives of *o*-hydroxymethylbenzoic acid, is comparatively stable. This greater stability of the γ-hydroxy-acids relatively to the δ-, as compared with the opposite behaviour of simple aliphatic compounds, is significant in view of von Braun's suggestion that in the formation of cyclic structures two carbon atoms of a benzene ring are sterically more nearly equivalent to one methylene group than to two (*Ber.*, 1925, **58**, 2765; 1927, **60**, 1257). On the other hand, 6-β-hydroxyethylpiperonylic acid (VI) (Perkin, J., 1890, **57**, 1020) and β-*o*-hydroxyphenylpropionic acid are fairly stable. The relative stabilities of these three δ-hydroxy-acids are in striking contrast to those of the δ-amino-acids prepared by von Braun and Reich (*Annalen*, 1925, **445**, 225), who observed that the lactam of *o*-aminomethylphenylacetic acid, analogous to (I), was *less* readily formed than those of the isomeric β-*o*-aminophenylpropionic and *o*-β-aminoethylbenzoic acids.

Experimental.

α-(6-*Hydroxymethylpiperonyl*)*cinnamolactone* (II).—The lactone (I) (10 g.) is dissolved in hot benzaldehyde (15 c.c.), piperidine (8—10 drops) added, and the mixture heated at 120° for 2 hours. The melt is dissolved in boiling acetic acid, and the solid (12 g.), which separates on cooling, recrystallised from alcohol or acetic acid. It forms pale yellow needles, m. p. 190—192°, fairly soluble in hot acetic acid and sparingly soluble in alcohol, and gives an intensely orange solution in concentrated sulphuric acid (Found: C, 72·9; H, 4·3. $C_{17}H_{12}O_4$ requires C, 72·9; H, 4·3%). It dis-

solves slowly in boiling aqueous alkali to a colourless solution: on acidification a colourless acid separates, which passes back into the lactone on being heated with dilute acids.

4 : 5-*Methylenedioxyphthalide* (III).—A solution of the lactone (II) (10 g.) in warm acetone (230—300 c.c.) is cooled (any crystallisation being disregarded), and stirred during the gradual addition of potassium permanganate (13 g.) and magnesium sulphate (13 g.) in warm concentrated aqueous solution. The mixture is boiled and filtered; much of the product then separates on cooling, and more may be obtained from the manganese sludge (5 g. in all). Methylenedioxyphthalide is soluble in about 100 parts of boiling water, and crystallises in white needles, m. p. 188—189°, which sublime readily without decomposition at about 150—160°. The sublimate consists principally of stout, short prisms which show the same m. p. as the original material and are reconverted into the needles on crystallisation from water (Found: C, 60·6; H, 3·7. $C_9H_6O_4$ requires C, 60·6; H, 3·4%). Attempts to oxidise the substance to the aldehydo-acid (V) with manganese or lead dioxide and sulphuric or acetic acid, or with chromic anhydride in acetic anhydride, were not successful.

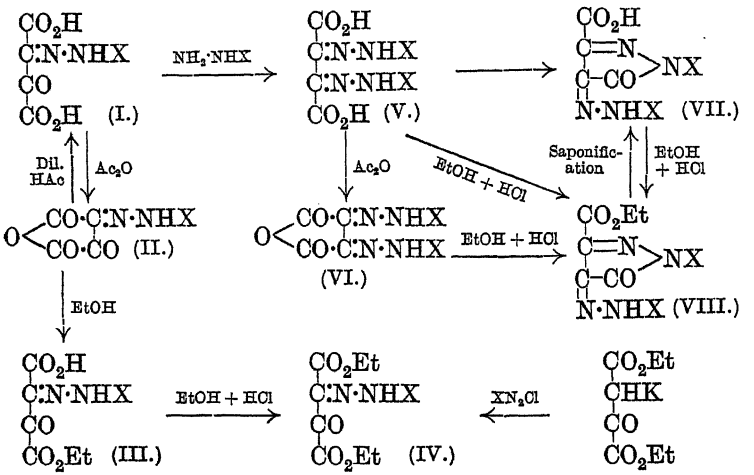
6-*Hydroxymethylpiperonylic Acid.*—The phthalide (III) is not attacked by cold carbonates, but rapidly dissolves in hot sodium hydroxide solution, and the hydroxy-acid is precipitated in minute crystals when the cold solution is acidified. It melts indefinitely at about 140—150°, quickly resolidifies, and then melts at the m. p. of the lactone (Found: *M*, by titration, 193. $C_9H_8O_5$ requires *M*, 196). The acid is readily soluble in hot water and crystallises unchanged on rapid cooling; boiling dilute mineral acids reconvert it at once into the lactone. The *silver* salt forms colourless, microscopic prisms which are sparingly soluble in boiling water (Found: Ag, 35·8. $C_9H_7O_5Ag$ requires Ag, 35·6%).

Hydrastic Acid (IV).—The phthalide (III) was dissolved in dilute alkali solution and oxidised in the cold with a moderate excess of aqueous potassium permanganate. On acidification of the filtrate from the manganese dioxide, hydrastic acid, m. p. 175° (decomp.), crystallised in a yield of more than 50% of the theoretical. It was characterised by conversion into the methylimide, m. p. 228°, and by analysis of the silver salt (Found: Ag, 51·0. Calc., Ag, 50·9%).

UNIVERSITY OF GLASGOW. [*Received, September 15th*, 1927.]

CCCLXXIII.—*The Action of Tolylhydrazines upon Dihydroxytartaric Acid.*

By Frederick Daniel Chattaway and William Gerald Humphrey.



Although the osazones of dihydroxytartaric acid have been thoroughly investigated, its monohydrazones have never been prepared in a pure condition. Gnehm and Benda (*Annalen*, 1897, 299, 100) showed that the action of *p*-nitrophenylhydrazine upon excess of dihydroxytartaric acid yielded the pure osazone with no trace of a monohydrazone, whilst phenylhydrazine gave a mixture of the monohydrazone and osazone, which they did not separate into the two constituents. The action of halogen-substituted phenylhydrazines results in the formation of similar mixtures (this vol., p. 1323).

The action of *o*- and *p*-tolylhydrazines upon dihydroxytartaric acid differs from that of other hydrazines in that pure monohydrazones are readily obtained. These are well-crystallised, yellow solids, which, like the corresponding osazones, are converted into deep red acid anhydrides on heating with acetic anhydride. On crystallising these anhydrides from dilute acetic acid, the original hydrazones are re-formed; similarly, on crystallising the anhydrides from anhydrous alcohol, half-esters are formed. The second carboxyl group undergoes esterification only with difficulty, requiring prolonged boiling with alcohol containing hydrogen chloride; the diethyl ester thus formed may also be obtained by coupling diazotised toluidine with the potassium derivative of ethyl oxalacetate.

The most important property of the osazones of dihydroxytartaric acid is the ease with which they lose a molecule of water to give pyrazoline derivatives. This property is completely absent from the monohydrazones, and all attempts to cause pyrazoline ring formation have been unsuccessful.

The *o*- and *p*-tolylosazones of dihydroxytartaric acid behave in the normal manner. They are sparingly soluble substances which cannot be crystallised unchanged from any solvent. They are converted into deep red anhydrides by heating with acetic anhydride, and into hydrazones of diketopyrazolinecarboxylic acids by crystallisation from acetic acid or by acidification of their sodium salts. In the former reaction, varying amounts of the isomeric anhydrides are simultaneously produced. These pyrazoline derivatives undergo esterification with difficulty and their esters are more easily obtained from the corresponding osazone.

The following scheme represents the reactions, X denoting the tolyl group:

EXPERIMENTAL.

Diketosuccinic acid o-*tolylhydrazone* (I) was prepared by adding a solution of 26 g. of sodium dihydroxytartrate (1 mol.) in 180 c.c. of moderately concentrated hydrochloric acid (1 : 1) to a solution of 16 g. of *o*-tolylhydrazine hydrochloride (1 mol.) in 1000 c.c. of very dilute hydrochloric acid (1 : 100). The *hydrazone* separated slowly as a deep yellow, crystalline powder, which was filtered off after 3—4 hours and crystallised from 75% acetic acid, in which it was moderately easily soluble and from which it separated in yellow, elongated, flat prisms, m. p. 192° (decomp.) (Found: N, 11·2. $C_{11}H_{10}O_5N_2$ requires N, 11·2%).

This hydrazone shows no tendency to lose water to form a pyrazoline derivative. It dissolves readily in hot sodium hydroxide solution and is reprecipitated on acidification. On boiling with acetic acid, partial conversion into the anhydride occurs, whilst boiling with alcohol containing hydrogen chloride causes esterification only.

Anhydrodiketosuccinic Acid o-*Tolylhydrazone* (II).—The hydrazone (I) was added to boiling acetic anhydride until no more would dissolve. A clear, deep red solution was thus obtained which on cooling deposited the *anhydride* in long, red, glistening prisms, m. p. 208° (decomp.) (Found: N, 12·2. $C_{11}H_8O_4N_2$ requires N, 12·1%).

Ethyl Hydrogen Diketosuccinate o-*Tolylhydrazone* (III).—The

above anhydride was boiled with anhydrous alcohol and the yellow solution thus obtained, on cooling, deposited the half-ester in yellow, irregular, thin plates, m. p. 115° (Found: N, 9·9. $C_{13}H_{14}O_5N_2$ requires N, 10·1%).

The half-ester may also be prepared by boiling the hydrazone (I) with alcohol containing 5% of dry hydrogen chloride for ½ hour.

A definite formula cannot be assigned to this ester, as there is nothing to indicate which of the two carboxyl groups is esterified. The product appears not to be a mixture; its melting point is not changed by recrystallisation, and the fact that the second group can be esterified only with great difficulty points to a particular one being concerned in the first reaction.

Ethyl Diketosuccinate o-*Tolylhydrazone* (IV).—Although one carboxyl group of diketosuccinic acid *o*-tolylhydrazone is readily esterified, the diethyl ester was formed only by boiling the half-ester for 12 hours with alcohol saturated with dry hydrogen chloride. A certain amount of decomposition and tar formation occurred, and a dark brown solution was obtained, which on cooling deposited the *diethyl* ester in bright yellow, hexagonal plates or flattened prisms, m. p. 90° (Found: N, 9·1. $C_{15}H_{18}O_5N_2$ requires N, 9·15%).

The same ester was prepared by adding slowly a cold aqueous solution of *o*-toluenediazonium chloride (1 mol.) to an aqueous solution of the potassium derivative of ethyl oxalacetate (1 mol.), cooled in a freezing mixture. A sticky, red mass separated, from which, by crystallisation from alcohol, ethyl diketosuccinate *o*-tolylhydrazone was obtained, identical with that prepared by direct esterification.

Diketosuccinic acid o-*tolylosazone* (V) was prepared by adding a solution of 26 g. of sodium dihydroxytartrate (1 mol.) in 180 c.c. of moderately concentrated hydrochloric acid (1 : 1) to a solution of 32 g. of *o*-tolylhydrazine (2 mols.) in 1500 c.c. of dilute hydrochloric acid (1 : 100). The mixture was stirred for 6 hours and heated at 80° for 2 hours. The *osazone* was filtered off without previous cooling, repeatedly washed with boiling water, and dried at 110°. It was thus obtained as an orange powder, m. p. 170° (decomp.) (Found: N, 15·6. $C_{18}H_{18}O_4N_4$ requires N, 15·8%).

Anhydrodiketosuccinic Acid o-*Tolylosazone* (VI).—The osazone (V) was added to boiling acetic anhydride until no more would dissolve. On cooling, the *anhydride* separated in long, glistening, red prisms, m. p. 198° (decomp.) (Found: N, 16·6. $C_{18}H_{16}O_3N_4$ requires N, 16·7%).

4 : 5-*Diketo*-1-o-*tolylpyrazoline*-3-*carboxylic acid* 4-o-*tolylhydrazone* (VII) is formed together with the isomeric anhydride (VI) on crystallising the osazone (V) from acetic acid. It is, however,

best obtained by acidifying the orange-coloured solution produced by dissolving the osazone in hot 10% sodium hydroxide solution; the *tolylhydrazone* thus obtained separates from acetic acid, in which it is sparingly soluble, in very small, yellow prisms, m. p. 229° (decomp.) (Found: N, 16·45. $C_{18}H_{16}O_3N_4$ requires N, 16·7%).

Its *ethyl* ester (VIII), obtained by boiling the osazone (V), the anhydride (VI), or the pyrazolone (VII) with alcohol containing 5% of dry hydrogen chloride, crystallises from alcohol, in which it is easily soluble, in long, orange-red prisms, m. p. 145° (Found: N, 15·5. $C_{20}H_{20}O_3N_4$ requires N, 15·4%).

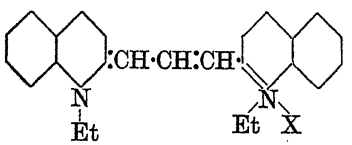
The following derivatives of *p*-tolylhydrazine were similarly prepared.

Diketosuccinic acid p-*tolylhydrazone* (I) is moderately easily soluble in 75% acetic acid, from which it separates in orange-yellow octahedra, m. p. 190° (decomp.) (Found: N, 11·3%). The *anhydride* (II) crystallises from acetic anhydride in deep red, elongated prisms, m. p. 192° (decomp.) (Found: N, 12·1%). The *half-ester* (III) is easily soluble in alcohol, from which it separates in lemon-yellow, slender prisms, m. p. 112° (Found: N, 10·05%).

Diketosuccinic acid p-*tolylosazone* (V) was obtained as a soft, orange-red powder, m. p. 175° (decomp.) (Found: N, 15·65%). The *anhydride* (VI) forms red, elongated prisms, m. p. 230° (decomp.) (Found: N, 16·5%).

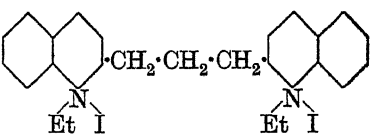
4 : 5-*Diketo*-1-p-*tolylpyrazoline*-3-*carboxylic acid* 4-p-*tolylhydrazone* (VII) is sparingly soluble in acetic acid, from which it separates in very small, pale yellow prisms, m. p. 233° (decomp.) (Found: N, 16·7%). Its *ethyl* ester (VIII) is easily soluble in alcohol, from which it separates in orange-red, slender prisms, m. p. 143° (Found: N, 15·55%).

THE QUEEN'S COLLEGE, OXFORD. [*Received, October 11th*, 1927.]



CCCLXXIV.—*A General Method for the Preparation of Carbocyanine Dyes.*

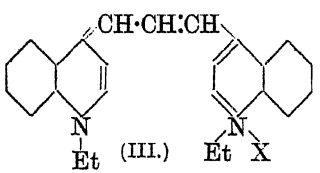
By FRANCES MARY HAMER.



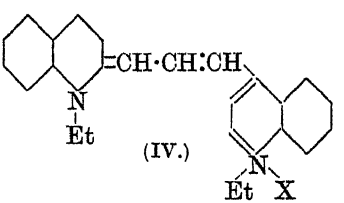
SINCE 1920, when the term "carbocyanine" was first applied to pinacyanol and similar dyes (Mills and Pope, *Phot. J.*, 1920, **44**, 253), other types of compounds have been discovered which, from their structure and properties, should be included under the same name. Before describing the present general method of preparing carbocyanines, it seems desirable to summarise these various types

and the methods which have hitherto been employed in making them.

The most important carbocyanine dye is 1 : 1′-diethyl-2 : 2′-carbocyanine halide (I), which, under the trade name of pinacyanol, is a well-known photographic sensitiser. Hitherto the best way of preparing it has consisted in adding formaldehyde and then alkali to a boiling alcoholic solution of a quinaldinium salt in the presence of a quinolinium salt, but the yield of pure dye is at most only 21% of that theoretically possible. The part played by formaldehyde may be taken by a trihalogenomethane (D.R.-P., 200,207/1908), or the methenyl residue may be provided by di-*o*-formylethylaminodiphenyl disulphide, reacting with quinaldine ethonitrate in pyridine solution (Mills and Braunholtz, J., 1923, **123**, 2804). König obtained pinacyanol by the condensation of quinaldine ethiodide with ethyl orthoformate in the presence of acetic anhydride (*Ber.*, 1922, **55**, 3293), but his claim to a 50% yield could not be confirmed (Hamer, J., 1925, **127**, 211). Finally, the dye has been derived from methylenediquinaldine diethiodide (II) by the action of alkali



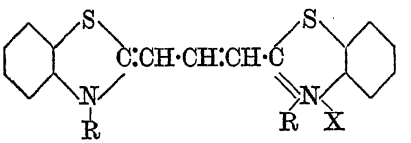
(I.)



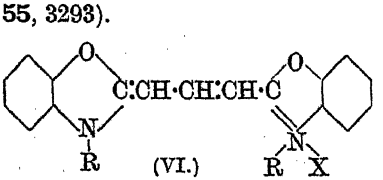
(II.)

in the presence of a quinolinium salt (Hamer, J., 1923, **123**, 246). The establishment of the constitution of pinacyanol (Mills and Hamer, J., 1920, **117**, 1550) led to the prediction of two similar groups of carbocyanines, possessing respectively a 4 : 4′- and a 2 : 4′-linking (III and IV) in place of the original 2 : 2′-linking. Mills and Braunholtz (*loc. cit.*) prepared a dye of the first type (III)

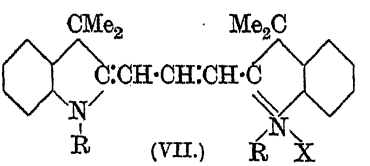
(III.)



(IV.)



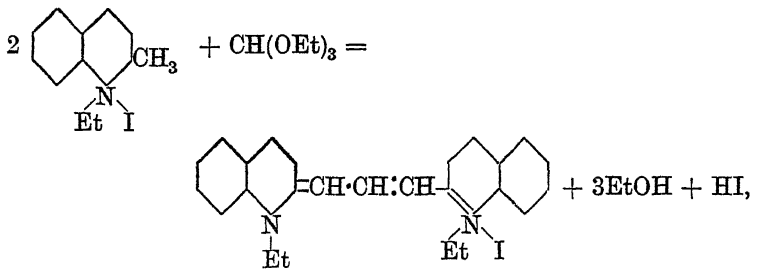
from lepidine ethonitrate by the action of the disulphide and pyridine, and showed the corresponding iodide, obtainable in 15% yield, to be identical with " kryptocyanine," which had previously been prepared, in 9% yield, by treating an alcoholic solution of lepidine ethiodide with alkali and formaldehyde or chloroform (Adams and Haller, *J. Amer. Chem. Soc.*, 1920, **42**, 2661). Mills



and Odams similarly synthesised the 2 : 4′-isomeride (IV) by the action of the disulphide on the ethonitrates of quinaldine and lepidine, and proved "dicyanine" to be a dye of this kind (J., 1924, **125**, 1913).

Besides these three closely related classes of carbocyanines, analogous dyes are obtained when the quinoline nuclei are replaced by other basic nuclei. Mills has shown that the dyes formed by the action of ammonia on the quaternary salts of 1-methylbenzthiazole and benzthiazole (Hofmann, *Ber.*, 1887, **20**, 2262) result in better yield (19%) when the salts are heated in pyridine solution, and has proved that they have formula (V) (J., 1922, **121**, 455). Substances of the same class were prepared by König and Meier,

(V.) 



by condensation of 1-methylbenzthiazole methohalide with ethyl orthoformate, or anhydrous sodium formate, in nitrobenzene solution; they mention that the reaction proceeds equally well in acetic anhydride or pyridine solution (*J. pr. Chem.*, 1925, **109**, 324). Repetition of the preparation of the methobromide in nitrobenzene solution, or of the methiodide in acetic anhydride solution, has been found to give unsatisfactory results. By heating 1-methylbenzoxazole methiodide with ethyl orthoformate in the presence of nitrobenzene or acetic anhydride, König and Meier prepared a dye of a new type (VI) (*loc. cit.*), whilst König prepared another class of carbocyanine (VII) by treatment of a 2 : 3 : 3-trimethylindoleninium salt with ethyl orthoformate and acetic anhydride (*Ber.*, 1924, **55**, 3293).

(VI.)

(VII.)

As regards the nomenclature of these last three groups of carbocyanine dyes, the term *thiocarbocyanine* is preferred to the name carbothiocyanine (Mills, *loc. cit.*), as being more consistent with the terms thio*iso*cyanine (Braunholtz and Mills, J., 1922, **121**, 2004), thio*pseudo*cyanine (Mills and Braunholtz, *loc. cit.*), and pyridocarbocyanine (*ibid.*). It is proposed that the dyes (VI) and (VII), derived from benzoxazole and indolenine, be named *oxacarbocyanines* and *indocarbocyanines* respectively.

Now the equation representing the reaction of quinaldine ethiodide

with ethyl orthoformate suggests that the pinacyanol condensation would be favoured by the use of a basic solvent. Boiling pyridine proved in fact to serve excellently, and to its use is attributable the whole success of the present method. The only precaution necessary is that of drying the solvent, whilst about four times the calculated quantity of ester should be taken. Three 2 : 2′-carbocyanines have been prepared by the pyridine method, the yields of pure product varying from 70 to 79%, and the method was subsequently applied to the preparation of carbocyanines of the other five classes. With the 2 : 4′-carbocyanines, the yield of crude material is higher and the labour involved is less than in any other published method of preparing dicyanines; their separation, by fractional crystallisation, from the 2 : 2′- and 4 : 4′-isomerides was not, however, carried out. The success of the method is especially striking in the case of the 4 : 4′-carbocyanines, the yields being 36 to 43% of the theoretical. In the preparation of 1 : 1′-diethyl-4 : 4′-carbocyanine iodide, there is formed in addition about half its amount of another dye, which may readily be isolated by virtue of its slight solubility. Its properties show it to be identical with " neocyanine," which has been described as a by-product in the preparation of kryptocyanine by the formaldehyde method, and which is a powerful sensitiser for the deep red and infra-red (Dundon, Schoen, and Briggs, *J. Opt. Soc. Amer.*, 1926, **12**, 397). The pyridine method is at its best in the case of the thiocarbocyanines, giving between 79 and 83% yields of pure dyes; with the oxacarbocyanines the yields are about 40% and with the indocarbocyanines about 70% of those theoretically obtainable.

It is concluded that the introduction of pyridine as solvent converts the synthesis of carbocyanines, by condensation of ethyl orthoformate with quaternary salts containing reactive methyl groups, into an excellent practical and general method of preparation; this is not only the simplest method to apply, but gives, in any and every instance, the best yield obtainable. The following

carbocyanines are now described for the first time : 6 : 6′-*dimethyl*-1 : 1′-*diallyl*-2 : 2′-*carbocyanine iodide* and *bromide*, 1 : 1′-*dimethyl*-4 : 4′-*carbocyanine iodide*, 1 : 1′-*diallyl*-4 : 4′-*carbocyanine iodide*, 2 : 2′-*diallylthiocarbocyanine bromide*, 2 : 2′-*diethyloxacarbocyanine iodide*, and 3 : 3 : 3′ : 3′-*tetramethyl*-1 : 1′-*diethylindocarbocyanine iodide*.

Mr. O. F. Bloch has examined the absorption spectra of all the dyes in alcoholic solution and tested their sensitising action, both by bathing plates in a solution and by adding the dye to the emulsion before coating. He has found that the indocarbocyanines and oxacarbocyanines are, like other cyanine dyes, photographic sensitisers, and it seems remarkable that their photographic properties have not previously been recorded. In the experimental section of this paper the photographic action is described only in those instances where this has not previously been done.

So far no carbocyanine containing two pyridine nuclei has been isolated, though Mills and Braunholtz (*loc. cit.*) attributed to a 2 : 2′-carbocyanine of this type absorption bands which they detected in the pyridine reaction mixture of 2-methylpyridine ethonitrate and di-*o*-formylethylaminodiphenyl disulphide. It is now found that a 2 : 2′-pyridocarbocyanine is not formed by condensation of 2-methylpyridine ethiodide with ethyl orthoformate in the presence of boiling pyridine, a negative result which is curious in view of the readiness with which 2-methylpyridine quaternary salts condense with *p*-nitrosodimethylaniline (Kaufmann and Vallette, *Ber.*, 1912, **45**, 1736) and with *p*-dimethylaminobenzaldehyde (Mills and Pope, J., 1922, **121**, 946).

Experimental.

1 : 1′-*Diethyl*-2 : 2′-*carbocyanine Iodide*.—Quinaldine ethiodide (5 g.; 2 mols.), ethyl orthoformate (5·5 c.c.; 4 mols.), and pyridine (20 c.c.), which had been dried by being left over barium oxide and subsequent decantation, were boiled under reflux for 3 hours; crystals then separated (yield 78%). After recrystallisation from dilute spirit, the yield was 70%. The dye was dried under reduced pressure at 100—120° and an iodine determination was made by the method of Carius; these methods of drying and analysis were used in all cases, except where otherwise stated (Found : I, 26·2. Calc. for $C_{25}H_{25}N_2I$: I, 26·4%).

6 : 6′-*Dimethyl*-1 : 1′-*diallyl*-2 : 2′-*carbocyanine Iodide*.—By heating 2 : 6-dimethylquinoline (5 g.; 1 mol.) and allyl iodide (3·4 c.c.; 1·2 mols.) in a sealed tube at 100° for 48 hours, extracting the product with ether, and recrystallising the residue from spirit, a 72% yield of 2 : 6-*dimethylquinoline alliodide* was obtained, in yellow crystals,

m. p. 198—199° (decomp.) (Found: I, 39·2. $C_{14}H_{16}NI$ requires I, 39·05%). The condensation of the alliodide (5 g.) with ethyl orthoformate was carried out as in the previous preparation and the product was washed with ether (yield 82%) and recrystallised from methyl alcohol (yield, 71%). It melts with decomposition at 280—281° (Found: I, 23·5. $C_{29}H_{29}N_2I$ requires I, 23·85%). In spirit solution there are absorption maxima at λ 5700 Å. and λ 6200, of which the latter is the stronger. When the dye is added to the emulsion the sensitising maxima lie at λ 5800 and λ 6450 and there is considerable fog. The fog is less when the plate is bathed in a solution of the dye, and the sensitising action is considerably greater, the principal band now extending from λ 6200 to λ 7300.

6 : 6′-*Dimethyl*-1 : 1′-*diallyl*-2 : 2′-*carbocyanine Bromide*.—A 76% yield of 2 : 6-*dimethylquinoline allobromide* is obtained by heating 2 : 6-dimethylquinoline (7 g.; 1 mol.) and allyl bromide (6·2 c.c.; 1·2 mols.) in a sealed tube at 100° for 48 hours and recrystallising the product from absolute alcohol. It is a colourless solid, m. p. 214—215° (decomp.) (Found: Br, 28·9. $C_{14}H_{16}NBr$ requires Br, 28·7%). Its condensation with ethyl orthoformate in the presence of pyridine gave an 84% yield of carbocyanine (14·6 g.) and on recrystallisation from methyl alcohol a 79% yield of pure dye. This forms green and gold crystals, m. p. 281—282° (decomp.) (Found: Br, 16·5. $C_{29}H_{29}N_2Br$ requires Br, 16·5%).

1 : 1′-*Dimethyl*-4 : 4′-*carbocyanine Iodide*.—This compound is mentioned in the literature (Adams and Haller, *loc. cit.*), but none of its properties has been recorded. After condensation of lepidine methiodide (1 g.) with ethyl orthoformate in the presence of pyridine, the reaction mixture was poured into water; a 71% yield of crude product then resulted. From methyl alcohol it separated in minute, bright green crystals (yield 38%), m. p. 290—295° (decomp.) (Found: I, 28·0. $C_{23}H_{21}N_2I$ requires I, 28·1%). The dye shows an absorption maximum at λ 7150. The sensitising action towards plates on bathing is poor and is accompanied by veil; the single sensitising band has its maximum at λ 7500. When the dye is added to the emulsion, the sensitising action is less but the fog greater.

1 : 1′-*Diethyl*-4 : 4′-*carbocyanine Iodide* (*Kryptocyanine*).—After the condensation of lepidine ethiodide with ethyl orthoformate in the usual way, the reaction mixture was cooled and filtered (0·89 g. removed); on addition of water to the filtrate, the kryptocyanine was precipitated (2·23 g., *i.e.*, 56% of the theoretical yield). The kryptocyanine was recrystallised from spirit (150 c.c.); the yield (1·67 g.) was then 42% (Found: I, 26·4. Calc. for $C_{25}H_{25}N_2I$: I, 26·4%). The less soluble neocyanine iodide also was recrystallised

from spirit (1000 c.c.; 0·72 g. obtained). When heated, it melts with decomposition at 286°.

1 : 1′-*Diallyl*-4 : 4′-*carbocyanine Iodide*.—Lepidine (3·9 c.c.; 1 mol.) and allyl iodide (3·2 c.c.; 1·2 mols.) were heated in a sealed tube at 100° for 2 days. The *lepidine alliodide* was recrystallised twice from dry spirit, charcoal being used once (Found: I, 40·8. $C_{13}H_{14}NI$ requires I, 40·8%). The condensation product from lepidine alliodide (1 g.) and ethyl orthoformate was precipitated as a tar on the addition of ether to the pyridine reaction liquid. Rapid crystallisation from a little methyl alcohol gave a 43% yield of green crystals, but the carbocyanine was unstable and decomposed on prolonged boiling with the solvent. When heated, decomposition began at about 150° (Found: I, 25·6. $C_{27}H_{25}N_2I$ requires I, 25·2%). The maximum absorption in spirit solution is at λ 7150. On a bathed plate, the dye confers a strong sensitisation band with its maximum at λ 7550. The band occupies the same position when the dye is added to the emulsion, but is in this case much weaker.

2 : 2′-*Dimethylthiocarbocyanine Iodide*.—Repetition of the preparation using ethyl orthoformate and acetic anhydride gave only 17% and 9% yields of crude and recrystallised dye respectively. By the new method, 1-methylbenzthiazole methiodide (4 g.; 2 mols.), pyridine (40 c.c.), and ethyl orthoformate (4·6 c.c.; 4 mols.) were boiled for an hour. The thiocarbocyanine (yield, 95%) was recrystallised from dilute spirit and obtained in 74% yield. Melting with decomposition occurs at about 280°; König and Meier (*loc. cit.*) give m. p. 254° (Found: I, 27·1. Calc. for $C_{19}H_{17}N_2IS_2$: I, 27·3%).

2 : 2′-*Diethylthiocarbocyanine Iodide*.—This dye was similarly prepared from 1-methylbenzthiazole ethiodide (2 g.), and recrystallised from methyl alcohol (yield, 82%); m. p. 264—265° (decomp.); Mills (*loc. cit.*) gives m. p. 269° (decomp.) (Found: I, 25·6. Calc. for $C_{21}H_{21}N_2IS_2$: I, 25·8%).

2 : 2′-*Diallylthiocarbocyanine Bromide*.—By heating 1-methylbenzthiazole (6·3 g.; 1 mol.) with allyl bromide (3·5 c.c.; 1·2 mols.) in a sealed tube at 100° for 48 hours and recrystallising the product from spirit, 1-*methylbenzthiazole allobromide* was obtained in almost colourless crystals (yield, 68%), m. p. 202° (decomp.) (Found: Br, 29·8. $C_{11}H_{12}NBrS$ requires Br, 29·6%). The crude dye (yield, 95%), obtained on condensation of 1-methylbenzthiazole allobromide (2 g.) with ethyl orthoformate, was recrystallised from methyl alcohol; the pure thiocarbocyanine (yield, 79%) forms purple crystals, m. p. about 260° (decomp.) (Found: Br, 17·0. $C_{23}H_{21}N_2BrS_2$ requires Br, 17·0%). In spirit solution, the stronger absorption band has its maximum at λ 5600 and the weaker at λ 5220. As used in the emulsion, the dye is a powerful sensitiser;

there is a strong band with its maximum at λ 6000 and a weaker one with a maximum at λ 5450. It acts as an excellent sensitiser when plates are bathed in its solution, the sensitisation being almost uniform up to λ 6200 and decreasing to zero at λ 6800; there is a slight gap at λ 4900.

2 : 2′-*Dimethyloxacarbocyanine Iodide.*—1-Methylbenzoxazole could not be obtained by interaction of *o*-aminophenol and ethyl acetate (Niementowski, *Ber.*, 1897, **30**, 3062), but was prepared by Ladenburg's method (*Ber.*, 1876, **9**, 1524). The methiodide, after being washed with dry ether as described by Clark (J., 1926, 232), was rapidly recrystallised from absolute alcohol; the colourless crystals obtained were washed with ether and dried in a vacuum desiccator before analysis (Found: I, 46·1. Calc. for $C_9H_{10}ONI$: I, 46·15%). M. p. 196° (decomp.) as recorded by Clark; König and Meier (*loc. cit.*) give m. p. 200°. 1-Methylbenzoxazole methiodide (2 g.; 2 mols.), ethyl orthoformate (3·0 c.c.; 4 mols.), and pyridine (20 c.c.) were boiled for an hour. The dye (yield, 57%) was recrystallised from absolute alcohol (yield, 40%). The yield is about half as great when acetic anhydride is used as solvent in the condensation. The oxacarbocyanine has m. p. 275—277° (decomp.); König and Meier give m. p. 259° (Found: I, 29·2. Calc. for $C_{19}H_{17}O_2N_2I$: I, 29·4%). The absorption maxima in spirit solution lie at λ 4850 and λ 4600, of which the former is the stronger. When added to the emulsion, the dye confers a region of extra sensitivity with a maximum at λ 5100. Both in this case and with the bathed plate the sensitisation curve is very uniform, reaching to λ 5700 for moderate exposures.

2 : 2′-*Diethyloxacarbocyanine Iodide.*—1-*Methylbenzoxazole ethiodide* was prepared by heating 1-methylbenzoxazole (5·5 g.; 1 mol.) and ethyl iodide (4·0 c.c.; 1·2 mols.) in a sealed tube at 100° for 48 hours. After extraction with dry ether, the crude product was rapidly recrystallised from absolute alcohol, washed with ether, and dried for analysis in a vacuum desiccator (yield, 74%); the colourless crystals thus obtained had m. p. 195—197° (decomp.) (Found: I, 43·7. $C_{10}H_{12}ONI$ requires I, 43·9%). Condensation of the ethiodide (8 g.) with ethyl orthoformate gave 2 : 2′-*diethyloxacarbocyanine iodide* (yield, 57%), which crystallised from pyridine, in 38% yield, in red crystals with a blue reflex; m. p. 277—279° (decomp.) (Found: I, 27·5. $C_{21}H_{21}O_2N_2I$ requires I, 27·6%). The absorption maxima in spirit solution are at λ 4600 and λ 4850, of which the latter is the stronger. For bathing plates the dye acts as a powerful sensitiser, extending the normal sensitivity by a band which shows a maximum at λ 5150. Its action is weaker when it is added to the emulsion.

1 : 3 : 3 : 1′ : 3′ : 3′-*Hexamethylindocarbocyanine Iodide.*—In this instance the yield obtained by using acetic anhydride as solvent is equal to that which results when pyridine is employed. 2 : 3 : 3-Trimethylindolenine methiodide (2 g.; 2 mols.), pyridine (20 c.c.), and ethyl orthoformate (3·0 c.c.; 4 mols.) were boiled for an hour and the reaction mixture was poured into water. The crude product (yield, 78%) gave on recrystallisation from dilute or dry spirit, acidified with hydrogen iodide, a 66% yield of beautifully crystalline dye, but the iodine content was invariably low (*e.g.*, a specimen which had been dried in a vacuum desiccator gave C, 60·6; H, 6·5; I, 24·0. Calc. for $C_{25}H_{29}N_2I$: C, 61·95; H, 6·0; I, 26·2%. $C_{25}H_{29}N_2I,C_2H_5{\cdot}OH$ requires C, 61·1; H, 6·65; I, 23·9%). The indocarbocyanine has m. p. about 228° (decomp.); König (*loc. cit.*) gives m. p. 229° (decomp.). The absorption maxima lie at λ 5120 and λ 5480. When added to the emulsion, the dye gives very clean plates and shows fair sensitising action; the maxima lie at λ 5320 and λ 5720. When plates are bathed in a solution of the dye, the sensitisation is very powerful, and maxima occur at λ 5300 and λ 5800.

3 : 3 : 3′ : 3′-*Tetramethyl*-1 : 1′-*diethylindocarbocyanine Iodide.*—Trimethylindolenine ethiodide has been previously prepared by the action of methyl iodide on 2-methyl-1-ethylindole (König and Müller, *Ber.*, 1924, **57**, 144), but in the present work it was obtained by heating 2 : 3 : 3-trimethylindolenine (8·2 g.; 1 mol.) and ethyl iodide (5 c.c.; 1·2 mols.) in a sealed tube at 100° for 48 hours. After recrystallisation from rectified spirit, the ethiodide (yield, 61%) had m. p. 224° (decomp.) (Found: I, 40·2. Calc. for $C_{13}H_{18}NI$: I, 40·3%). The crude carbocyanine (yield, 86%), obtained by condensation with ethyl orthoformate, was recrystallised from dilute spirit acidified with hydrogen iodide, and was obtained in 75% yield. It forms pleochroic crystals, which are olive-green and steel-blue. If rapidly heated, it softens at 204—210°, or, if slowly heated, melts and resolidifies; it melts at 260—263° (decomp.) (Found: I, 24·8. $C_{27}H_{32}N_2I$ requires I, 24·8%). In spirit solution, the chief absorption maximum occurs at λ 5480 and there is a weaker band with its maximum at λ 5120. When added to the emulsion, the dye shows moderate sensitising action and has three maxima, at λ 5350, 5750 and 6000, respectively. In sensitising by bathing, it shows two maxima, at λ 5320 and λ 5700, and its action is more powerful.

[*Received, October 3rd*, 1927.]

CCCLXXV.—*Quaternary Salts in the Benzselenazole Series.*

By Leslie Marshall Clark.

The zinc salt of *o*-aminoselenophenol, which reacts with benzoyl chloride to give phenylbenzselenazole (Bauer, *Ber.*, 1913, **46**, 92), reacts similarly with formic acid to give *benzselenazole* (I).

(I.) $C_6H_4<^{Se}_{N}>CH$ $\qquad$ $\left[C_6H_4<^{Se}_{NMe\cdot CHO}\right]_2$ (II.)

Benzselenazole methiodide, when titrated in aqueous solution with sodium hydroxide and phenolphthalein, requires two equivalents of alkali for neutralisation. The neutral solution reduces one equivalent of iodine, a compound, $(C_8H_8ONSe)_2$, being formed. This behaviour of benzselenazole methiodide is clearly analogous to that of benzthiazole methiodide (Mills, Clark, and Aeschlimann, J., 1923, **123**, 2353) and must be ascribed to formation of the carbinol base, subsequent opening of the heterocyclic ring to give the sodium salt of *o*-formylmethylaminoselenophenol, $CHO\cdot NMe\cdot C_6H_4\cdot SeNa$, and oxidation of this by iodine (or other mild oxidising agents) to *di*-o-*formylmethylaminodiphenyl diselenide* (II).

Similar reactions occur when 2-phenylbenzselenazole methiodide is treated with two equivalents of sodium hydroxide, followed by one of iodine, and are, therefore, probably general for all 2-alkyl- and 2-aryl-substituted benzselenazolinium salts.

Atmospheric oxidation of benzselenazole methiodide in ammoniacal solution gives *di*-o-*methylaminodiphenyl diselenide*, the formyl groups of (II) having been removed by contact with ammonium hydroxide. Similar treatment of benzthiazole methiodide gives di-*o*-formylmethylaminodiphenyl disulphide, di-*o*-methylaminodiphenyl disulphide being produced only when sodium hydroxide is substituted for ammonium hydroxide (compare Mills, Clark, and Aeschlimann, *loc. cit.*).

Confirmation of the correctness of the explanations advanced above is obtained by the benzoylation of the di-*o*-methylaminodiphenyl diselenide obtained from benzselenazole methiodide. The product is identical with the compound obtained from 2-phenylbenzselenazole methiodide by treatment with alkali and oxidation.

During the preparation of benzselenazole, *di*-o-*formylaminodiphenyl diselenide* was isolated as a by-product. This compound, when treated in alcoholic solution with stannous chloride, gave some benzselenazole by preliminary reduction to *o*-formylaminoselenophenol, which then underwent condensation by loss of water.

The formyl groups in di-*o*-formylaminodiphenyl diselenide are readily removed by heating with phenylhydrazine, since α-formylphenylhydrazine is obtained from the reaction mixture.

Experimental.

The zinc salt of *o*-aminoselenophenol was prepared by Bauer's method (*loc. cit.*), but a better yield (56%) of di-*o*-aminodiphenyl diselenide was obtained by oxidising the solution of *o*-aminoselenophenol, well stirred and cooled below 6°, with potassium ferricyanide instead of hydrogen peroxide.

Benzselenazole (I).—The zinc salt of *o*-aminoselenophenol (17 g.) was boiled during 14 hours with anhydrous formic acid (140 c.c.), and the solution poured into water; a light-coloured oil, which rapidly solidified, was then precipitated. Excess of ammonium hydroxide was added and the oily suspension and the solid deposit (A) were extracted by means of ether. The extract was dried over sodium carbonate, the solvent removed, and the residue distilled, giving *benzselenazole* (4·5 g.), a slightly yellow liquid, b. p. 154°/45 mm., having an odour very similar to that of benzthiazole (Found : N, 8·0. C_7H_5NSe requires N, 7·7%).

Benzselenazole Methiodide.—A mixture of the base (4·2 g.) and methyl iodide (5 g.) was kept for 24 hours and then heated on the water-bath for 3 hours. The resulting solid, after being washed with ether, crystallised from alcohol in very pale yellow needles (yield, 80%), m. p. 188—189° (Found : C, 29·4; H, 2·45; N, 4·2; I, 39·1; Se, 24·1. C_8H_8NISe requires C, 29·6; H, 2·5; N, 4·3; I, 39·2; Se, 24·4%). *Benzselenazole methopicrate*, obtained from the methiodide and picric acid in alcoholic solution, had m. p. 173° (Found : N, 12·8. $C_{14}H_{10}O_7N_4Se$ requires N, 13·2%).

Action of Sodium Hydroxide on Benzselenazole Methiodide.—Benzselenazole methiodide (1·500 g.) in aqueous solution required 9·3 c.c. of 1·02*N*-sodium hydroxide for neutralisation (Calc. for two equivs. of NaOH, 9·1 c.c.). On oxidation of the cold solution with potassium ferricyanide a yellowish, oily substance was precipitated. This was extracted with benzene, and the extract was dried over sodium carbonate and concentrated, and light petroleum added until a permanent turbidity appeared; *di-o-formylmethylaminodiphenyl diselenide* (II) slowly separated in small, colourless prisms, m. p. 104° (Found : C, 45·0; H, 3·8; N, 6·7; *M*, cryoscopic in camphor, 424. $C_{16}H_{16}O_2N_2Se_2$ requires C, 45·1; H, 3·75; N, 6·6%; *M*, 426).

Oxidation of o-Formylmethylaminoselenophenol by Iodine.—Benzselenazole methiodide (0·3240 g.), dissolved in water, was treated with two equivalents of sodium hydroxide. The slightly yellow solution required 9·3 c.c. of *N*/10-iodine for oxidation (Calc. for 1 equiv.,

10·0 c.c.). The error in the titration is undoubtedly due to atmospheric oxidation, which appears to be more rapid in the case of the selenophenols than in that of the thiophenols. Di-*o*-formylmethylaminodiphenyl diselenide, m. p. 104°, was isolated as before.

Atmospheric Oxidation of o-Formylmethylaminoselenophenol.—Benzselenazole methiodide (0·3 g.) was dissolved in water (30 c.c.), and ammonium hydroxide (2 c.c.; *d*, 0·880) added. The solution became yellow and slightly turbid; after it had been kept for several hours in the dark, a crystalline, yellow substance separated on the surface. If the concentration of ammonium hydroxide was greater than that stated, the crystals were accompanied by a yellow oil. When the solution had lost its yellow colour, the crystals were removed and purified by evaporation of a solution in light petroleum. After several repetitions of this procedure, *di-o-methylaminodiphenyl diselenide* was obtained, m. p. 89° (Found: C, 45·3; H, 4·2; N, 7·5. $C_{14}H_{16}N_2Se_2$ requires C, 45·4; H, 4·3; N, 7·6%). This diselenide is very readily soluble in organic solvents. It separates from ether in yellow, hexagonal tablets, very similar in appearance to those of di-*o*-methylaminodiphenyl disulphide (Mills, Clark, and Aeschlimann, *loc. cit.*).

Di-*o*-methylaminodiphenyl diselenide (0·2 g.), shaken with benzoyl chloride and sodium hydroxide, gave a pasty mass; after crystallisation from aqueous alcohol, this had m. p. 170°, alone or when mixed with di-*o*-benzoylmethylaminodiphenyl diselenide obtained from 1-phenylbenzselenazole methiodide (see below).

1-*Phenylbenzselenazole Methiodide.*—1-Phenylbenzselenazole (2 g.), prepared by Bogert and Chen's method (*J. Amer. Chem. Soc.*, 1922, **44**, 2355), was heated at 100° during 26 hours with methyl iodide (2·5 c.c.). After removal of the excess of methyl halide, the residue was extracted with ether to remove unchanged base. The crude *methiodide* crystallised from alcohol in golden-yellow needles, m. p. 211—212° (decomp.) (Found: I, 31·5. $C_{14}H_{12}NISe$ requires I, 31·75%). 1-*Phenylbenzselenazole chloroplatinate* was prepared from alcoholic-hydrochloric acid solutions of the base and platinic chloride and separated in flattened, yellowish-brown needles [Found: Pt, 20·8. $(C_{13}H_9NSe)_2H_2PtCl_6$ requires Pt, 21·0%].

Action of Sodium Hydroxide on 1-*Phenylbenzselenazole Methiodide: Di-o-benzoylmethylaminodiphenyl Diselenide.*—The methiodide (0·210 g.), dissolved in water, was titrated at 50° with sodium hydroxide and phenolphthalein. The addition of each portion of alkali caused the transient red coloration of the indicator which is characteristic of pseudo-base formation (Required: 19·3 c.c. of *N*/20-sodium hydroxide. Calc. for two equivs., 19·5 c.c.). This solution, cooled and titrated with 0·0625*N*-iodine, required 7·0 c.c. for complete

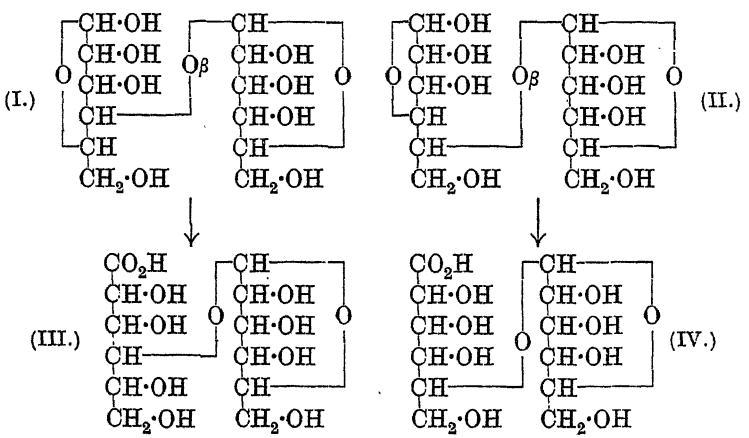
oxidation, whereas the amount calculated for one equivalent of iodine is 8·4 c.c. This discrepancy must again be ascribed to atmospheric oxidation. The colourless solid, *di-o-benzoylmethylaminodiphenyl diselenide*, which separated after the iodine oxidation crystallised from aqueous alcohol in stout needles, m. p. 170° (Found : C, 58·4; H, 4·1; N, 5·1; Se, 27·0. $C_{28}H_{24}O_2N_2Se_2$ requires C, 58·1; H, 4·15; N, 4·8; Se, 27·3%).

Di-o-formylaminodiphenyl Diselenide.—The deposit A, obtained from the formylation of *o*-aminoselenophenol, crystallised from alcohol (charcoal) in soft, pale yellow needles, m. p. 174°. Analysis showed it to be *di-o-formylaminodiphenyl diselenide*, which must have been produced by atmospheric oxidation of aminoselenophenol to the corresponding diselenide, followed by formylation of the amino-groups (Found : C, 42·4; H, 3·1; N, 7·0. $C_{14}H_{12}O_2N_2Se_2$ requires C, 42·2; H, 3·0; N, 7·0%).

Preparation of Benzselenazole from Di-o-formylaminodiphenyl Diselenide.—The diselenide (1·8 g.), dissolved in alcohol–acetone, was reduced with excess of stannous chloride in dilute hydrochloric acid solution. The mixture was heated at 100° for ½ hour and then evaporated to dryness. The residue was treated with sodium hydroxide solution and the oil liberated was taken up in ether, dried over sodium carbonate, and distilled in a vacuum. The distillate was heated with excess of methyl iodide at 70—80° for 4 hours, the uncombined methyl iodide boiled off, and the partly crystalline residue dissolved in acetone; on addition of ether to this solution a crystalline deposit was formed which, after purification, melted at 187°, alone or when mixed with authentic benzselenazole methiodide.

Reaction between o-Diformylaminodiphenyl Diselenide and Phenylhydrazine.—The diselenide (0·5 g.) was heated with phenylhydrazine (1·2 g.) at 100° for 3 hours and the orange-red oil produced was cooled and diluted with ether; colourless plates of α-formylphenylhydrazine were deposited; these, after crystallisation from water, had m. p. 144°, alone or when mixed with an authentic specimen.

A satisfactory method for the estimation of selenium in organic compounds of the type described in this paper is as follows : The compound is decomposed by treatment with 50 c.c. of 8% potassium permanganate solution and 10 c.c. of concentrated nitric acid. The mixture is evaporated to dryness on the steam-bath, 10 c.c. of the permanganate solution and 5 c.c. of nitric acid are added to the residue, and the evaporation is repeated. The addition of permanganate and acid and the evaporation are repeated, 80 c.c. of concentrated hydrochloric acid are added to the residue, and the



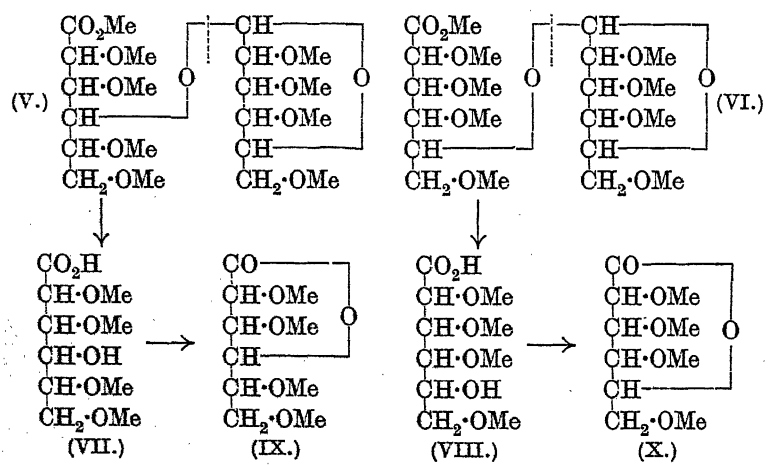
mixture is boiled until chlorine and nitric acid are removed. The solution is then diluted and selenium determined by reduction with sulphurous acid.

22 STANLEY ROAD, TEDDINGTON. [*Received, October 6th*, 1927.]

CCCLXXVI.—*The Constitution of the Disaccharides. Part XVI. Cellobiose.*

By WALTER NORMAN HAWORTH, CHARLES WILLIAM LONG, and JOHN HERBERT GEOFFREY PLANT.

A CONSTITUTIONAL study of cellobiose was undertaken in this series (Part V) six years ago (Haworth and Hirst, J., 1921, **119**, 193), and the experimental results were as follows: Methylated cellobiose ⟶ crystalline tetramethyl glucose + crystalline 2 : 3 : 6-trimethyl glucose; and a structural formula was ascribed to the disaccharide on this basis. In common with all carbohydrate formulæ, this constitution was modified by the recognition of the revised formula of glucose in its normal derivatives (Charlton, Haworth, and Peat, J., 1926, 98), and the structure represented by (I) was assigned to cellobiose by the latter authors:



Consideration was given to an alternative formula for cellobiose (II), and it was stated that the isolation of 2 : 3 : 6-trimethyl glucose by cleavage of methylated cellobiose rendered it possible to regard the attachment of the reducing hexose component through position (5) to the other hexose residue, in which case the oxide ring of this first residue would be a butylene or γ-oxide (1 : 4) and not an amylene or δ-oxide (1 : 5). In the former case, cellobiose would be

to the extent of one residue a γ-sugar, but this was stated to be an unlikely contingency. Whilst making this reservation, therefore, the formula (I) for cellobiose was advocated, inasmuch as it correctly represented the properties of the disaccharide and was consistent with all the facts.

Meanwhile, we have instituted a series of experiments designed to eliminate any remaining doubt as to the structure of cellobiose. This disaccharide undergoes oxidation at its reducing position to give a monobasic acid designated cellobionic acid, and this compound can be formed only by opening of the ring of the reducing glucose component. The structure of cellobionic acid will thus be represented by formula (III) if (I) be accepted for the disaccharide, whilst (IV) will represent the acid if (II) be the structure of the disaccharide. It will therefore be seen that, in the two rival formulæ for the acid, the position of the oxygen link connecting the two C_6 chains differs in that in (III) this link engages the carbon in position (4), and in formula (IV) it engages the carbon in position (5).

We have been able to decide between these two alternative formulæ by methylating cellobionic acid completely, and the product, which was *methyl octamethylcellobionate*, was then submitted to hydrolysis. The cleavage products to be expected are seen to be different according as we accept formula (V) or formula (VI) as a correct representation of the methyl octamethylcellobionate. In addition to 2 : 3 : 4 : 6-tetramethyl glucose, the cleavage products

should contain a monobasic acid of the C_6 series which, if formula (V) be correct, would be the γ-hydroxy-acid (VII); or if formula (VI)

be correct, the δ-hydroxy-acid (VIII). Since each of these acids is already known and has been fully characterised by one of us in earlier investigations, a way was opened up enabling us to reach a decision through identification of this essential product. It will be seen that an acid of formula (VII) would give on heating a 1 : 4- or γ-lactone, recognisable as 2 : 3 : 5 : 6-tetramethyl gluconolactone, and similarly an acid of formula (VIII) would yield a 1 : 5- or δ-lactone, identifiable as 2 : 3 : 4 : 6-tetramethyl gluconolactone; and since each of these lactones has been fully characterised and degraded by oxidation methods (Haworth, Hirst, and Miller, this vol., p. 2436), there can be no dubiety in assigning a final constitution to each of them, and therefore to cellobiose itself.

When methyl octamethylcellobionate was hydrolysed with mineral acid, the cleavage products were isolated in an analogous manner to that described in recent papers on maltose (Haworth and Peat, J., 1926, 3094) and lactose (Haworth and Long, this vol., p. 544). Crystalline 2 : 3 : 4 : 6-tetramethyl glucose was isolated (yield, 92·7% of the theoretical), and the acid product originally retained as the barium salt was regenerated and distilled as a lactone which crystallised, m. p. 26—27° (yield, 80% of the theoretical). This compound gave a phenylhydrazide of the corresponding acid, m. p. 135—136°, and the melting point was not depressed in admixture with the phenylhydrazide of 2 : 3 : 5 : 6-tetramethyl gluconic acid which had been prepared from (*a*) methyl octamethyl-maltobionate or methyl octamethyl-lactobionate or (*b*) 2 : 3 : 5 : 6-tetramethyl γ-glucose (1 : 4) (compare Haworth and Long, Haworth and Peat, *locc. cit.*).

Again, the above lactone was shown to be identical with 2 : 3 : 5 : 6-tetramethyl γ-gluconolactone isolated from the sources (*a*) and (*b*). There was, therefore, no doubt that the tetramethyl gluconic acid which had been formed from methyl octamethylcellobionate was that represented by formula (VII), since the lactone referred to is indicated by formula (IX). The results furnish evidence which seems to us conclusive in favour of the formulation (V) for methyl octamethylcellobionate, and therefore, if this be accepted, and it be assumed that no displacement of the biose linking had occurred in any of these transformations, cellobionic acid should be expressed by formula (III) and cellobiose by (I). This experimental result substantiates the constitutional formula which had previously been advocated by one of us and serves to remove the need for any reservation in favour of formula (II).

It should be noted in this connexion that, as indicated by Haworth and Peat (*loc. cit.*), maltose possesses the same structural formula as

cellobiose, the essential difference between these two bioses being that maltose is a glucose-α-glucoside and cellobiose a glucose-β-glucoside.

These experimental results are opposed to the views of Irvine (*Chemical Reviews*, 1927, **4**, 216), who has perceived a difference in the positions of (*a*) the biose linking in maltose and cellobiose and (*b*) the oxide ring in each of these bioses (compare Irvine and Black, J., 1926, 869; Irvine and Macdonald, *ibid.*, 1508; Irvine and Robertson, *ibid.*, 1496).

EXPERIMENTAL.

Cellobiose octa-acetate (m. p. 223—225°), prepared as described by Haworth and Hirst (J., 1921, **119**, 193) from pure cellulose, was hydrolysed by alcoholic potash to give potassium cellobiosate, and a representative sample of the latter was converted into cellobiose having $[\alpha]_D$ +24° ($c = 3{\cdot}33$) (equilibrium value) (Maquenne, *Bull. Soc. chim.*, 1904, **31**, 854). The remaining portion of potassium cellobiosate was dissolved in a little water, and bromine was admitted, which speedily dissolved. The solution was kept in a stoppered bottle at room temperature for 10 days; it was then almost devoid of reducing action towards Fehling's solution. The unchanged bromine was removed by aeration, followed by treatment with hydrogen sulphide. The colourless solution was shaken with finely ground litharge, filtered, then agitated in presence of silver oxide in the dark, and filtered. Hydrogen sulphide was again passed into the solution, and the excess of this gas removed by aeration. The clear solution was warmed gently for a day in presence of calcium carbonate, filtered, and evaporated to small bulk. This contained calcium cellobionate along with potassium bromide.

Methyl Octamethylcellobionate.—The methylation of calcium cellobionate was carried out in a similar manner to that described in the case of the corresponding salt of maltobionic acid (Haworth and Peat, *loc. cit.*), methyl sulphate and sodium hydroxide being used initially, followed by several treatments with moist silver oxide and methyl iodide, and finally by dry silver oxide and methyl iodide. The crude product at this stage was a yellow, mobile liquid (7·1 g.; OMe, 54·6%). This distilled under 0·05 mm. from a bath heated to 203°, and the first fraction (1·5 g.) of low boiling point was rejected. The major portion of the distillate (5·1 g.) was a pale yellow, viscid syrup, $n_D^{13°}$ 1·4604 (Found: OMe, 54·3%). The latter was again distilled under 0·05 mm., the first fraction (0·3 g.) being collected on heating the bath to 176°, and the main fraction (4·6 g.) distilled at 169—171°/0·05 mm. from a bath heated

to 192°. This product did not reduce Fehling's solution and had $n_D^{14°}$ 1·4609, and the analytical data agreed with the formula of *methyl octamethylcellobionate* (Found: C, 52·0; H, 8·3; OMe, 54·3. $C_{21}H_{40}O_{12}$ requires C, 52·1; H, 8·3; OMe, 57·6%).

Hydrolysis. The above product (3·1 g.) was dissolved in 100 c.c. of 7% hydrochloric acid, and heated at 80—90° until the specific rotation of the solution appeared to show no further changes. $[\alpha]_D^{19°}$ + 5·4° (initial), + 32·1° (after 1 hour), 50·2° (2 hours), 54·6° (3 hours), 55·0° (4 hours; constant). At this stage finely divided barium carbonate was gradually added, and the solution aerated at 50° to assist the neutralisation. After being kept over-night, the solution was filtered and evaporated at 40°/16 mm. To the white residue, alcohol was added and distilled off under 16 mm. The dry solid was digested with boiling ether many times and the collected extracts were evaporated, leaving a syrup which crystallised in colourless needles. These were purified from light petroleum (weight, 1·5 g.; yield, 92·7%) and identified as 2 : 3 : 4 : 6-tetramethyl glucose by the following properties: m. p. 93—94°; mixed m. p. determination with a specimen prepared from methylated maltose, 93—94°; $[\alpha]_D^{14°}$ in water (c = 2·02) + 99·9° (5 mins.), 88·0° (30 mins.), 85·5° (1 hour), 83·0° (2 hours; constant).

The original white residue of barium salts from which the tetramethyl glucose had been extracted was warmed to eliminate traces of ether, dissolved in water, and treated with a slight deficiency of dilute hydrochloric acid. The water was evaporated at 50°/15 mm. and finally the residue was heated at 60—80°/0·09 mm. for 2 hours. Repeated digestion of this dried residue with boiling ether yielded 1·2 g. (80% of the theoretical) of a pale yellow syrup which distilled under 0·09 mm. from a bath heated to 119°, leaving only 0·1 g. of residue.

Nucleation of the cooled distillate with 2 : 3 : 5 : 6-tetramethyl gluconolactone (from methyl octamethyl-lactobionate; Haworth and Long, this vol., p. 547) resulted in immediate crystallisation; m. p. 26—27°, mixed m. p. determination 26—27° (with the specimen from which the nucleus had been taken) (Found: C, 51·2; H, 7·8; OMe, 51·4. Calc.: C, 51·3; H, 7·7; OMe, 53·0%).

Phenylhydrazide of 2 : 3 : 5 : 6-*Tetramethyl Gluconic Acid.*—A specimen of the above lactone (0·16 g.) in contact with phenylhydrazine (1 mol.) dissolved in ether was heated on a water-bath. Crystals of the phenylhydrazide separated, m. p 135—136° (from benzene), mixed m. p. 135—136° [with specimens prepared from the 2 : 3 : 5 : 6-tetramethyl gluconolactone obtained from methyl octamethylmaltobionate (Haworth and Peat, *loc. cit.*) and from 2 : 3 : 5 : 6-tetramethyl (γ-)glucose (Charlton, Haworth, and Peat, *loc. cit.*)]

(Found : C, 56·1; H, 7·65; OMe, 35·0; N, 8·45. Calc. : C, 56·1; H, 7·6; OMe, 36·3; N, 8·2%).

The authors are indebted to the Department of Scientific and Industrial Research for grants to two of them.

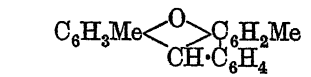
CCCLXXVII.—*Substituted Diaryl Ethers. Part II. The Friedel–Crafts Reaction applied to Di-*p*-tolyl Ether.*

By JOSEPH REILLY and PETER J. DRUMM.

ALTHOUGH there are two similar benzene nuclei in di-*p*-tolyl ether in both of which substitution may occur, the authors find that this ether yields only monoketonic derivatives in the Friedel–Crafts reaction. The condensation of di-*p*-tolyl ether proceeds more readily with phthalic anhydride than with benzoyl chloride, substitution occurring in one position only; from benzoyl chloride more than one substance appears to be formed.

Condensation of 2-hydroxy-5-methylbenzophenone-2′-carboxylic acid with *p*-bromotoluene gives 2-o-*carboxybenzoyldi*-p-*tolyl ether* (I), identical with the product of interaction between phthalic anhydride and di-*p*-tolyl ether. The formation of a 2-ketone in the latter reaction is what would be expected and is in line with the authors' recent work on the nitration of di-*p*-tolyl ether (this vol., p. 68) showing that the oxygen atom exerts the main orienting influence.



The substance (I) has also been obtained by condensing *p*-cresol with the chloromethylbenzophenone-*o*-carboxylic acid which Heller and Schulke (*Ber.*, 1908, **41**, 3627) prepared from *p*-chlorotoluene and phthalic anhydride. Their ketone therefore has formula (III), not (II), the chlorine atom exerting a greater directive influence than the methyl group.

The product obtained by heating (I) with concentrated sulphuric acid is, not an anthraquinone derivative, but 2 : 7-dimethylfluoran,

identical with that obtained by Drewsen (*Annalen*, 1882, **212**, 341) from phthalic anhydride, *p*-cresol, and sulphuric acid; it gives 2 : 2′-dihydroxy-5 : 5′-dimethylbenzophenone and benzoic acid on fusion with potassium hydroxide.

Although 2-*benzoyldi*-p-*tolyl ether* (formula as I) has not been directly synthesised, its constitution as an ortho-substituted diaryl ether is indicated by the following facts. Its solutions in acetic and sulphuric acids are yellow and fluorescent, indicating xanthhydrol formation through ring closure. From these solutions, 9-phenyl-2 : 7-dimethylxanthen was isolated identical with that obtained by Feuerstein and Lipp (*Ber.*, 1902, **35**, 3255) by the dry distillation of 6 : 6′-dihydroxy-3 : 3′-dimethyltriphenylmethane.

The conditions employed by Feuerstein and Lipp in preparing the phenyldimethylxanthen were so drastic that its constitution is not beyond doubt. Moreover, its formation from benzoyldi-*p*-tolyl ether in acetic acid—the change is more readily effected by boiling alcoholic hydrochloric acid—is difficult to understand. It seems to the authors that the substance may be a fluorene,

but to this view there is the objection that the molecule of such a substance would be in a state of considerable strain; the formula also shows linkage at a position (1 in the xanthen ring) which is not only sterically hindered but is also meta with respect to the oxygen atom. In support of the fluorene formula, however, may be quoted the following facts: (1) Phenyldi-α-naphthylcarbinol, on boiling with acetic acid, changes into phenyldi-α-naphthafluorene (Schoepfle, *J. Amer. Chem. Soc.*, 1922, **44**, 190); (2) Ullmann and Mourawiew-Winigradoff (*Ber.*, 1905, **38**, 2213), on heating diphenyl-α-naphthylcarbinol with an acetic acid solution of sulphuric acid, zinc chloride, or hydrochloric acid, obtained phenylchrysofluorene. In offering the above suggestion, it is appreciated that phenyl groups exhibit less tendency than naphthyl groups to formation of fluorene linkages.

It was not found possible to prepare the oxime from 2-*o*-carboxybenzoyldi-*p*-tolyl ether (I), and the phenylhydrazone was only obtained under drastic conditions. These appear to be cases of steric hindrance by substituents in the two ortho-positions with respect to the carbonyl group. 2-Benzoyldi-*p*-tolyl ether, under identical conditions, did not give a phenylhydrazone, the reaction proceeding in a different direction.

Contrary to the generally accepted view that the reaction between benzoyl chloride and phenols in presence of aluminium chloride

results in poor yields of hydroxybenzophenones unless the hydroxyl group has been previously protected (compare Fries and Finck, *Ber.*, 1908, **41**, 4276; Heller, *Ber.*, 1913, **46**, 1498), it is now found that with acetylene tetrachloride as solvent 2-hydroxy-5-methylbenzophenone is obtained in good yield from *p*-cresol and benzoyl chloride.

EXPERIMENTAL.

2-o-*Carboxybenzoyldi*-p-*tolyl Ether* (I).—A mixture of di-*p*-tolyl ether (8 g.) and phthalic anhydride (6 g.) was slowly added to anhydrous aluminium chloride (9 g.), covered with dry carbon disulphide and protected from moisture. After 12 hours, the product was poured on ice, the carbon disulphide and other volatile products were removed in steam, and the colourless residue was repeatedly dissolved in aqueous sodium hydroxide and precipitated by dilute acid. The product then crystallised from aqueous ethyl alcohol in long, hexagonal prisms (yield, 70%), m. p. 155° (Found: C, 76·2; H, 5·5; *M*, cryoscopic in naphthalene, 360. $C_{22}H_{18}O_4$ requires C, 76·3; H, 5·2%; *M*, 346).

Repetition of the above experiment, twice the quantities of phthalic anhydride and aluminium chloride being used, gave the same product, namely, 2-o-*carboxybenzoyldi*-p-*tolyl ether*, in approximately the same yield, no diketonic derivative being isolated.

Synthesis of 2-o-*Carboxybenzoyldi*-p-*tolyl Ether*.—*p*-Bromotoluene (10 g.), the dipotassium derivative (10 g.; dried at 120° in a vacuum) of 2-hydroxy-5-methylbenzophenone-2′-carboxylic acid prepared by Ullmann's method (*Ber.*, 1919, **52**, 2102), and a trace of copper bronze (Naturkupfer C, washed with ether to remove oily impurities) were heated in absolute-alcoholic solution in a sealed tube for 10 hours at 200°. The product was distilled in steam; unchanged *p*-bromotoluene passed over, followed by di-*p*-tolyl ether (1 g.). The residual oil was extracted with hot dilute sodium hydroxide solution, the extract acidified, and the viscous precipitate obtained crystallised from acetic acid (80%); 2-o-carboxybenzoyldi-*p*-tolyl ether slowly separated in colourless prisms, m. p. 154—155°, identical with the ether described above.

2-o-Carboxybenzoyldi-*p*-tolyl ether is readily soluble in glacial acetic acid, absolute alcohol or ether and very sparingly soluble in light petroleum (b. p. 60—80°) or water. It dissolves in concentrated sulphuric acid to an orange solution exhibiting a greenish fluorescence; the colour is discharged on dilution with water. Its *silver* salt is sparingly soluble in water, but readily soluble in dilute aqueous ammonia (Found: Ag, 23·9. $C_{22}H_{17}O_4Ag$ requires Ag, 23·8%). The ether, on fusion with potassium hydroxide, is decom-

posed into di-*p*-tolyl ether and phthalic acid. It unites with anhydrous aluminium chloride to give an orange-coloured solid.

The formation of di-*p*-tolyl ether in the above reaction was at first suspected to result from hydrolysis of the 2-*o*-carboxybenzoyldi-*p*-tolyl ether formed, but on heating *p*-bromotoluene and alcoholic potassium hydroxide under identical conditions di-*p*-tolyl ether was isolated in small quantity.

2-*o*-Carboxybenzoyldi-*p*-tolyl ether was recovered unchanged after being heated with hydroxylamine hydrochloride in strongly alkaline solution for 8 hours on the water-bath. The *phenylhydrazone* was obtained only by heating the ether (1 mol.) and phenylhydrazine (2 mols.) for 3 hours at 160—170°. The cooled product was extracted with very dilute hydrochloric acid; from an alcoholic solution of the residue, the *phenylhydrazone* separated in pale yellow needles, m. p. 156° (Found: N, 6·6. $C_{28}H_{24}O_3N_2$ requires N, 6·4%).

Action of Sulphuric Acid on 2-o-*Carboxybenzoyldi*-p-*tolyl Ether.*—The ether (1 g.) and concentrated sulphuric acid (8 c.c.) were heated on a boiling water-bath for 3 hours. The solution was then cooled and mixed with ice, and the precipitate obtained was collected and digested with aqueous sodium hydroxide solution; the extract was purple, owing probably to the presence of an anthraquinone derivative. The part insoluble in alkali was crystallised from absolute ethyl alcohol, 2 : 7-dimethylfluoran being obtained in colourless, glistening prisms (yield, 90%), m. p. 254° (Drewsen, *loc. cit.*, gives m. p. 246°) (Found: C, 80·6; H, 5·1. Calc. for $C_{22}H_{16}O_3$: C, 80·5; H, 4·9%).

The nature of this substance was established by fusion with potassium hydroxide at 220—240°. The dark yellow aqueous extract of the product was acidified and then boiled with sufficient alcohol to give a clear solution; on standing, yellow needles of 2 : 2′-dihydroxy-5 : 5′-dimethylbenzophenone separated which, after one recrystallisation from alcohol, had m. p. 104—106°. Distillation in steam of the filtrate from the fusion product gave benzoic acid.

Equal weights of 2-*o*-carboxybenzoyldi-*p*-tolyl ether and phosphorus pentachloride were heated in benzene solution until evolution of hydrogen chloride ceased. To the cooled, light orange solution was added the same weight of anhydrous aluminium chloride; hydrogen chloride was then again evolved. The deep red solution was finally refluxed for a short time and poured on ice; the product, isolated in the usual way, was 2 : 7-dimethylfluoran.

Constitution of Heller and Schulke's Ketone (III).—A mixture of the potassium salt of Heller and Schulke's ketone (*loc. cit.*) (1 mol.),

potassium *p*-tolyloxide (1·5 mols.), *p*-cresol (solvent), and a trace of copper bronze was slowly heated, with stirring, to 200°; at 160° potassium chloride separated. After being heated for an hour at 190—200°, the product was dissolved in water, and the solution was extracted with ether, acidified, and extracted with chloroform. The chloroform was evaporated, and the residue dissolved in hot acetic acid (80%); 2-*o*-carboxybenzoyldi-*p*-tolyl ether slowly crystallised in short, colourless prisms, m. p. 153—154°.

2-*Benzoyldi*-p-*tolyl Ether* (formula as I).—The preparation from di-*p*-tolyl ether (7 g.), benzoyl chloride (5 g.), and aluminium chloride (12 g.) is very similar to that of the carboxylic acid (I) described above. The residue obtained after the steam-distillation set to a crystalline mass which separated from boiling, absolute ethyl alcohol in colourless, glistening rhombohedra (5·5 g.), m. p. 185—186° (Found: C, 83·1; H, 6·3. $C_{21}H_{18}O_2$ requires C, 83·4; H, 6·0%). A viscous oil (4 g.) obtained from the mother-liquor resisted all attempts to crystallise it.

A second experiment with di-*p*-tolyl ether (7 g.), benzoyl chloride (10 g.), and aluminium chloride (24 g.) was carried out under identical conditions, but the same monobenzoyl compound was obtained (7·8 g.) and no dibenzoyl compound was isolated.

2-*Benzoyldi*-p-*tolyl ether* is readily soluble in chloroform, acetone or benzene, much less soluble in ethyl alcohol, and insoluble in light petroleum (b. p. 60—80°). It dissolves in concentrated sulphuric acid to a bright yellow solution with a green fluorescence; dilution with water discharges the fluorescence but not the colour. It combines with anhydrous aluminium chloride to form a bright orange solid which immediately decomposes in contact with water.

Glacial acetic acid in contact with 2-benzoyldi-*p*-tolyl ether is coloured yellow; it becomes orange on heating and reddish-orange on boiling. On cooling, 9-phenyl-2 : 7-dimethylxanthen separates in colourless, glistening needles which, alone or mixed with an authentic specimen, melt at 195—196° (Found: by the micro-method, C, 87·8; H, 6·2; *M*, cryoscopic in camphor, 312. Calc. for $C_{21}H_{18}O$: C, 88·1; H, 6·3%; *M*, 286. Calc. for $C_{21}H_{16}O$: C, 88·7; H, 5·6%; *M*, 284). The same xanthen was obtained when 2-benzoyldi-*p*-tolyl ether was heated with phenylhydrazine at 160° for 2 hours.

2-*Hydroxy*-5-*methylbenzophenone*.—To *p*-cresol (10 g.) and benzoyl chloride (14·1 g.), dissolved in dry acetylene tetrachloride and protected from moisture, anhydrous aluminium chloride (26·7 g.) was added during 1 hour. The mixture was then heated for 4 hours at 100—110°, hydrogen chloride being copiously evolved. After cooling, the dark brown solution was poured into water, a dark oil

separating. On distillation in steam, acetylene tetrachloride passed over, followed slowly by a light yellow oil which quickly solidified and was highly pure 2-hydroxy-5-methylbenzophenone (yield, 80%), m. p. 84·5° (Cox, *J. Amer. Chem. Soc.*, 1927, **49**, 1029, gives m. p. 87°).

2-p-*Tolyloxy*-5-*methylacetophenone*, prepared in the usual manner, was obtained as a red oil which was purified by distillation; the fraction, b. p. 320—340°, set to a crystalline solid which separated from alcohol in colourless, glistening plates, m. p. 168° (Found: C, 79·6; H, 7·0; *M*, cryoscopic in naphthalene, 251. $C_{16}H_{16}O_2$ requires C, 80·0; H, 6·7%; *M*, 240). This ketone has the characteristic odour of acetophenone and is readily soluble in ether, benzene, or hot alcohol. It dissolves in sulphuric acid to a yellow solution.

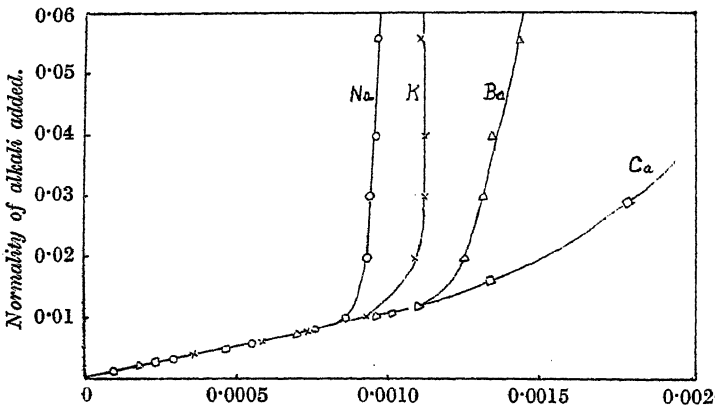
Addendum.—Since the above work was completed, a paper by Rosenmund and Schulz has appeared (*Arch. Pharm.*, 1927, **265**, 308), in which it is stated that the reaction between phenols and acid chlorides with aluminium chloride in nitrobenzene solution, giving phenolic ketones, is of general applicability. The unique behaviour of nitrobenzene is ascribed to its solvent action on the aluminium chloride complexes. Monohydric phenols react readily except when the *p*-position to the hydroxyl group is occupied. We have observed that acetylene tetrachloride also can be used as solvent in the preparation of phenolic ketones, and this holds even when the *p*-position to the hydroxyl group is occupied (*e.g.*, the yield of 2-hydroxy-5-methylbenzophenone is 80%).

UNIVERSITY COLLEGE, CORK. [*Received, September 5th*, 1927.]

CCCLXXVIII.—*The Action of Alkalis on Clay.*

By HENRY BOWEN OAKLEY.

IN the study of the physical and chemical properties of soils, much attention has always been directed towards the clay fraction which, together with humus, is responsible for the colloidal properties of the soil, and is one of the most reactive components chemically.



Although many diverse hypotheses have been put forward to account for the " absorption " of bases by clay, the trend of modern opinion is to regard the action as chemical in nature, being due to the formation of insoluble aluminosilicates, as opposed to the hypothesis of " physical absorption of ions," which is still largely adopted in many branches of colloid chemistry. The view that clay acts as a weak acid towards alkalis is supported by the electrometric titration curves of Bradfield (*J. Amer. Chem. Soc.*, 1923,

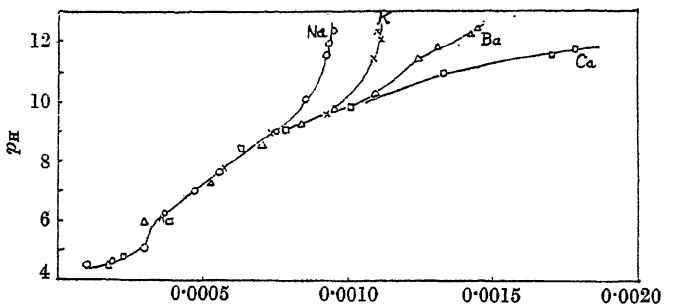
45, 2669), and is confirmed by the results presented in this paper. A fairly full bibliography on this subject is given by Bradfield (*J. Amer. Soc. Agronomy*, 1925, **17**, 253).

The clays used in this work were separated by sedimentation in 0·05% sodium carbonate, flocculated by dilute hydrochloric acid (N/100), and purified to a high resistance by dialysis (Joseph and Hancock, J., 1924, **125**, 1888).

The Effect of the Concentration of Alkali on the Amount of Base removed from Solution by Clay.—The clay used in these experiments was No. 10195 prepared from a heavy cotton soil: it was practically identical with No. 6640 (Joseph and Hancock, *loc. cit.*). 10 C.c. samples of a 5% suspension were treated with different

FIG. 1.

Equivalents of base taken up by 1 *g. of clay in the presence of* N/2*-chloride;* 1 % *suspensions.*



quantities of standard alkali in centrifuge tubes. Water and a standard chloride solution of the appropriate base were added to make the total volume 50 c.c. and N/2 with respect to the chloride. This treatment completely flocculated the clay. The tubes were centrifuged, and 25 c.c. of the clear, supernatant liquid were treated with excess of N/10-hydrochloric acid and titrated back with N/10-sodium hydroxide, as this procedure was found to give the sharpest end-point. Methyl-orange was used as indicator. A further portion was withdrawn for the p_H determination in a Clark cell with a Leeds and Northrup potentiometer. From the change in concentration of the alkali, the amount removed by the clay can be calculated, since any soluble silicates or aluminates which may be formed behave in titration as free alkali.

The results are illustrated in Figs. 1 and 2. The equivalents of base taken up per g. of clay are identical for sodium, potassium,

barium, and calcium up to an initial concentration of alkali of 0·01*N*, or an equilibrium p_H of about 9; but with a further increase in the concentration of alkali the amounts taken up are in the increasing order sodium, potassium, barium, and calcium. The amounts of sodium and potassium taken up attain fairly constant values above a p_H of 11, whereas barium and calcium show no such limit. This order is the same as that found for amorphous silica (Joseph and Oakley, J., 1925, **127**, 2813), and suggests that the quantity of any base retained in the solid phase is partly determined by the solubility or stability of the aluminosilicates and their products of decomposition with increasing concentrations of alkali.

The Total Amounts of Sodium and Calcium Hydroxides neutralised by Clay.—That the quantity of bases removed in the solid phase

FIG. 2.

Equivalents of base taken up by 1 g. of clay in the presence of N/2-chloride; 1% suspensions.

is closely connected with the solubility of the products of combination is illustrated by the following results for calcium and sodium hydroxides, giving the total amount of alkali neutralised in the two cases. No chloride was added in this experiment, and a lower concentration of clay was used so that the necessarily dilute calcium hydroxide could be present in a greater excess than in the previous experiment.

To determine the total sodium hydroxide neutralised, a series of p_H measurements was made on caustic soda solutions of various strengths; the hydroxyl-ion concentrations were then calculated by subtracting these values of the p_H from the values of Michaelis for $\log 1/K_w$ at the appropriate temperature (Clark, "The Determination of Hydrogen Ions," p. 29). These calculated values of the hydroxyl-ion concentrations were then plotted against the concentration of sodium hydroxide. In a similar manner, the concentration of hydroxyl-ions was calculated from the p_H of the clay suspensions. The corresponding concentration of sodium

hydroxide was read from the curve, and this value was subtracted from the original concentration of caustic soda added. The temperatures varied from 30° to 35°, but this was allowed for both in the calculation of the p_H and in the subsequent calculation. The error in the determination of the total hydroxide neutralised may be as much as 10%. An exactly similar method was applied for calcium. The results are in the following table (compare Bradfield, *Soil Sci.*, 1924, **17**, 411).

Total amount of calcium and sodium hydroxide neutralised by clay after standing 1 day. Concentration: 0·52% clay.

Initial conc. of hydroxide.	Equiv. of alkali neutralised per g. of clay.		Final p_H.	
	Sodium.	Calcium.	Sodium.	Calcium.
0·036	0·0018	0·0027	11·92	11·81
0·020	0·0012	0·0021	11·67	11·50
0·008	0·0010	0·0012	11·00	10·75

These results show that, although the total sodium hydroxide neutralised is about twice the amount taken up in the solid phase (compare Fig. 1), thus demonstrating the formation of soluble compounds, yet the amount of calcium hydroxide neutralised is still greater, although no soluble compounds are formed. This is shown by the fact that, for an initial calcium hydroxide concentration of 0·038 and a final p_H of 11·93, the amount of calcium hydroxide neutralised per g. of clay, as calculated from the p_H, was 0·0031, whereas that calculated from titration of the excess of alkali was 0·0032. (The concentration of the clay was 0·26%.)

The compounds formed by silica and calcium hydroxide were also found to be insoluble, but in this case they were equivalent in amount to the total sodium compounds formed under the same conditions (Joseph and Oakley, *loc. cit.*).

The influence of the concentration of the sodium on the amount of base taken up by 1 g. of clay is illustrated by the following figures with various concentrations of chloride:

Conc. of NaOH, 0·04*N*; conc. of clay, 1%.

Conc. of NaCl	1·0	0·5	0·2	0·1
Na taken up (equiv. × 10^4) ...	9·68	9·56	9·17	9·15
p_H	12·10	12·16	12·22	12·25

A comparison of the effect of *N*-solutions of chlorides on the amounts of sodium, potassium, and calcium taken up by 1 g. of clay is given in the following figures (equivs. × 10^4):

Chloride.	Concentration of hydroxide.		
	0·08*N*-NaOH.	0·08*N*-KOH.	0·03*N*-$Ca(OH)_2$.
0·0*N*	8·46	10·4	14·9
1·0*N*	9·60	12·8	17·8

As had been previously found with silica, the addition of the chloride of the base to an alkaline suspension always increased the amount of base taken up.

The removal of the base from solution by clay is very rapid. This is illustrated by the following figures for 1 g. of clay.

Conc. of NaOH, 0·04*N*; conc. of NaCl, 0·5*N*; conc. of clay, 1%.

Time	10 mins.	1 hr.	3 hrs.	1 day
Na taken up	9·7	9·9	9·8	10·3

The Relation between the Soluble and Insoluble Sodium Compounds with Clay.—In order to determine the relation between the soluble and the insoluble sodium compounds formed with increasing concentrations of sodium hydroxide, a series of 0·5-g. samples of clay was treated with different concentrations of standard caustic soda, the volume being always 50 c.c. After standing for 1 hour, 10 c.c. were withdrawn for a p_H determination. The remainder was filtered through a collodion filter and an aliquot portion of the clear filtrate was titrated with standard acid and alkali as before. The difference between the total amount neutralised (calculated from p_H) and the amount taken up (calculated from the titration) gave the equivalents of sodium neutralised in a soluble form. These results are in the following table.

The amounts of sodium neutralised in the solid phase and in solution by 1 g. of clay after 1 hour. Concentration of clay, 1%.

Initial conc. of NaOH.	p_H at equilibrium.	Equivs. Na in solid phase, × 10^4.	Equivs. Na neutralised in solution, × 10^4.	Ratio, Soluble/ Insoluble.
0·07	12·33	9·7	7	0·72
0·04	12·03	9·7	5	0·51
0·02	11·60	9·9	2	0·20
0·01	10·72	8·1	1	0·11
0·006	9·77	5·4	0·6	0·11
0·004	8·62	3·9	0·1	0·02

The amount of soluble sodium compounds formed is small until the p_H exceeds 10·5, or until the concentration of alkali is greater than 0·01*N*.* This is just the concentration at which the amounts of different bases taken up begin to diverge (Fig. 1). These results leave no doubt, I think, that the later process of the neutralisation of bases by clay at higher concentrations of hydroxide differs from the initial reaction at low concentrations, in that the more concentrated alkali begins to break down the clay substance, forming

* In the case of silica, the amount of sodium in the solid phase is always very small compared with the total silicate formed (J., 1925, **127**, 2816, Table IV).

silicates and aluminates. In the case of calcium, these are insoluble, and in the case of sodium, they are easily soluble, whilst potassium and barium occupy intermediate positions. In one special experiment, the amount of lithium taken up by 1 g. of clay in the presence of 0·5*N*-lithium chloride was $9{\cdot}0 \times 10^{-4}$ equiv. at a p_H of 9·8, and the amount for sodium under similar conditions was $9{\cdot}5 \times 10^{-4}$.

At the lower concentrations of alkali (below 0·01*N*), the identity of the amounts of different bases taken up shows that these solubility relationships do not come into play, the compounds formed with any of the bases being equally insoluble. In this case, there appears to exist a direct reversible equilibrium between these insoluble compounds and the bases in solution, the equilibrium with alkalis having characteristics similar to those of a weak acid in true solution; this is indicated by the shape of the curves for sodium in Figs. 2 and 4.

From these curves it is seen that the clay acid is half converted into its sodium compound at about p_H 8. If the laws of dissociation of a weak acid are applicable, this would mean that its dissociation constant is about 10^{-8}. Bradfield (*J. Physical Chem.*, 1924, **28**, 170), from the variation of the p_H with concentration of a clay suspension, calculated a value of 3×10^{-7}.

Further evidence that clay behaves as an insoluble acid in direct equilibrium with the bases in solution is afforded by the liberation of acid when a neutral salt is added to clay, and by the fact that clay so treated hydrolyses on being washed with water, giving an alkaline solution. The equivalence of the exchange of bases when clay is washed with the salt of another base also supports the view that the reactions are purely chemical in nature (*Trans. Faraday Soc.*, 1925, **22**, 251). The speed with which all these reactions take place and the influence of various electrolytes on the electrokinetic potential and stability of clay suspensions (Oakley, *J. Physical Chem.*, 1926, **30**, 902) seem to indicate that the reactions are mainly ionic. The fact that clay, with its weakly acidic properties, can remove some of the base from the salt of a strong acid, thus setting free this acid, also receives a natural explanation on the above view.

In order to determine the composition of the material dissolved from the clay, 5 g. of clay were shaken with *N*/10-sodium hydroxide in the presence of *N*/2-sodium chloride, the volume being adjusted so that the concentration of the clay was 1%. This was centrifuged and the clear supernatant liquid analysed for silica, alumina, and ferric oxide. This treatment was repeated four times for increasing periods of time with fresh additions of sodium hydroxide and chloride. Two further experiments were made with two separate

portions of the stock clay for periods of 1 hour and 3 days, respectively. The results are in the following table.

Material dissolved from 1 g. of clay by $N/10$-sodium hydroxide in the presence of $N/2$-sodium chloride. Concentration of clay (No. 14637), 1%.

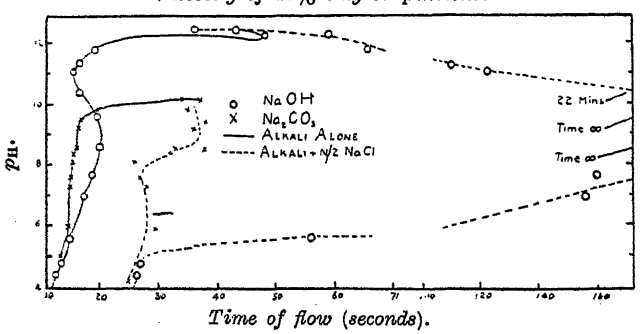
A. Successive treatments on the same portion of clay.

Time.	SiO_2.	$Al_2O_3 + Fe_2O_3$.	$SiO_2/(Al_2O_3 + Fe_2O_3)$.
5 mins.	0·0050	0·0046	1·1
1 hour	0·0052	0·0020	2·6
1 day	0·0107	0·0018	6·0
3 days	0·0109	0·0017	6·4

B. Treatment on two separate portions of clay.

1 hour	0·0065	0·00466	1·41
3 days	0·0115	0·0044	2·62
Untreated clay	0·475	0·328	1·44

On the assumption that the soluble compounds formed are Na_2SiO_3 and $NaAlO_2$, the sodium so combined is $2·8 \times 10^{-4}$ and $4·4 \times 10^{-4}$ equiv., respectively, for the last two experiments (the ferric oxide also was estimated in these cases). The value obtained from p_H measurements after 3 days' standing was $4·5 \times 10^{-4}$, and the sodium removed in the solid phase was $7·6 \times 10^{-4}$. The figures in the last column show that the proportion of sesquioxides rapidly falls in successive treatments with caustic soda, there being a higher proportion of sesquioxides in the first extract than in the clay itself. Another notable result is that the amount of material dissolved increases very slowly on prolonging the time of contact of the alkali with the clay, and this independently of whether the clay has had previous treatments with caustic soda or not. These results suggest that the material which goes into solution strongly inhibits further solvent action of the alkali. Since the concentration of the sodium hydroxide is reduced only by about 15% in the case of the initial treatments, and by about 5% in the other cases, the decreased rate of solvent action is unlikely to be due to diminished alkali concentration.



The Effect of Sodium Hydroxide and Sodium Carbonate on the Viscosity of Clay Suspensions.—It was thought that the difference in composition of the material removed by the early treatments compared with that from the later treatments might indicate that this material was identical with the hypothetical " layer of gel " on clay particles, which, according to some writers, gives clay its peculiar plastic and water-holding properties (*Brit. Assoc.*, 3rd Report on Colloid Chemistry, 1920, pp. 113—153).

If this is the case, the viscosity of clay in caustic soda solution of strength sufficient to dissolve this layer should be markedly less

than the value for clay in the presence of alkali too weak to dissolve the layer, since the particle size should be greatly reduced by the former treatment. Complicating factors in the comparison are the state of flocculation, and the state of saturation of the clay with regard to sodium. The times of flow of 10% suspensions of clay in an Ostwald viscometer were determined in a thermostat at 35°. One series of measurements was made on suspensions containing varying amounts of sodium hydroxide, and a similar series was made with sodium carbonate. After these measurements had been completed, sodium chloride was added in amount sufficient to make its concentration $N/2$. The times of flow of the deflocculated suspensions could be accurately repeated, but when the clay was flocculated, the time rapidly decreased with successive readings until an approximately constant value was reached, but this rose

FIG. 3.

Viscosity of 10% *clay suspensions.*

again on standing. The latter measurements are therefore very rough. The suspensions were too thick for the determination of their p_H; they were therefore diluted to one-fifth of their original concentration, and the p_H determinations were made on the diluted samples. If there was no buffer action, this dilution would decrease the p_H value by 0·7 unit, but since both the clay itself and the material dissolved by the alkali exert considerable buffer action, it is safe to conclude that the effect of dilution would not reduce the p_H by more than 0·3. The measurements were made on the suspensions after the addition of the sodium chloride.

The times of flow are plotted against the p_H in Fig. 3. The following data show the concentration of alkali added and the corresponding times of flow before the addition of sodium chloride. The time of flow of water was 10·4 seconds. [It is desirable to point out that the following figures cannot in any way be said to represent *true* viscosity values, for two reasons: (1) The rate of flow of the

uncoagulated suspensions was so high as to cause turbulent flow; and (2) Poiseuille's law is not obeyed by clay suspensions. Nevertheless, the results are of interest in showing that the comparative "thickness" of clay suspensions is affected differently by sodium hydroxide and by sodium carbonate.]

Conc. of NaOH or Na_2CO_3.	Time with NaOH (secs.).	Time with Na_2CO_3 (secs.).	Conc. of NaOH or Na_2CO_3.	Time with NaOH (secs.).	Time with Na_2CO_3 (secs.).
0·01	12·6	12·3	0·10	16·5	15·6
0·02	13·6	12·7	0·15	15·4	16·1
0·03	15·0	13·6	0·20	16·2	16·2
0·04	17·5	14·7	0·25	19·2	16·5
0·05	19·0	15·0	0·40	48·0	19·5
0·07	20·0	15·0	0·80	43·0	37·0
0·08	18·4	15·3			

The results show that at corresponding p_H values, the viscosity of clay treated with sodium carbonate is never greater than that of the clay treated with sodium hydroxide. The rapid rise in viscosity of the suspensions without sodium chloride at the highest values of the p_H is due to the flocculation of the clay by the alkali. Since the amount of material dissolved by the sodium hydroxide will be far greater than that dissolved by the sodium carbonate (carbonic acid being strong enough to decompose silicates and aluminates), it follows that this dissolved material cannot have existed in the clay in a particularly bulky and gelatinous condition. If this had been the case, its removal would have had a marked effect on the viscosity as compared with the values in the presence of sodium carbonate.

A striking feature of the results is that the curve for sodium hydroxide shows a maximum in viscosity between p_H 8 and 10, and this maximum is enormously enhanced when the clay is flocculated with sodium chloride. There is a complete absence of this effect with sodium carbonate, which suggests that it is connected with the much greater solvent power of the hydroxide. The hypothesis which accounts for the facts is that the sodium hydroxide at certain concentrations, instead of actually dissolving some of the clay, forms a comparatively non-viscous sol with this material. The addition of sodium chloride coagulates this sol, forming a coagulum of a very gelatinous nature. At higher concentrations of sodium hydroxide, this sol dissolves and cannot be coagulated by sodium chloride. This explains (1) why the maximum is only slight with caustic soda alone, but very pronounced in the presence of sodium chloride, (2) why the viscosity of the coagulated clay again falls when excess of caustic soda is added, and (3) why sodium carbonate does not show the effect.

This hypothesis is further supported by the fact that the clay

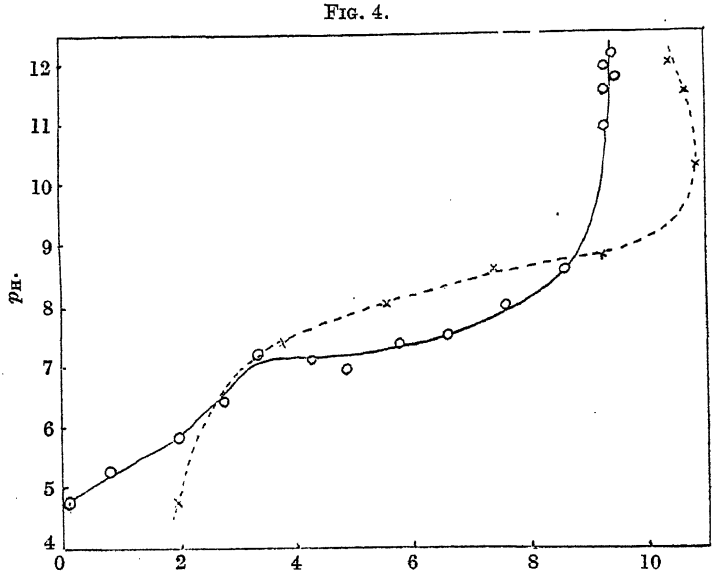
is more bulky with sodium hydroxide in the same range of p_H values at which the maximum in viscosity is observed, and that the maximum is not shown by sodium carbonate.

The following figures show the volume of 1 g. of clay (*i.e.*, of the clay plus its interstitial water after 10 minutes' centrifuging) after standing 1 day with various concentrations of alkali in the presence of *N*/2-sodium chloride.

Conc.	p_H with NaOH.	Vol., c.c.	p_H with Na_2CO_3.	Vol., c.c.	Conc.	p_H with NaOH.	Vol., c.c.	p_H with Na_2CO_3.	Vol., c.c.
0·0	4·0	4·1	—	—	0·1	12·3	5·1	8·3	4·1
0·02	7·6	4·6	—	—	0·2	12·9	4·7	8·8	4·3
0·03	8·0	5·4	—	—	0·3	13·1	4·4	9·0	4·2
0·04	9·5	5·7	—	—	0·5	13·3	4·2	10·2	4·3
0·05	11·1	5·5	8·1	4·0	1·0	13·6	4·1	10·4	4·5
0·07	12·2	5·3	—	—					

The fact that the clay without sodium hydroxide occupies the same volume as the clay in the presence of *N*-hydroxide affords further evidence that the material dissolved by the alkali is not specifically more bulky than the rest of the clay material.

Finally, the fact that the imbibitional water of the clay was unaltered by the prolonged treatment with sodium hydroxide points to the same conclusion. This water is the volume of water retained by 100 c.c. of the clay less the volume of xylene retained by the same clay after centrifuging for 40 minutes under a force of 1000 times gravity (compare Fisher, *J. Agric. Sci.*, 1924, **14**, 204). It was determined on the original clay (1) after drying with the addition of 9 c.c. of *N*/10-sodium hydroxide per g. of clay, and (2) on the clay left over after the four successive treatments with caustic soda described previously (p. 2825). This was washed until it was deflocculated and then collected on a collodion filter. Separate determinations were made, water and *N*-sodium chloride being used as the wetting liquids.



Imbibitional water of clay No. 14637.

A Comparison of the Properties of a Synthetic Aluminosilicate and of Clays.—Although, in the comparison of different soil clays, some degree of correlation can be traced between base-absorbing capacity and certain colloidal properties such as heat of wetting, imbibitional water, and general clay-like properties, yet it is equally true that a substance having a composition similar to clay, a fair imbibitional water content, and a very large base-absorbing capacity may, nevertheless, show clay-like properties only to a very small

extent. This is well illustrated by the following experiments on a synthetic aluminosilicate. This was prepared (see de Sigmond, *Proc. 4th Inter. Confer. Pedology*, 1924, 2, 434) by mixing solutions of sodium aluminate and sodium silicate (both $N/10$ with regard to sodium; $Na_2O : SiO_2 = 1 : 2$) in such proportion that the molecular ratio $SiO_2 : Al_2O_3 = 3 : 1$. Under such conditions, as de Sigmond has shown (*loc. cit.*), almost complete precipitation takes place of the compound $3SiO_2,Al_2O_3,Na_2O,3H_2O$. When the p_H of the mixture was progressively altered by the addition of different

FIG. 4.

Equivalents of sodium taken up, $\times 10^4$.

Full curve: 1/2000 *mol.* (0·17 *g.*) *of synthetic aluminosilicate in* 50 c.c. *Dotted curve:* 1 *g. of clay No.* 14637; 1% *suspension.*

amounts of standard hydrochloric acid, the amount of sodium retained by the compound varied with the p_H in a manner rather similar to that in the case of clay (Fig. 4). This very highly gelatinous compound was washed several times by decantation after centrifuging, and evaporated to dryness on a water-bath with frequent stirring to cause the formation of small aggregates. It was then dried at 100° and subjected to a process of alternate grinding in a wet condition in an agate mortar and sedimentation. The product was kept for 4 weeks with $N/100$-hydrochloric acid, the acid being renewed at intervals. It was then washed by decantation and centrifuging until it deflocculated and the specific resistance of a 1% suspension was 13,000 ohms. The alternate

grinding and sedimentation was then repeated, but even after this, most of the material sedimented within 3 hours, so that it was still much coarser than clay, which may be stable for months. This material on standing developed an alkaline reaction (p_H 8). The following table compares the imbibitional water and the behaviour towards sodium and calcium hydroxides of this substance with the same properties of different clays and silica as given by Joseph (*J. Agric. Sci.*, 1927, **17**, 14).

Sample No.	Description.	Na taken up in solid phase: 0·5*N*-NaCl+ 0·04*N*-NaOH (1% clay).	Total NaOH neutralised (0·08*N*-NaOH; 1% clay).	Ca removed in solid phase (0·3% clay).	Imbibitional water.
14637	Gezira.	$10·0 \times 10^{-4}$	12×10^{-4}	30×10^{-4}	143
10118	Kaolin.	0·0	0·0	1	5
13107	Mongalla (red).	3·1	19	22	54
—	Bentonite.	7·6	20	36	362
—	Synthetic alumino-silicate.	24	40	51	74
—	Amorphous silica.	4	About 70	About 70	40
10120	Ball clay.	—	—	—	40

The synthetic product is remarkable for its high sodium-absorbing capacity. All the clays neutralise more calcium than sodium hydroxide. This may be connected with the fact mentioned by Vernadsky (*Rep. Brit. Assoc.*, 1923, 435) that it is a general property of zeolites to form additive compounds with calcium hydroxide. The synthetic material shows a marked contrast with kaolin both in its reactions with bases and in its imbibitional water. It retains 13% of moisture at 150°, in this respect also resembling clays. Kaolin has been prepared synthetically by Schwarz and Walcker (*Z. anorg. Chem.*, 1925, **145**, 304) by precipitating silicic acid with aluminium chloride in an *acid* medium.

Although the first-mentioned synthetic aluminosilicate resembled clay in some important respects, yet its physical properties, as exemplified by its plasticity in the hand, showed that this most characteristic property of clay was only present to a very limited extent—possibly this may be due to the coarseness of its particles. Notwithstanding that bentonite is by far the most highly colloidal clay-like substance known, yet it takes up less sodium than the Gezira clay, whilst silica, which has no clay-like properties, takes up more sodium than the Mongalla clay. The sodium absorption of these substances is therefore not necessarily related to their colloidal properties or to the fineness of division of their particles.

Summary.

1. Clay which has been purified after a mild acid treatment takes up equivalent quantities of bases up to a p_H of about 9.

When the p_H is greater than this, the amounts removed are in the order lithium < sodium < potassium < barium < calcium. These amounts are increased by the presence of neutral salts of the metals.

2. The amount of sodium hydroxide neutralised in the form of *soluble* compounds is negligible until the p_H is above 9, but increases rapidly when the alkalinity is greater than this.

3. These results, taken in conjunction with evidence from elsewhere, are accounted for on the supposition that clay is an insoluble or a colloidal weak acid in *direct* equilibrium with bases in solution, the salts formed with the various bases being equally insoluble; but unless the alkali is very dilute ($p_H = 9$), the clay begins to break down, giving silicates and aluminates. With sodium these are easily soluble, and with calcium they are insoluble, whilst barium and potassium occupy intermediate positions.

4. About 1% of the clay was immediately dissolved by $N/10$-sodium hydroxide, but this amount was only slightly increased on prolonged standing. Renewal of the alkali, however, rapidly caused the dissolution of 1% more. The ratio of silica to sesquioxides in solution increased from 1 to 6 in four successive treatments. The imbibitional water of the clay was unaltered by the above treatment.

5. The viscosity and specific volume of coagulated clay show pronounced maxima between p_H 8 and 10 with caustic soda, but not with sodium carbonate at the same p_H values.

6. In base-absorption, water-retention, and imbibitional water a synthetic aluminosilicate showed considerable analogy with clay, although the material was comparatively coarse and was only slightly "clay-like" to the touch. Large sodium absorption by aluminosilicates does not necessarily indicate highly developed colloidal properties or a particularly fine state of division. Comparisons are made between three different clays—kaolin, silica, and bentonite.

WELLCOME TROPICAL RESEARCH LABORATORIES,
KHARTOUM. [*Received, May 23rd*, 1927.]

CCCLXXIX.—*On Active Nitrogen. Part IV. The Independence of the Afterglow and the Chemical Properties of Active Nitrogen.*

By ERIC JOHN BAXTER WILLEY.

SINCE the discovery by the present Lord Rayleigh (Strutt, *Proc. Roy. Soc.*, 1911, *A*, **85**, 219) that nitrogen which has been subjected to the action of a condenser discharge at low pressures shows both

an afterglow and chemical activity, there has been much discussion as to whether this active modification of the element is (*a*) atomic, (*b*) molecular and metastable, or (*c*) triatomic. The evidence for each of these views may shortly be summarised:

(*a*) (i) The decay process of the glow follows a bimolecular law (Angerer, *Physikal. Z.*, 1921, **22**, 97).

(ii) An analysis of the banded afterglow spectrum (Birge, *Nature*, 1926, **117**, 80), critical potential measurements in connexion with this (Sponer, *Z. Physik*, 1925, **34**, 622), and observations upon the spectra excited by active nitrogen (Mulliken, *Physical Rev.*, 1924, **23**, 259, 767; 1925, **26**, 1) lead to the view that the energy associated with this glowing gas is of the order of 200,000—250,000 cals./g.-mol. (10—12 volts).

(*b*) Saha and Sur (*Phil. Mag.*, 1924, **118**, 421) consider that the spectroscopic evidence indicates a metastable molecule of heat of formation 190,000 cals./g.-mol.

(*c*) Trautz (*Z. Elektrochem.*, 1919, **25**, 299), from mathematical considerations, favours a triatomic molecule with a heat of formation of 5,000—10,000 cals./g.-mol.

The consensus of opinion regards active nitrogen as possessing a *high* heat of formation and its existence as due to atomic recombination, an excited or metastable and chemically reactive molecule thus being produced.

In Parts I, II, and III of this series (J., 1926, 1804; this vol., pp. 669, 2188), evidence has been presented for the view that the energy of active nitrogen is 45,000 cals./g.-mol. (2 volts), and deductions from the spectra excited by active nitrogen have been criticised on the ground that chemiluminescence has not been sufficiently considered as a possible means of production of these luminous phenomena (*Nature*, 1926, **118**, 735). Efforts recently made (Ruark, Foote, Rudnick, and Chenault, *J. Opt. Soc. Amer.*, 1927, **14**, 17) to answer these objections are unsatisfactory, since the calculations made here are based upon mercurous azoimide, HgN_3, and not upon the substituted ammonias, Hg_3N_2 and Hg_3N, which are the products of the reaction between active nitrogen and mercury vapour.

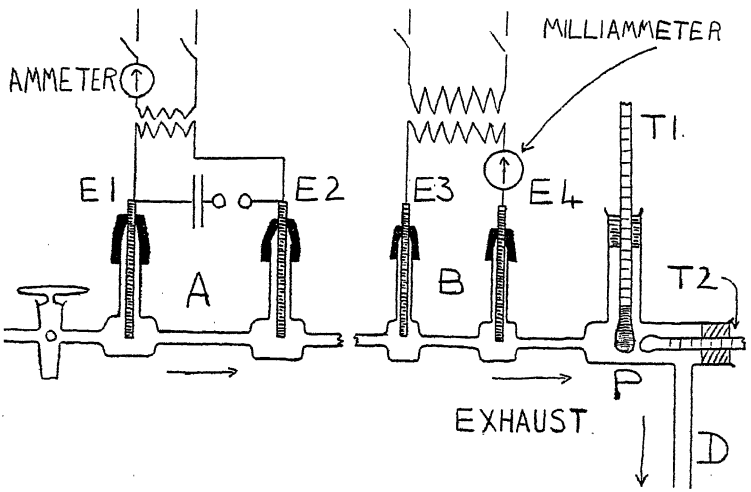
Thus we are left to reconcile two entirely different views on the energy and nature of active nitrogen, each supported by abundant experimental evidence, and as a tentative explanation it was suggested (Part II) that active nitrogen might emit its energy in a series of 45,000-cal. (2-volt) stages.

Early in 1925 it had been felt that certain seemingly inconsistent observations upon active nitrogen could best be explained by the theory that *two* luminous forms of the element were concerned,

differing both in chemical activity and in nature, but as this view led to the assumption of a possible change in the spectrum of the glow during decay, owing to the transformation rates of the two species not being the same, the hypothesis was for the time being abandoned. Dr. H. W. B. Skinner has recently suggested to the author that the discrepancy in these two sets of experiments can be overcome if we do not regard the chemically active nitrogen as luminous at all, but ascribe all the luminous phenomena (if this be possible upon the basis of available experimental evidence) to the effects of a few atoms produced at the same time as the former substance. This theory has, it is believed, been completely verified, for it has been found that the destruction of the glow by a second weak discharge and also by heat, noticed by Lord Rayleigh, is not accompanied by any decomposition of the chemically active nitrogen; furthermore, activity can be produced in the gas by the use of a discharge which does not give rise to any glow.

Experimental.

First Method.—Lord Rayleigh has shown (*Proc. Roy. Soc.*, 1916, *A*, **92**, 438) that when a stream of glowing nitrogen is drawn through a second and weak discharge, the glow is completely or very largely destroyed, and it appeared possible that this second discharge might prove fatal to the luminous nitrogen without affecting the chemically active modification which is, *ex hypothesi*, also present. This possibility was tested in the following manner.



Nitrogen, purified as described in Part I, was drawn at 10 mm. pressure and a constant speed (1—3 litres/hr., at *N.T.P.*) through the discharge tubes A and B and the test chamber P to exhaust at D (Fig. 1). The aluminium electrodes E1, E2, E3, and E4 were held in position by rubber sleeves and their relative positions so adjusted that the distance between E2 and E3 was $1\frac{1}{2}$ times the distance between E3 and E4. Projecting into the test chamber P were two identical and carefully calibrated thermometers, T1 and T2, the bulb of the former being coated with a small and closely adherent piece of oxidised copper gauze, while the latter was bare. It was found in calibration experiments that, when active nitrogen was drawn through the apparatus, the glow was extinguished at the surface of the copper oxide, and that the rise in temperature shown by T1 above that indicated by T2 was strictly proportional to the concentration of active nitrogen at the position of the bulb of T1, this concentration being determined by means of nitric oxide, as described in Part I. This heating effect in T1 is obviously due to the catalytic decay of the active nitrogen at the copper oxide surface (compare Part III), as was proved by warming the tubes A and B

by small flames while a stream of inert nitrogen was drawn through the apparatus; the temperatures recorded on T1 and T2 were then identical.

The difference in temperature between T1 and T2 is thus a measure of the concentration of active nitrogen in the gas. A strong discharge, capable of developing the afterglow, was maintained in A from the coil, condensers, and spark gaps connected as shown, and a weak direct induction coil or transformer discharge from another circuit could, if desired, be run in B.

Lord Rayleigh's observation as to the destruction of the afterglow in these circumstances was confirmed, no luminosity being visible in the gases emerging from B when a weak discharge was maintained

FIG. 1.

between E3 and E4. (Any tendency for the auxiliary discharge to wander and pass between E2 and E3, E2 being connected to earth, was overcome by the electrode-spacing arrangement already mentioned.)

It was found, however, that provided too strong a discharge was not employed in B, the concentration of active nitrogen as measured on T1 and T2 did not change appreciably, in spite of the complete destruction of the glow by the auxiliary discharge; too strong a discharge in B destroyed both the glow and the chemical activity (Table I). The conditions necessary for the retention of the latter were best realised in practice by means of a discharge from a small transformer run off the 100-volt A.C. mains and provided with a series resistance of 825 ohms in the primary; the secondary current was then about 0·1 milliamp. (R.M.S. value) at 500 volts. The same

effect could be produced by the use of a direct coil discharge in B, but on account of the difficulty in regulation, the transformer was more generally used.

Furthermore, whilst in some cases a decrease in the concentration of active nitrogen was noticed, this was by no means comparable with the complete or almost complete destruction of the afterglow, and hence it appears that there is no simple relation between the intensity of the afterglow and the amount of chemically active nitrogen present.

Second Method.—In view of the comparatively insensitive nature of this device for detecting and determining the active nitrogen, the experiments were repeated, the estimations being carried out with nitric oxide; the other experimental arrangements remained unaltered. The technique of this method has been considerably improved and a short account of it may be given.

The nitrogen from the discharge tube B entered the reaction chamber at E (Fig. 2), and at N an inlet was provided for the nitric oxide, regulation of this gas being effected by means of the capillary choke at C and the tap S5. (The nitric oxide was prepared by dropping a solution of sodium nitrite into an acidified solution of ferrous sulphate, and was dried by phosphorus pentoxide.) The gases then passed to exhaust *via* the two-way tap S1, the condensing trap R1, and the second two-way tap S2. The system S3, R2, and S4 was identical with and parallel to the circuit just described. One side of S1 and S3 was connected to a supply of pure, dry hydrogen, and S2 and S4 were connected to exhaust and also to a train of absorption bulbs for the determination of the nitrogen peroxide. Hence, by the use of these two condensing systems, continuous estimations of the concentration of active nitrogen can be made without stopping the apparatus; the nitrogen peroxide

produced by the action of the active nitrogen upon nitric oxide condenses in R1 (or R2), which is cooled by liquid air. At the end of the experiment the gas stream is diverted to the other condensing system, the contents of R1 are allowed to warm to room temperature, and then blown by means of hydrogen (admitted at S1) through a train of absorption bottles containing a 10% solution of potassium iodide, the current of gas being maintained for some 20 minutes in order to clear the last traces of nitric oxide from the solution; the iodine is then titrated by means of standard sodium thiosulphate solution and the concentration of active nitrogen

calculated as already described (Part I). The results of these experiments are given in Table II, and it will be noticed that, whilst in some cases the concentration of active nitrogen has diminished,

yet in other cases it has increased when the second discharge is employed. Since in every case the destruction of the glow is complete in the gases issuing from the auxiliary discharge, it appears that the results already obtained are confirmed, and that it is possible by this method to destroy the glow and yet retain the chemical properties of active nitrogen.

Third Method.—It was felt that these observations could be made still more convincing if a stream of non-luminous but chemically active nitrogen could be obtained by a single operation, and in view of the known production of active nitrogen in the arc, where none of the luminous phenomena connected with active nitrogen are to be seen (Willey, *J. Soc. Chem. Ind.*, 1924, **43**, 260), it was decided to study the effect of the uncondensed discharge upon nitrogen.

For this purpose, the apparatus employed was as in Fig. 2, except that the tubes A and B were replaced by another discharge tube with water-cooled Armco electrodes. The discharge was obtained from a rotary converter and transformers and took 10—20 milliamps. at 2000—3000 volts; in these circumstances, the emergent gases showed no perceptible luminosity but contained a considerable quantity of active nitrogen (Table III). No traces appeared here

TABLE III.

Series	1	2	3	4	5	6	7

of the green flame usually to be seen where nitric oxide enters a stream of glowing nitrogen, and hence we must conclude that most probably this particular development of luminosity is independent of the actual chemical reaction in progress (compare Lord Rayleigh, *Proc. Roy. Soc.*, 1911, *A*, **86**, 56). Furthermore, strong indications of the presence of active nitrogen were obtained by the use of the two-thermometer device already described.

Fourth Method.—The methods of extinguishing the luminosity of the active nitrogen have hitherto been electrical in nature, and it is obviously of importance that other means should be attempted in order that a satisfactory mechanism may be formulated for the glow-destruction process. Lord Rayleigh has shown (*Proc. Roy. Soc.*, 1911, *A*, **85**, 219) that, when a stream of glowing nitrogen is drawn through a tube which is heated, the luminosity ceases at the hot portions and reappears in the colder parts if the temperature is not too high; if the tube be heated too strongly, however, the glow is not restored at all, and it was thought advisable to study this phenomenon in the light of the present observations.

The apparatus employed is as in Fig. 2, except that the auxiliary discharge tube was replaced by a U-tube of some 10″ over-all length and ¼″ internal diameter; determination of the active nitrogen was made with nitric oxide as before. The U-tube was immersed in an electrically heated bath of heavy paraffin; for temperatures above 250° the paraffin was replaced by a mixture of sodium and potassium nitrates.

When a stream of glowing nitrogen was drawn through the apparatus at a rate of 2000 c.c./hr. and 10 mm. pressure, the luminosity was considerably enhanced as the temperature of the bath was raised from 20° to 80°; from this point to about 225° no appreciable change in intensity was noticed, but at 235° the luminosity began to decrease in the gas entering the detection chamber, at 250° the effect was pronounced, and at 300—320° the gas lost all glow. Contrary to the observations of Lord Rayleigh, the glow did not as a rule reappear beyond the hot zone when once it had been destroyed, although a 2-litre chamber was provided in the exhaust line in order that this point might be examined; in some cases, however, his observations were confirmed, and it appears that the nature of the hot surface is a very important factor in this connexion.

TABLE IV.

Determinations of the active nitrogen in these experiments showed (Table IV) that, in spite of the alterations in the degree of luminosity, the concentration of the active gas remained sensibly unchanged throughout.

Discussion.

The experiments just described provide, it is thought, not only a fairly complete solution to the difficulty in reconciling spectroscopic and other optical work upon active nitrogen with the observations made upon the same subject in this laboratory, but also an explanation of certain phenomena alluded to by Lord Rayleigh and others.

Just before these experiments were completed, Bonhoeffer and Kaminsky (*Z. Elektrochem.*, 1926, **32**, 536) showed that the concentration of active nitrogen (measured chemically) and the intensity of the glow are not simply related to one another, at least four

terms being necessary in any expression connecting these two quantities. Details of their experimental procedure are not available, but the present work is in complete agreement with theirs. It may also be noticed that Koenig and Elöd (*Ber.*, 1914, **47**, 516) suspected that the presence of a glow was not a necessary criterion of chemical activity in nitrogen, but here again no experimental evidence was adduced. Furthermore, Lord Rayleigh has stated that "there does not appear to be any close or necessary connexion between the luminous phenomena associated with active nitrogen and the chemical ones" (J., 1918, **113**, 200; see also *Proc. Roy. Soc.*, 1913, *A*, **88**, 539). It appears that we must decide between two theories for an explanation of these phenomena:

(i) Active nitrogen may be regarded as a homogeneous substance which emits its energy in two or more stages, one of these being invariable and giving rise to the chemical activity, and the other or others being capable of modification so that the residual energy may be lost either as ultra-violet radiation or by an increase in the kinetic energy of the molecule. Saha and Sur (*loc. cit.*) regard the visible or α-radiation of the afterglow as *secondary* (the primary band in nitrogen lying in the vicinity of $\lambda = 1400$ Å.U.); it is possible therefore that some influence might lead to suppression of these α-bands and a corresponding development of other parts of the spectrum without affecting the chemical activity.

(ii) The whole of the observations and measurements which have been made with regard to active nitrogen can, in the author's opinion, be much more readily explained if it is assumed that the luminous and chemically active forms are quite distinct, although usually coexistent. The multiplicity of ionised and excited bodies produced by the discharge in any gas renders this quite likely, and examples are known of the formation under these conditions of more than one active form of an element, *e.g.*, the active oxygen, distinct from ozone, of Koenig and Elöd (*loc. cit.*), and the mono-, di-, and tri-atomic forms of hydrogen, all chemically active, whose existence has been claimed severally by Bonhoeffer (*Z. physikal. Chem.*, 1924, **113**, 199; 1925, **116**, 114, 391; 1926, **119**, 474; *Z. Elektrochem.*, 1925, **31**, 521), Phipps and Taylor (*Physical Rev.*, 1927, **29**, 309), and Wendt and Landauer (*J. Amer. Chem. Soc.*, 1922, **44**, 510).*

* It may be suggested that differences in the reactions of active hydrogen reported by certain of these investigators, *e.g.*, the formation of ammonia with nitrogen, noticed by Wendt and Landauer (*loc. cit.*) and denied by Bonhoeffer (*loc. cit.*; see also Paneth, Klener, and Peters, *Z. Elektrochem.*, 1927, **33**, 102), may be due to differences in their experimental conditions leading to the formation of different substances: the chemical activity of H, H_2, and H_3 is not likely to be the same.

If this view is adopted, it is apparent that the difficulties discussed earlier are overcome, since the observations of an active nitrogen made by spectroscopists and by workers in this laboratory have really been upon different modifications of the same element. The author now suggests that active nitrogen consists of a mixture of (i) metastable molecules with a heat of formation of *ca.* 45,000 cals./g.-mol. (2 volts), which are exclusively responsible for the chemical activity, and (ii) a much smaller proportion (probably of the order of 10^{-7}) of atoms which upon recombination produce high-level excited molecules, the energy set free, equivalent to 200,000—250,000 cals./g.-mol. (10—12 volts) being liberated as radiation; all the luminous phenomena and excitation of spectra, with the possible exception of certain cases of chemiluminescence arising from reactions of the 2-volt metastable molecules, are to be ascribed to this second constituent.

The decay of the afterglow follows a process which is bimolecular only with respect to the atoms, but is in reality a ternary reaction, for it has been shown (Herzfeld, *Z. Physik*, 1922, **8**, 132; Polyani, *ibid.*, 1920, **1**, 337; Born and Franck, *Ann. Physik*, 1925, **76**, 255) that, when two atoms recombine to form a diatomic molecule, the presence of a third body is nearly always necessary in order that considerations of the conservation of energy and momentum shall be satisfied. Such a view would presuppose a relation between the total pressure of the gas and the rate of decay of the afterglow; this has actually been observed by Lord Rayleigh (*Proc. Roy. Soc.*, 1916, *A*, **92**, 438) and studied by the present author, and it is hoped to publish details in a later communication.

The action of traces of impurities in developing the afterglow would appear to be adequately accounted for by Lord Rayleigh's original explanation (*Proc. Roy. Soc.*, 1912, *A*, **86**, 262; **87**, 179). Its behaviour towards heat and cold will be discussed in a later communication.

The catalytic destruction of the glow by surfaces, and by copper and other metals in particular, may readily be explained by the well-known analogous case of the surface recombination of hydrogen atoms. The extinction of the luminosity when a metal surface begins to be active in promoting the decay of the *chemically* active nitrogen is also accounted for when we remember that the surface is, *ex hypothesi*, composed of the metal, and not of the nitride, when the point of activity is reached; there is no apparent reason why a nitride surface should catalyse the recombination of nitrogen atoms, but the parent metal itself may, from the analogy already mentioned, be very effective in this connexion. It follows that the action of the discharge in extinguishing the luminosity is not intrinsically

electrical, but that the bombardment of the glass of the discharge tube by the ions and electrons present simply leads to the production of a " clean " surface, upon which the recombination of atoms can take place with ease; heat also leads to the production of this very active surface. The production of a few ions during the decay of the afterglow in phenomena studied by Constantinides (*Physical Rev.*, 1927, **30**, 95) is probably due to a side reaction among the atoms undergoing recombination on the surface.

It is clear that the relationship between concentration of active nitrogen, C, and glow intensity, I, as well as the magnitude and sign of dI/dC at any instant, will vary with the nature and area of the surfaces present. It appears probable that the mechanism whereby the chemically active nitrogen is destroyed in the discharge is analogous to that of the electrical production of ozone, and that the same complicated mixture of electrical and surface factors is involved: much more experimental evidence is needed upon this point.

It remains to discuss the probable nature of the chemically active modification of nitrogen. If this were triatomic, it would be expected that such a large molecule should condense easily (see Lord Rayleigh, *Proc. Roy. Soc.*, 1911, *A*, **86**, 56), and the author is indebted to Sir J. J. Thomson for the information that evidence is not lacking that such a separation can be effected under appropriate conditions.

The present author suggests, however, that the most cogent evidence as to the nature of active nitrogen is provided by the compounds it produces in its chemical reactions. With the metals, compounds are produced which, as a rule, give quantitative yields of ammonia when hydrolysed, *e.g.*, magnesium nitride; pentane gives hydrogen cyanide, amylenes, and ammonia (Koenig and Elöd, *loc. cit.*); and in general *when active nitrogen reacts with other substances it gives rise to derivatives of ammonia and not to substituted azoimides, hydrazines, etc.* These substances are invariably of the type produced in the few reactions of *inert* nitrogen, and hence the presumption is that active and ordinary nitrogen cannot be very different in structure. It is clear that if active nitrogen were atomic in character we should have to postulate dissociation of the molecule as an invariable prelude to the reactions of *inert* nitrogen, which does not appear likely. May it not be that the active modification is simply an isomeride of nitrogen, such as an acetylenic molecule? By analogy with its family congeners of the Periodic Table, nitrogen might be expected to exhibit allotropy, but much more experimental evidence is necessary before any conclusions can be reached upon this point.

Summary.

Four series of experiments are described in which it is shown that nitrogen can be chemically active and yet show no visible luminosity whatever. These are believed to indicate that "active" nitrogen consists of a mixture of a non-luminous, chemically active substance together with a very small proportion of atoms, the latter being responsible, upon a termolecular recombination, for the afterglow and the greater part of the excitation of spectra observed when various substances are admitted to the glowing gas. The heats of formation of the two varieties, the former of which is regarded as being most probably a metastable diatomic or an acetylenic molecule, are respectively about 45,000 and 200,000—250,000 cals./g.-mol.

This explanation is thought to reconcile the chemical and spectroscopic views, and also accounts for the whole of the phenomena connected with active nitrogen.

The author's thanks are due to the Department of Scientific and Industrial Research for a grant which enabled the converter and transformers to be purchased; to Dr. E. K. Rideal for his continued interest in these researches; to Mr. R. E. D. Clark, who has proved a capable assistant in some of the experimental work; and above all to Dr. H. W. B. Skinner, to whom this particular investigation must be dedicated.

Addendum.—Since the above was written, Crew and Hulbert (*Physical Rev.*, 1927, **30**, 124) have described some experiments on the dissociation of gases in the discharge at low pressures (5 mm. and less). The extent of dissociation is about 100% for wet hydrogen, rather less for the dry gas, 60% for oxygen, but close to zero for nitrogen, carbon monoxide, and carbon dioxide under the same conditions; the results with uncondensed and with condensed discharges, the latter producing the afterglow in nitrogen, are almost identical. This would appear to show once again that the chemically active nitrogen (which is produced to the extent of at least 5% under these conditions) cannot be atomic in character, and the work confirms the author's view upon this subject.

LABORATORY OF PHYSICAL CHEMISTRY,
CAMBRIDGE. [*Received, September 6th*, 1927.]

CCCLXXX.—*Molecular Structure in Solution. Part III. The Electrical Conductivities of Aqueous Solutions of Cobalt Chloride and Hydrochloric Acid, with a Note on the Prediction of Crystal Structure.*

By Owen Rhys Howell.

The densities, viscosities, refractive indices, and surface tensions of a series of solutions containing a constant amount of cobalt chloride with increasing amounts of hydrochloric acid, and the same properties of an exactly similar series of solutions of hydrochloric acid alone have already been determined (this vol., pp. 158, 2039). The differences in the values of each of these properties for corresponding members of the two series throw light upon the change in the state of the cobalt atom in solution with increasing acid concentration. All the results obtained have been fully interpreted by assuming that, in accordance with the theory of the colour of the cobaltous compounds suggested by Hill and Howell (*Phil. Mag.*, 1924, **48**, 833), the cobalt atom is forced out of its association with 6 molecules of water into one with 4 atoms of chlorine.

The electrical conductivities of these solutions have now been examined, and the conclusions drawn from the results are in complete accord with those already indicated.

Experimental.

Determination of Electrical Conductivity.—The electrical conductivities were determined in the usual way by the use of a standard resistance, an alternating current from a small coil, a metre bridge, and a low-resistance telephone. A small **U**-shaped cell made of resistance glass and having a capacity of about 3 c.c. was employed. It was immersed to below the level of the solution in a thermostat at 20° ± 0·02°. With each solution at least three different known resistances were employed and the point of balance was determined at least four times for each. With each known resistance the mean point of balance was taken and the conductance of the cell calculated. In almost every instance, the values lay within 0·05% of the mean, and in no case did the difference exceed 0·1%.

The cell constant was determined with *N*-potassium chloride solution, prepared from the pure salt (Kahlbaum's), which was first recrystallised and dried. The conductivity of this solution at 20° is 0·10207 mho (Kohlrausch, Holborn, and Diesselhorst, *Wied. Ann.*, 1898, **64**, 417); the actual resistance was found to be 3028

ohms, whence the conductance was 0·0003302 mho and the cell constant 309·1.

Materials.—The solutions used for these determinations were the same as those employed for the measurement of the refractive index and surface tension (*loc. cit.*). A few new solutions were also prepared from the same stock solutions as those previously employed. The water used for preparing these solutions was twice redistilled; its conductivity was negligible compared with that of any of the solutions.

Results.

Conductivities.—The conductivities of the series of solutions of hydrochloric acid alone are given in column 3 of Table I. Previous measurements for concentrated solutions of hydrochloric acid have been made at 18° by Kohlrausch (*Pogg. Ann.*, 1876, **159**, 233) and at 25° by Masson and Green (J., 1908, **93**, 2023). Direct comparison with these is not possible because of the different temperatures employed, but the curve of the values now given lies smoothly between those of the other observers. The values of the conductivity are plotted against the normality of the acid (at 18°) in Fig. 1 (upper curve).

The results obtained with the series of solutions of cobalt chloride and hydrochloric acid are given in column 2 of Table I, and plotted against the normality of the acid in Fig. 1 (lower curve). The two curves are very different in form: that for the acid only rises to a sharp maximum, whereas that for the solutions containing cobalt is greatly flattened at its maximum.

The differences in conductivity between corresponding solutions in the two series are given in col. 4 of Table I and are plotted against

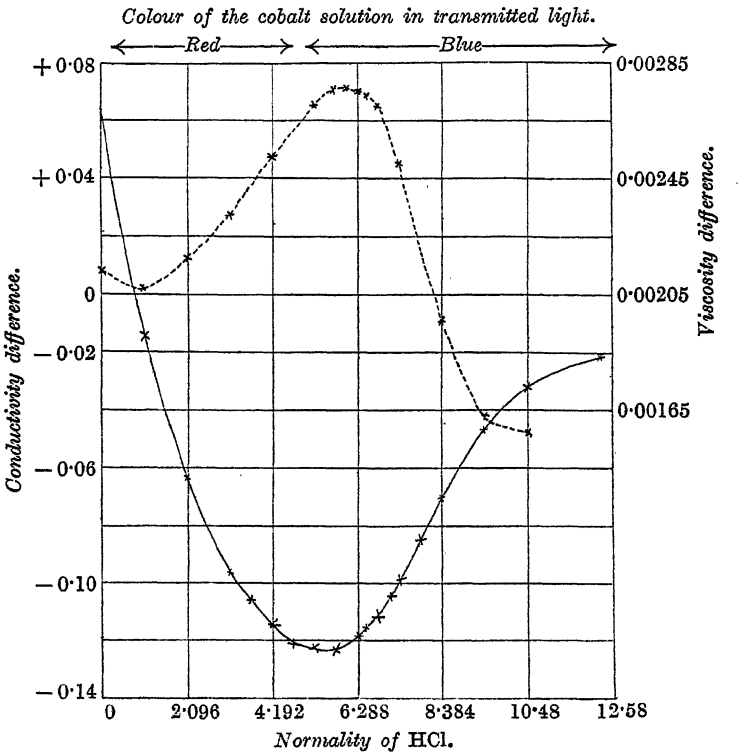
the normality of the acid in Fig. 2. It is seen that the conductivity-differences curve is almost the exact complement of the viscosity-differences curve, which is also reproduced for comparison; the minimum of the one occurs at the same concentration of acid as the maximum of the other. There is one point of difference, *viz.*, that whereas the viscosity-differences curve first falls slightly

FIG. 1.

Upper curve: Solutions of hydrochloric acid only.
Lower curve: Solutions of hydrochloric acid + cobalt chloride.

before rising to its maximum, the conductivity-differences curve falls continuously to its minimum. The same reasoning which accounted for the form of the first (this vol., p. 168) also explains that of the second, including this respect in which they differ.

The effect of increasing the concentration of acid is to throw more and more of the cobalt out of its association with 6 molecules of water, $Co(H_2O)_6^{\cdot\cdot}$, into one with 4 atoms of chlorine, $CoCl_4^{\prime\prime}$. When this transition is complete, continued increase in the con-



centration of acid would be without further effect, and the difference in physical properties between the solutions containing cobalt and the corresponding solutions of acid alone should become and remain constant. It is seen that the conductivity-differences curve, like the viscosity-differences curve, flattens out at the highest concentrations of acid to become parallel to the axis of concentration, indicating that this transition is practically complete. Moreover, both curves exhibit this characteristic at approximately the same concentration of acid.

It is seen that the conductivity differences at the end of the series (blue solutions) are smaller than those at the beginning (red solutions). The curve does not, however, fall evenly from the initial to the final value, but exhibits a very deep minimum, just as the viscosity-differences curve similarly shows a well-defined maximum. Since the red and the blue ions, $Co(H_2O)_6^{\cdot\cdot}$ and $CoCl_4''$, are oppositely charged, there will undoubtedly be combination between them where they are present together in solution; they will not remain wholly as free ions. The combination of these ions will result in further dissociation of the compounds from which they are derived, thus liberating chlorine ions and hydrogen ions respectively. These, however, will not remain free, the ionisation being depressed by the hydrochloric acid already present in high concentration, so that the conductivity of the solution will diminish. The greater the combination, the less will be the conductivity of the solution; therefore, as transformation of the red $Co(H_2O)_6^{\cdot\cdot}$ into the blue $CoCl_4''$ proceeds, the conductivity-differences curve falls sharply. The combination will evidently be greatest when these two oppositely charged ions are present in equal amounts, so that the conductivity differences should decrease up to this point. Thereafter, continued transformation of the $Co(H_2O)_6^{\cdot\cdot}$ ions into $CoCl_4''$ ions will result in an increasing surplus of free $CoCl_4''$ and the conductivity differences should increase again up to a constant value. This is seen to be so and it is therefore suggested that the minimum of the conductivity-differences curve occurs when half the cobalt is present as $Co(H_2O)_6^{\cdot\cdot}$ and half as $CoCl_4''$.

The viscosity-differences curve exhibits an initial decrease before rising to its maximum, whereas the conductivity-differences curve falls sharply to its minimum. When discussing the viscosity-differences curve (*loc. cit.*), it was pointed out that the first effect of the addition of hydrochloric acid is to depress the ionisation of the cobalt chloride because of the addition of a common ion. There is thus at first a decrease in the number of the viscous $Co(H_2O)_6^{\cdot\cdot}$ ions, resulting in a decrease of viscosity. This effect is soon overwhelmed by the conversion of $Co(H_2O)_6^{\cdot\cdot}$ ions into $CoCl_4''$ ions,

so that the curve exhibits only a small dip and then rises rapidly. The two effects are thus opposed when the viscosity of the solutions is concerned; but they operate together when the conductivity is considered. Both the initial depression of ionisation and (as discussed above) the conversion of $Co(H_2O)_6^{\cdot\cdot}$ ions into $CoCl_4''$ ions result in a decrease of conductivity, so that the conductivity-differences curve falls continuously to its minimum.

FIG. 2.

Full curve: Conductivity differences.
Broken curve: Viscosity differences.

It may readily be shown that the curve of the differences of specific resistance is quite different in form from that of the differences of specific conductance. It is very similar to the density-differences and refractive-index-differences curves found previously (*loc. cit.*), in that it exhibits a point of inflexion at the same concentration of acid and then falls, eventually becoming parallel to the axis of concentration, just as these do, and at about the same concentration of acid. It differs from them in first rising to a

maximum, whereas they fall continuously from the beginning; and this difference is explained in exactly the same way as that between the conductivity-differences and viscosity-differences curves.

Note on the Prediction of Crystal Structure.

When the metallic atom of a colourless insoluble compound is replaced, wholly or partly, by cobalt, a pigment is obtained which may be either blue or red, and it has been shown (Hill and Howell, *loc. cit.*), by carrying out this replacement in compounds of known crystal structure, that when the metallic atom is surrounded by *four* other atoms or groups, the resulting pigment is *blue*, and when surrounded by *six*, the pigment obtained is *red*. Thus, when the magnesium atom in spinelle (magnesium aluminate, where it is surrounded by four oxygen atoms) is replaced by cobalt, a blue pigment (cobalt blue) is obtained, but when the magnesium atom in magnesium oxide (where it is surrounded by six oxygen atoms) is similarly replaced, a red pigment (cobalt pink) is produced.

For comparison of their absorption spectra, pigments were prepared, not only from compounds of known crystal structure, but also from a number the structure of which was at that time unknown. From the colour of the pigment obtained, it was possible to predict the structure of the compound from which it was derived. Since that work was published, two of the compounds have been submitted to *X*-ray analysis by different observers, and the structure is in both instances in accord with that predicted from the colour of the corresponding cobalt pigment. The structures of cobalt oxide and cobalt fluoride have also been subsequently determined and are in agreement with the predictions from the theory.

Zinc orthosilicate. If the zinc atom in zinc orthosilicate is replaced by cobalt, a *blue* pigment is obtained. It follows from the theory that in the pigment the cobalt atom is surrounded by *four* other atoms or groups, and therefore that the zinc atom in the original compound is similarly situated. The crystal structure of willemite (zinc orthosilicate) has recently been determined by Zachariasen (*Norsk. Geol. Tidsskr.*, 1926, **9**, 65), who showed it to be isomorphous with phenacite (beryllium orthosilicate), the crystal structure of which was elucidated by W. L. Bragg (*Proc. Roy. Soc.*, 1927, *A*, **113**, 642), who established that the beryllium atom is between four oxygen atoms. It follows that in zinc orthosilicate the zinc atom is similarly placed, as predicted from the theory.

Magnesium orthosilicate. If the magnesium atom in magnesium orthosilicate is replaced by cobalt, a *red* pigment is produced, so that, according to the theory, the magnesium atom in this compound is surrounded by *six* other atoms. This prediction has been verified

by the work of W. L. Bragg and Brown (*Z. Krist.*, 1926, **63**, 538) on olivine (magnesium orthosilicate).

Cobalt oxide. It is well known that when cobalt oxide is melted in the electric furnace, it crystallises in rose-coloured needles (Moissan, *Compt. rend.*, 1892, **115**, 1034; *Bull. Soc. chim.*, 1893, **9**, 955; *Ann. Chim. Phys.*, 1895, **4**, 136). Although the crystal structure of the compound was unknown, the theory enabled us to predict that, since the compound was of the *red* form, the cobalt atom should be surrounded by *six* oxygen atoms, and verification was forthcoming in the work of Goldschmidt, Barth, and Lunde (*Skrifter Norske Videnskaps Akad.*, No. 7, 1925), of Natta and Reina (*Atti R. Accad. Lincei*, 1926, **4**, 48), and of Bravo (*Anal. Fís. Quím.*, 1926, **24**, 611), who found that the compound possesses the rock-salt structure, *i.e.*, the cobalt atom is between six oxygen atoms.

Cobalt fluoride. Since anhydrous cobaltous fluoride is *red* (Poulenc, *Compt. rend.*, 1892, **114**, 1426), it could be predicted that the cobalt atom should lie between *six* fluorine atoms. Actually, it has been found (Ferrari, *Atti R. Accad. Lincei*, 1926, **3**, 324) to have the same crystal structure as rutile, in which the titanium atom is surrounded by six oxygen atoms (Vegard, *Phil. Mag.*, 1916, **32**, 65, 505; 1917, **33**, 395; 1926, **1**, 1151; Williams, *Proc. Roy. Soc.*, 1917, **93**, 418; Greenwood, *Phil. Mag.*, 1924, **48**, 654).

Summary.

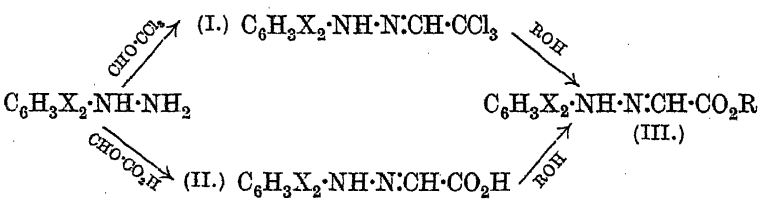
1. The electrical conductivities of a series of solutions containing a constant amount of cobalt chloride and increasing amounts of hydrochloric acid have been determined.

2. The same properties of an exactly similar series containing hydrochloric acid only have also been determined.

3. The curve of the differences of conductivity of corresponding solutions plotted against the concentration of acid is almost the exact complement of the viscosity-differences curve found in a previous investigation. It exhibits a minimum at the same concentration of acid where the other curve exhibits a maximum. It differs in falling constantly to the minimum, whereas the viscosity-differences curve first falls slightly before rising to its maximum. Both its resemblance to and difference from the viscosity-differences curve are fully explained on the same reasoning as that employed in previous investigations.

4. It is noted that the crystal structure of compounds which yield pigments when the metallic atom is replaced by cobalt can be predicted from the colour of the pigment so obtained. The structures of two compounds (zinc and magnesium orthosilicates) have been determined since the theory of the colour of the cobaltous

compounds was suggested, and they verify the predictions made from the theory. The structures of cobalt oxide and cobalt fluoride are similarly in accordance with prediction from the theory.



The author would again express his thanks to Prof. F. L. Pyman, F.R.S., for giving him every facility for doing this work.

MUNICIPAL COLLEGE OF TECHNOLOGY,
UNIVERSITY OF MANCHESTER. [*Received, September 1st*, 1927.]

CCCLXXXI.—*The Interaction of Chloral and Arylhydrazines.*

By FREDERICK DANIEL CHATTAWAY and RANDLE BENNETT.

OWING to the violence with which the hydrazone initially formed decomposes, the behaviour of chloral with phenylhydrazine has been little studied. When, however, a 2 : 4-dihalogen-substituted phenylhydrazine is used, the decomposition occurs more quietly and the final products can be isolated. These differ according to the nature of the solvent in which interaction occurs. When any alcohol is used as the solvent, the 2 : 4-dihalogen-substituted phenylhydrazone of the corresponding alkyl glyoxylate (III) is produced identical with the ester yielded by the corresponding dihalogen-substituted phenylhydrazone of glyoxylic acid :

Bromal behaves in an exactly similar manner, although the reaction is not so vigorous as when chloral is used.

When, on the other hand, interaction takes place in water or acetic acid, one molecule of water and one molecule of hydrogen chloride are eliminated and beautifully crystalline, brilliant red compounds formed. When strongly reduced, these yield 2 : 4-dihalogen-substituted aniline; the chlorine atom lost in the decomposition must therefore be one of those contained in the chloral. They are unaffected by heating with acetic anhydride, whilst their intense red colour recalls that of compounds containing an azo-group. Bromine replaces one hydrogen atom not in the nucleus, the substitution product still retaining its red colour.

These red compounds therefore appear to be αα-dichloro-β-2 : 4-dihalogenobenzeneazoethylenes (IV), and the bromine substitution products αα-dichloro-β-bromo-β-2 : 4-dihalogenobenzeneazoethylenes (V), formed thus :

(I.) ⟶ (IV.) $C_6H_3X_2{\cdot}N{:}N{\cdot}CH{:}CCl_2$ ⟶ (V.) $C_6H_3X_2{\cdot}N{:}N{\cdot}CBr{:}CCl_2$.

When the azoethylenes are heated with alcohols they are converted into the corresponding alkyl glyoxylate arylhydrazones (III), but the reaction is not so rapid as that by which the latter compounds are formed from the chloral hydrazones.

EXPERIMENTAL.

Action of 2 : 4-*Dichlorophenylhydrazine Hydrochloride on Chloral Hydrate dissolved in Ethyl Alcohol.*—When 21·5 g. of 2 : 4-dichlorophenylhydrazine hydrochloride (1 mol.) and 16·5 g. of chloral hydrate (1 mol.) were added to 100 c.c. of ethyl alcohol, the liquid became yellow, but little action appeared to take place at the ordinary temperature. On heating, the colour deepened to dark orange and at about 60° hydrogen chloride was evolved, much heat liberated, and the liquid boiled spontaneously for several minutes. The bulk of the alcohol was then slowly distilled off; the residual clear deep yellow liquid, on cooling, deposited bright yellow crystals of *ethyl glyoxylate* 2 : 4-*dichlorophenylhydrazone*, the yield being practically theoretical. This substance is easily soluble in warm alcohol and separates in pale yellow, very slender prisms, m. p. 121·5° (Found : C, 45·8; H, 3·8; N, 11·1; Cl, 27·2. $C_{10}H_{10}O_2N_2Cl_2$ requires C, 46·0; H, 3·8; N, 10·8; Cl, 27·2%). It yielded ethyl alcohol and glyoxylic acid 2 : 4-dichlorophenylhydrazone on hydrolysis, and 2 : 4-dichloroaniline on reduction.

Methyl glyoxylate 2 : 4-*dichlorophenylhydrazone* crystallises in pale yellow, slender prisms, m. p. 136·5° (Found : C, 43·9; H, 3·4; Cl, 28·8. $C_9H_8O_2N_2Cl_2$ requires C, 43·7; H, 3·2; Cl, 29·0%), n-*propyl glyoxylate* 2 : 4-*dichlorophenylhydrazone* in short, pale yellow, flattened prisms, m. p. 65° (Found : Cl, 25·6. $C_{11}H_{12}O_2N_2Cl_2$ requires Cl, 25·8%), and n-*butyl glyoxylate* 2 : 4-*dichlorophenylhydrazone* in slender, yellow, flattened prisms, m. p. 59° (Found : Cl, 24·3. $C_{12}H_{14}O_2N_2Cl_2$ requires Cl, 24·5%).

Action of 2 : 4-*Dibromophenylhydrazine Hydrochloride on Chloral Hydrate dissolved in Methyl Alcohol.*—2 : 4-Dibromophenylhydrazine hydrochloride (15 g.; 1 mol.), chloral hydrate (8 g.; 1 mol.), and methyl alcohol (60 c.c.), when heated together under reflux on a water-bath for an hour, reacted vigorously with liberation of hydrogen chloride. A deep yellow liquid was obtained, from which *methyl glyoxylate* 2 : 4-*dibromophenylhydrazone* separated on cooling.

It crystallises from boiling methyl alcohol, in which it is moderately easily soluble, in slender, pale yellow, flattened prisms, m. p. 136° (Found: C, 32·2; H, 2·5; Br, 47·6. $C_9H_8O_2N_2Br_2$ requires C, 32·1; H, 2·4; Br, 47·6%).

Similar esters were obtained when chloral was allowed to interact with 2 : 4-dibromophenylhydrazine, 2-chloro-4-bromophenylhydrazine, and 4-chloro-2-bromophenylhydrazine in presence of alcohols and were all found to be identical with the corresponding esters prepared from glyoxylic acid.

Ethyl glyoxylate 2 : 4-*dibromophenylhydrazone* crystallises in slender, pale yellow, flattened prisms, m. p. 119° (Found: Br, 45·6. $C_{10}H_{10}O_2N_2Br_2$ requires Br, 45·7%), n-*propyl glyoxylate* 2 : 4-*dibromophenylhydrazone* in short, pale yellow, flattened prisms, m. p. 75° (Found: Br, 44·0. $C_{11}H_{12}O_2N_2Br_2$ requires Br, 43·9%), and *ethyl glyoxylate* 2-*chloro*-4-*bromophenylhydrazone* (Found: Cl, 11·6; Br, 26·3. $C_{10}H_{10}O_2N_2ClBr$ requires Cl, 11·6; Br, 26·2%) and *ethyl glyoxylate* 4-*chloro*-2-*bromophenylhydrazone* in slender, pale yellow prisms, m. p. 120° and 115°, respectively.

Glyoxylic Acid 2 : 4-*Dichlorophenylhydrazone*.—Glyoxylic acid (made by the electrolytic reduction of oxalic acid) and 2 : 4-dichlorophenylhydrazine hydrochloride reacted at once in aqueous solution at 60° and the *hydrazone* separated as a yellow solid. It is sparingly soluble in water, very easily soluble in alcohol, and crystallises from hot aqueous alcohol in pale yellow needles, decomp. about 150° (Found: Cl, 30·3. $C_8H_6O_2N_2Cl_2$ requires Cl, 30·4%).

The 2 : 4-*dibromophenylhydrazone* of glyoxylic acid resembles the dichloro-hydrazone very closely. It crystallises in pale yellow needles, decomp. about 150° (Found: Br, 49·5. $C_8H_6O_2N_2Br_2$ requires Br, 49·7%).

Action of 2 : 4-*Dichlorophenylhydrazine Hydrochloride on Bromal dissolved in Ethyl Alcohol*.—A mixture of 11 g. of 2 : 4-dichlorophenylhydrazine hydrochloride, 14 g. of bromal, and 100 c.c. of ethyl alcohol was boiled under reflux for an hour, hydrogen bromide being liberated in quantity and ethyl bromide (recognisable by its odour) formed. The bright yellow liquid obtained, on cooling, deposited ethyl glyoxylate 2 : 4-dichlorophenylhydrazone, m. p. 121·5°, identical in every respect with that prepared both from chloral and from glyoxylic acid.

Methyl glyoxylate 2 : 4-dibromophenylhydrazone, m. p. 136°, was similarly obtained when 2 : 4-dibromophenylhydrazine hydrochloride was heated with bromal dissolved in methyl alcohol.

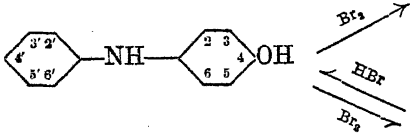
Action of 2 : 4-*Dichlorophenylhydrazine Hydrochloride on Chloral Hydrate dissolved in Acetic Acid or Water*.—To a solution of 16·5 g. (1 mol.) of chloral hydrate in 100 c.c. of acetic acid, 21·5 g. (1 mol.)

of 2 : 4-dichlorophenylhydrazine hydrochloride and 33 g. of anhydrous sodium acetate (4 mols.) were added. The liquid became pale yellow, but little apparent change occurred until the temperature was raised to about 60°; obvious action then took place and the liquid became bright red. It was heated on a water-bath for ½ hour to complete the reaction and poured into water; *αα-dichloro-β-2 : 4-dichlorobenzeneazoethylene* (IV) then separated as a scarlet-red solid.

If aqueous solutions of equivalent quantities of chloral hydrate and 2 : 4-dichlorophenylhydrazine hydrochloride are mixed and slowly heated, the same compound separates at about 80° as a crimson, viscid liquid which solidifies on cooling and from which the supernatant liquid, now strongly acid from the hydrogen chloride set free in the reaction, can be decanted.

The red solid is readily soluble in boiling chloroform, acetic acid, and alcohol, and separates from warm alcohol in slender, flattened, golden-red prisms, m. p. 84·5° (Found : C, 35·6; H, 1·6; N, 10·2; Cl, 52·5; *M*, cryoscopic in benzene, 262. $C_8H_4N_2Cl_4$ requires C, 35·6; H, 1·5; N, 10·4; Cl, 52·6%; *M*, 270). It does not react with acetic anhydride. When it was boiled with ethyl alcohol for 8 hours, a deep orange-coloured liquid was obtained from which, on cooling, ethyl glyoxylate 2 : 4-dichlorophenylhydrazone separated.

Action of Bromine upon αα-Dichloro-β-2 : 4-dichlorobenzeneazoethylene.—To a solution of 5 g. (1 mol.) of αα-dichloro-β-2 : 4-dichlorobenzeneazoethylene in 20 c.c. of warm acetic acid, 3·5 g. (1 mol.) of bromine in 5 c.c. of acetic acid were added. The bromine slowly disappeared and the solution became paler in colour. The solution was then poured into water; *αα-dichloro-β-bromo-β-2 : 4-dichlorobenzeneazoethylene* (V) separated as a brownish-red solid. It is easily soluble in warm acetic acid or alcohol and separates in small, red needles, m. p. 90° (Found : Cl, 40·5; Br, 22·7. $C_8H_3N_2Cl_4Br$ requires Cl, 40·7; Br, 22·9%).



αα-Dichloro-β-2 : 4-dibromobenzeneazoethylene crystallises in slender, orange-red, flattened prisms, m. p. 96·5° (Found : Cl, 19·9; Br, 44·9. $C_8H_4N_2Cl_2Br_2$ requires Cl, 19·8; Br, 44·6%), *αα-dichloro-β-2-chloro-4-bromobenzeneazoethylene* in small, slender, orange-red prisms, m. p. 84° (Found : Cl, 33·6; Br, 25·3. $C_8H_4N_2Cl_3Br$ requires Cl, 33·8; Br, 25·4%), and *αα-dichloro-β-4-chloro-2-bromobenzeneazoethylene* in slender, orange-red prisms, m. p. 81°.

THE QUEEN'S COLLEGE, OXFORD. [*Received, August 27th,* 1927.]

CCCLXXXII.—*The Halogenation of* p-*Hydroxydiphenylamine. Part II.*

By Alan Edwin Bradfield, Leslie Hugh Norman Cooper, and Kennedy Joseph Previté Orton.

The main reaction between bromine or chlorine and *p*-hydroxydiphenylamine and its derivatives (Smith and Orton, J., 1908, **93**, 314) may follow one of two paths, leading either to a halogen-substituted *p*-hydroxydiphenylamine (A) or to a quinoneanil (benzoquinonephenylimine) (B). More drastic treatment leads to a disruption of the molecule.

$$C_{12}H_{10}NOBr + HBr \quad (A)$$

$$C_6H_5{\cdot}N{:}C_6H_4{:}O + 2HBr \quad (B)$$

The bromination of *p*-hydroxydiphenylamine, which is very rapid (*loc. cit.*), indicates that the imino-group is much more powerful as a directing group than the hydroxyl, the 2 : 2′ : 4′-trisubstituted compound being the first isolable product. The influence of the imino-group is then diminished and bromine enters successively into positions 5 and 3, and, finally, positions 6 and 6′ simultaneously. It is now found that, when the hydroxyl group is previously esterified by means of benzoyl chloride or *p*-toluenesulphonyl chloride, the 4′-bromo-, 2 : 2′ : 4′-tribromo-, and, finally, 2 : 6 : 2′ : 4′ : 6′-pentabromo-compounds are successively obtained.

In acetic acid, the first main action of bromine on 2 : 6 : 2′ : 4′ : 6′-pentabromohydroxydiphenylamine is oxidation to the quinoneanil. The reaction is reversible and, provided the hydrogen bromide formed is not removed, an equilibrium is reached. The small amount of the hydroxy-compound present undergoes slow nuclear substitution (irreversible), displacing the equilibrium, and in time the whole is converted into the 2 : 3 : 5 : 6 : 2′ : 4′ : 6′-heptabromohydroxy-derivative, the original violet colour of the solution fading as the quinoneanil is reduced by the hydrogen bromide and brominated. If the hydrogen bromide be removed by the addition of sodium acetate, reduction and bromination are prevented.

Chlorine has a disruptive action on *p*-hydroxydiphenylamine; the benzoate or *p*-toluenesulphonate, however, may be chlorinated by the chloroamine method (Orton and King, J., 1911, **99**, 1185; Orton and Bradfield, this vol., p. 986), the reaction following a similar

course to that of bromination of the esters, yielding finally the 2 : 6 : 2′ : 4′ : 6′-pentachloro-compound. The rate of further substitution in 2 : 6 : 2′ : 4′ : 6′-pentachloro-*p*-hydroxydiphenylamine, obtained from the ester, has now become so diminished that when it is treated with chlorine, oxidation to the quinoneanil initially predominates. This is succeeded, however, by reduction and substitution as in the further bromination of pentabromohydroxydiphenylamine, yielding the 2 : 3 : 6 : 2′ : 4′ : 6′-hexachloro- and 2 : 3 : 5 : 6 : 2′ : 4′ : 6′-heptachloro-derivatives.

The action of hydrochloric acid on an acetic acid solution of the pentachloroquinoneanil obtained by oxidation of pentachlorohydroxydiphenylamine with chromic anhydride or mercuric oxide yields the same hexa- and hepta-chloro-compounds. This fact is entirely in harmony with the view of the course of the reaction of *p*-hydroxydiphenylamine derivatives with halogens which has been put forward above; in so far as it relates to the production of halogenated derivatives from the quinoneanil, it closely resembles the scheme first advanced by Wichelhaus (*Ber.*, 1879, **12**, 1500) to explain the action of hydrochloric acid on quinone.

Several mixed chlorobromo-*p*-hydroxydiphenylamine derivatives have been prepared.

Amongst the properties of the halogen derivatives of *p*-hydroxydiphenylamine, certain anomalies appear for which at present no explanation can be offered. These are:

(1) The majority of the compounds are, as would be expected, soluble in aqueous alkali; but the following are not, although they are soluble in alcoholic potash: 2 : 2′ : 4′-trichloro-5 : 6′-dibromo-, 2 : 5 : 2′ : 4′-tetrabromo-, 2 : 2′ : 4′-trichloro-3 : 5 : 6 : 6′-tetrabromo-, 2 : 3 : 5 : 2′ : 4′-pentabromo-, 2 : 3 : 5 : 2′ : 4′ : 6′-hexabromo-, 2 : 3 : 5 : 2′ : 4′ : 6′-hexachloro- and heptabromo-*p*-hydroxydiphenylamine.

Further, these same compounds have resisted all attempts at sulphonylation with *p*-toluenesulphonyl chloride, not only by the Schotten–Baumann procedure, but in pyridine or quinoline, in which they are soluble, indicating that the phenomenon, although concomitant, is not attributable simply to insolubility.

(2) Although 2 : 5 : 2′ : 4′-tetrabromo- and 2 : 3 : 5 : 2′ : 4′-pentabromo-*p*-hydroxydiphenylamine react with bromine, the benzoyloxy-derivatives prepared from them react very slowly or not at all under the conditions usually successful, in spite of the fact that positions ortho to the imino-group remain vacant, *i.e.*, esterification not only retards substitution in the ortho-position to the hydroxyl group, but greatly diminishes the reactivity of the molecule as a whole, even transmitting the effect through nitrogen to an attached

benzene ring. It is hoped to study this observation, which appears to be unique, in greater detail.

EXPERIMENTAL.

In the preparation of *p*-hydroxydiphenylamine by Calm's method (*Ber.*, 1883, **16**, 2786; 1884, **17**, 2431) the yield is much improved by the employment of crude aniline, and both yield and purity are enhanced if pure aniline to which a drop of sulphuric acid has been added is used. The product, after distillation in superheated steam and then under 12 mm. pressure, melts at 73°.

The p-*toluenesulphonyl* derivative, prepared from *p*-toluenesulphonyl chloride (210 g.), *p*-hydroxydiphenylamine (185 g.), benzene (900 c.c.), and aqueous sodium hydroxide, crystallises from alcohol in thin plates, m. p. 126·5°, soluble in benzene and chloroform, less soluble in alcohol, petroleum, and acetic acid (Found: S, 9·5. $C_{19}H_{17}O_3NS$ requires S, 9·5%).

The acetic acid used as a medium for halogenation was purified by Orton and Bradfield's method (this vol., p. 983).

Chloro-compounds.

The following chloro-4-acyloxydiphenylamines were prepared by chlorination by the chloroamine (*N* : 2 : 4-trichloroacetanilide or dichloramine T) method and were usually precipitated on addition of water. They were hydrolysed by boiling alcoholic potassium hydroxide, and the hydroxy-compounds precipitated by addition of water to the acidified solutions. The anils were prepared by oxidising the corresponding chlorohydroxydiphenylamines in boiling benzene with yellow mercuric oxide or in boiling acetic acid with chromic acid; they were usually isolated by evaporation of the solvent and addition of petroleum in the former method and by addition of water in the latter. Fission of the anils was effected in acetic acid by addition of sulphuric acid; on dilution with water and basification, the expected chloroaniline was obtained in every case.

4′-*Chloro*-4-*benzoyloxydiphenylamine* is prepared from *p*-benzoyloxydiphenylamine; the reaction, initiated by the addition of one drop of hydrochloric acid, is completed in 15 minutes. The product (yield, 30%) crystallises from petroleum or 98% acetic acid in silvery plates, m. p. 148·5°. The presence of isomerides is indicated (Found: Cl, 10·6. $C_{19}H_{14}O_2NCl$ requires Cl, 11·0%).

4′-*Chloro*-4-*hydroxydiphenylamine* forms pale green leaflets (yield, 72%), m. p. 91° (Found: Cl, 15·9. $C_{12}H_{10}ONCl$ requires Cl, 16·2%). The p-*toluenesulphonate* has m. p. 93—94° (Found: Cl, 9·3. $C_{19}H_{16}O_3NClS$ requires Cl, 9·5%).

4′-*Chlorobenzoquinoneanil* crystallises in dark red, massive prisms,

m. p. 83·5°, insoluble in water, sparingly soluble in alcohol, hot or cold, and in cold petroleum and acetic acid, readily soluble in chloroform and benzene (Found: Cl, 16·0. $C_{12}H_8ONCl$ requires Cl, 16·3%).

2 : 2′ : 4′-*Trichloro*-4-*benzoyloxy*- and -4-p-*toluenesulphonyloxy*-*diphenylamines* are prepared at 50—55° from the 4-acyloxy-compounds or their monochloro-derivatives and separate on cooling. The *benzoyloxy*-compound has m. p. 114° (Found: Cl, 27·3. $C_{19}H_{12}O_2NCl_3$ requires Cl, 27·1%); the *toluenesulphonyloxy*-compound crystallises from hot benzene–petroleum or from acetic acid in prisms, m. p. 130·5° (Found: Cl, 24·3. $C_{19}H_{14}O_3NCl_3S$ requires Cl, 24·1%).

2 : 2′ : 4′-*Trichloro*-4-*hydroxydiphenylamine*, crystallised from glacial acetic acid and then from petroleum, forms prisms, never quite colourless, m. p. 128° (Found: Cl, 36·7. $C_{12}H_8ONCl_3$ requires Cl, 36·9%).

2 : 2′ : 4′-*Trichlorobenzoquinoneanil* separates from petroleum (b. p. 40—60°), containing a very little benzene, in long, bronzy needles, m. p. 72·5°. It is readily soluble in all organic solvents except light petroleum (Found: Cl, 37·1. $C_{12}H_6ONCl_3$ requires Cl, 37·2%).

2 : 6 : 2′ : 4′-*Tetrachloro*-4-p-*toluenesulphonyloxydiphenylamine* is obtained from the trichlorotoluenesulphonyloxydiphenylamine at 45—50°, and is separated from the other isomerides produced only by a tedious series of fractional precipitations from chloroform and light petroleum. It is much more soluble in common solvents than the tri- and penta-chloro-derivatives, and crystallises from acetic acid, chloroform, and petroleum (b. p. 110°) in prisms, m. p. 126° (Found: Cl, 30·1. $C_{19}H_{13}O_3NCl_4S$ requires Cl, 29·8%).

The *tetrachlorohydroxy*-compound solidifies with difficulty, but after being thoroughly washed and dried it may be obtained crystalline by the addition of petroleum, b. p. 40—60°, to a solution in petroleum, b. p. 110°; it then melts at 113° (Found: Cl, 44·3. $C_{12}H_7ONCl_4$ requires Cl, 44·0%). The *tetrachlorobenzoyloxy*-compound is obtained by benzoylating the tetrachlorohydroxy-compound in pyridine; after crystallisation from petroleum (b. p. 60—85°) it melts at 114·5° (Found: Cl, 33·1. $C_{19}H_{11}O_2NCl_4$ requires Cl, 33·3%).

2 : 6 : 2′ : 4′-*Tetrachlorobenzoquinoneanil* separates from ethyl acetate in violet crystals, m. p. 143° (Found: Cl, 44·5. $C_{12}H_5ONCl_4$ requires Cl, 44·2%).

2 : 6 : 2′ : 4′ : 6′-*Pentachloro*-4-*benzoyloxydiphenylamine* is prepared from the mono- or trichloro-derivative; after crystallisation from alcohol (yield, 62%) it melts at 133—134° (Found: Cl, 38·0. $C_{19}H_{10}O_2NCl_5$ requires Cl, 38·4%). The *toluenesulphonyloxy*-compound is prepared from the trichlorosulphonyloxy-compound

at 55°; on cooling, it separates in quantitative yield, in prisms, m. p. 156·5°, unaltered by crystallisation from acetic acid. It is also obtained by passing chlorine into a hot acetic acid solution of 4-*p*-toluenesulphonyloxydiphenylamine in presence of anhydrous sodium acetate. It is soluble in chloroform, but sparingly soluble in other solvents (Found: Cl, 34·7. $C_{19}H_{12}O_3NCl_5S$ requires Cl, 34·7%). The *pentachlorohydroxy*-compound crystallises from petroleum in clear brown prisms, m. p. 156° (Found: Cl, 49·2. $C_{12}H_6ONCl_5$ requires Cl, 49·6%). The *monoacetyl* derivative, obtained by treating the hydroxy-compound in acetic acid with acetic anhydride in the presence of sodium acetate, has m. p. 126°. It is insoluble in alkali, very soluble in benzene, petroleum, and chloroform, and sparingly soluble in acetic acid (Found: Cl, 44·0. $C_{14}H_8O_2NCl_5$ requires Cl, 44·4%).

2 : 6 : 2′ : 4′ : 6′-*Pentachlorobenzoquinoneanil* (prepared by the chromic acid method) forms fine, bronzy-red needles with a metallic lustre, m. p. 163° (Found: Cl, 49·5. $C_{12}H_4ONCl_5$ requires Cl, 49·9%).

All attempts to chlorinate further *p*-benzoyloxy- and 4-*p*-toluenesulphonyloxy-diphenylamine have been unsuccessful, as is to be expected.

2 : 3 : 6 : 2′ : 4′ : 6′-*Hexachloro*-4-*hydroxydiphenylamine* is prepared from pentachlorohydroxydiphenylamine and forms hemispherical nodules, m. p. 114° (Found: Cl, 53·6. $C_{12}H_5ONCl_6$ requires Cl, 54·3%). Benzoylation in pyridine gives the *benzoyloxy*-derivative, which, crystallised from alcohol and then from petroleum, forms small clusters of hard, glistening, brown prisms, m. p. 125° (Found: Cl, 42·5. $C_{19}H_9O_2NCl_6$ requires Cl, 42·9%). The *toluenesulphonyloxy*-derivative crystallises from glacial acetic acid in white prisms, m. p. 141° (Found: Cl, 39·0. $C_{19}H_{11}O_3NCl_6S$ requires Cl, 39·0%).

2 : 3 : 6 : 2′ : 4′ : 6′-*Hexachlorobenzoquinoneanil** is obtained by the

* The synthesis of this compound establishes the hitherto uncertain constitution of the isomeride yielding the same fission products which was obtained by Orton and Smith (J., 1905, **87**, 389) as a product of the transformation of *s*-trichlorophenylnitroamine, as the 2 : 3 : 5 : 2′ : 4′ : 6′-compound. Similarly, the preparation of 2 : 6 : 2′ : 4′ : 6′-pentabromobenzoquinoneanil (p. 2861) establishes the constitution of the isomeride produced by transformation of *s*-tribromophenylnitroamine (Orton and Smith, J., 1907, **91**, 146) as the 3 : 5 : 2′ : 4′ : 6′-pentabromo-compound. It is regretted that, owing to a clerical error, the melting points of the penta- and hexa-bromobenzoquinoneanils given in that paper have become interchanged. Further examination has shown that the hexabromoquinoneanil then obtained was not completely pure. The following corrected melting points are given to avoid ambiguity:

3 : 5 : 2′ : 4′ : 6′-Pentabromo-4-hydroxydiphenylamine, m. p. 157°.
3 : 5 : 2′ : 4′ : 6′-Pentabromobenzoquinoneanil, m. p. 150·5°.
2 : 3 : 5 : 2′ : 4′ : 6′-Hexabromo-4-hydroxydiphenylamine, m. p. 216°.
2 : 3 : 5 : 2′ : 4′ : 6′-Hexabromobenzoquinoneanil, m. p. 171°.

chromic acid method as a black, crystalline solid, m. p. 114° after recrystallisation from alcohol. It dissolves in ordinary solvents, except alcohol, to give violet solutions (Found: Cl, 54·2. $C_{12}H_3ONCl_6$ requires Cl, 54·65%). On treatment of the red-brown solution in sulphuric acid (1 in 100) with water, the colour changes to light yellow and a mixture of yellow plates and red needles separates. The mixture is collected and digested with a little cold alcohol; the yellow trichlorobenzoquinone remaining undissolved melts, after crystallisation from hot alcohol, at 162—163°. Careful dilution of the alcoholic extract gave *s*-trichloroaniline, m. p. 77·5° (acetyl derivative, m. p. 204°).

Heptachloro-4-hydroxydiphenylamine.—The pentachlorohydroxydiphenylamine (5 g.; 1 mol.) in 15 c.c. of acetic acid is treated with a solution of *N*-chloroacetamide (1·35 g.; 1 mol.) in 5 c.c. of the same solvent, together with two drops of 20% hydrochloric acid, the mixture becoming at once deep violet. After 1 hour, a like amount of chloroamine is added. No chlorine remains after 18 hours. The solution is decolorised by heating with zinc dust and the boiling suspension is filtered at once. White needles (55%) separate on cooling, m. p. 158—159°, unchanged on recrystallisation from petroleum or slightly diluted acetic acid (Found: Cl, 58·05. $C_{12}H_4ONCl_7$ requires Cl, 58·3%).

The *benzoyloxy*-derivative crystallises from glacial acetic acid in massive, white plates, m. p. 164° (Found: Cl, 46·5. $C_{19}H_8O_2NCl_7$ requires Cl, 46·8%). The sulphonylation of the heptachlorohydroxy-derivative is characterised by its slowness, due no doubt to the presence of two ortho-substituents. After 45 minutes' shaking, a violet solid has separated; after being washed with water and with benzene, it crystallises from glacial acetic acid in white needles, m. p. 141·5° (Found: Cl, 42·4. $C_{19}H_{10}O_3NCl_7S$ requires Cl, 42·8%).

Heptachlorobenzoquinoneanil separates from alcohol in small, black crystals, m. p. 114°. Its solutions are violet. Fission by dilute sulphuric acid (1 in 50) and addition of water gives successively tetrachlorobenzoquinone (which sublimes in pale yellow, iridescent plates, not molten at 260°) and *s*-trichloroaniline, m. p. 77·5°.

Action of Hydrochloric Acid on 2 : 6 : 2′ : 4′ : 6′-Pentachlorobenzoquinoneanil.—Concentrated hydrochloric acid (2 c.c.) was added to the quinoneanil (1·5 g.) in glacial acetic acid (100 c.c.). After 18 hours, the bluish-green solution was treated with zinc dust to remove the excess of hydrochloric acid, filtered, and diluted with 300—400 c.c. of water. Hexachlorohydroxydiphenylamine separated as white, crystalline crusts, m. p. 114° after recrystallisation. The action of hydrochloric acid on 2 : 3 : 6 : 2′ : 4′ : 6′-hexachlorobenzo-

quinoneanil in a similar manner yielded heptachlorohydroxydiphenylamine.

Bromo-compounds.

4′-Bromo-4-benzoyloxydiphenylamine. — *p*-Benzoyloxydiphenylamine (5 g.; 1 mol.) and anhydrous sodium acetate (2 mols.), dissolved in 250 c.c. of acetic acid, were treated with a solution of bromine (0·865 c.c.; 1 mol.) in 125 c.c. of acetic acid. After ½ hour, dilution to 75% caused slow separation of white, fibrous needles, which, after crystallisation from alcohol or benzene–ligroin, melted at 150·5°: yield, 33% (Found: Br, 21·2. $C_{19}H_{14}O_2NBr$ requires Br, 21·7%).

By hydrolysis of the above, the *hydroxy*-compound was obtained as thin laminæ, m. p. 108°, in 75% yield (Found: Br, 29·7. $C_{12}H_{10}ONBr$ requires Br, 30·3%).

4′-Bromobenzoquinoneanil was obtained by oxidation of the hydroxy-compound with excess of yellow mercuric oxide. The solution was evaporated to a small volume and the quinoneanil then separated in scarlet crystals, m. p. 100—104°. The melting point of this substance, which appears to be dimorphic, is not sharp and depends on the nature and temperature of the solvent (Found: Br, 29·8. $C_{12}H_8ONBr$ requires Br, 30·5%). Fission gave *p*-bromoaniline, but no trace of *p*-benzoquinone was found.

2 : 2′ : 4′-Tribromo-4-p-toluenesulphonyloxydiphenylamine was prepared, by the method described above, from 4-*p*-toluenesulphonyloxydiphenylamine at 50°, and crystallised from benzene–petroleum, acetone, or glacial acetic acid (Found: Br, 41·7; S, 5·6. $C_{19}H_{14}O_3NBr_3S$ requires Br, 41·7; S, 5·5%). The tribromo-4-benzoyloxy-compound obtained by Smith and Orton (*loc. cit.*) is produced in better yield by the Schotten–Baumann method or by bromination of *p*-benzoyloxydiphenylamine. Both esters are sparingly soluble in common organic media, and give on hydrolysis the tribromohydroxydiphenylamine described by Smith and Orton (*loc. cit.*), this synthesis providing the further evidence required to establish it as *2 : 2′ : 4′-tribromo-4-hydroxydiphenylamine*.

The low solubility of tribromoacyloxydiphenylamines necessitated the following procedure: Finely powdered tribromo-4-*p*-toluenesulphonyloxydiphenylamine was exposed to the vapour of bromine in the presence of anhydrous sodium phosphate or sodium borate, and after 20 hours the absorbed bromine was removed by evacuation. Extraction with boiling benzene gave a quantitative yield of white, prismatic crystals of the sparingly soluble *2 : 6 : 2′ : 4′ : 6′-pentabromo-4-p-toluenesulphonyloxydiphenylamine*, m. p. 210° (Found: Br, 54·1. $C_{19}H_{12}O_3NBr_5S$ requires Br, 54·5%).

The *hydroxy*-compound (yield, 60%) crystallised from ligroin containing 5% of benzene, or from 75% alcohol, in massive, brown prisms, m. p. 206—207° (Found: Br, 68·5. $C_{12}H_6ONBr_5$ requires Br, 69·0%). The *benzoyloxy*-derivative, prepared by benzoylation in pyridine, separated after 24 hours and was precipitated from benzene solution by light petroleum in white needles, m. p. 141—142° (Found: Br, 58·6. $C_{19}H_{10}O_2NBr_5$ requires Br, 58·5%).

2 : 6 : 2′ : 4′ : 6′-*Pentabromobenzoquinoneanil*, prepared by the chromic acid method, has m. p. 184—185° (Found: Br, 68·7. $C_{12}H_4ONBr_5$ requires Br, 69·2%). Fission gave *s*-tribromoaniline and 2 : 6-dibromobenzoquinone.

Pentabromo-4-hydroxydiphenylamine with bromine in acetic acid solution in the absence of an absorbent for hydrogen bromide, yielded heptabromohydroxydiphenylamine (Smith and Orton, *loc. cit.*), but in the presence of sodium acetate oxidation to the violet quinoneanil occurred. An attempt to sulphonylate the heptabromohydroxy-compound by the Schotten–Baumann method gave a *substance*, m. p. 188°, soluble in 5% alcoholic potash, which was neither the initial material nor the desired sulphonyloxy-compound (Found: Br, 70·4%).

All attempts to sulphonylate 2 : 5 : 2′ : 4′-tetrabromo- and 2 : 3 : 5 : 2′ : 4′-pentabromo-4-hydroxydiphenylamine (Smith and Orton, *loc. cit.*) by the Schotten–Baumann procedure and the various modifications of Einhorn's method (compare Fischer and Pfaehler, *Ber.*, 1920, **53**, 1642; Ohle, *Ber.*, 1924, **57**, 409; Ohle and Dickhäuser, *Ber.*, 1925, **58**, 2593) failed.

In general, the sulphonyloxy-compounds are brominated more smoothly than the benzoyloxy-compounds, but the failure to sulphonylate the two hydroxy-compounds above led us to investigate the effect of bromine on the corresponding benzoyloxydiphenylamines. Although two positions ortho to the powerfully directing imino-group are present in 2 : 5 : 2′ : 4′-tetrabromo-4-benzoyloxydiphenylamine, this substance brominates too slowly to permit isolation of higher derivatives. Prolonged refluxing with bromine in carbon tetrachloride solution is followed by recovery of initial material. More drastic conditions such as the gaseous bromine–sodium phosphate method, or in chloroform in the presence of ferric chloride, lead to complete disruption of the molecule. Somewhat similar results followed from the work on 2 : 3 : 5 : 2′ : 4′-pentabromo-4-benzoyloxydiphenylamine, but gaseous bromine converted it into a viscous, dark liquid from which a small amount of heptabromobenzoyloxydiphenylamine was isolated.

Chlorobromo-compounds.

6 : 6′-*Dichloro*-2 : 2′ : 4′-*tribromo*-4-p-*toluenesulphonyloxy-* and -4-*benzoyloxy-diphenylamines.*—Because of low solubility, the tribromo-4-acyloxydiphenylamines were chlorinated in suspension in acetic acid solutions of dichloramine T (100% excess); after 18 hours, 2 equivalents of chlorine had disappeared, a quantitative yield of pentahalogenated derivative having separated.

The *sulphonyloxy*-compound melted, after crystallisation from petroleum, at 185° (Found: * Hals., 131·2; AgCl, 111·6. $C_{19}H_{12}O_3NCl_2Br_3S$ requires Hals., 131·9; AgCl, 111·3). The *benzoyloxy*-compound, after crystallisation from acetic acid, melted at 153° (Found: Hals., 140·9; AgCl, 119. $C_{19}H_{10}O_2NCl_2Br_3$ requires Hals., 143; AgCl, 120·6). Both esters are very sparingly soluble in all solvents. Hydrolysis of these gave the *hydroxy*-compound in small, brown prisms which, after twice crystallising from petroleum, melted at 166° (Found: Hals., 171·6; AgCl, 145·1. $C_{12}H_6ONCl_2Br_3$ requires Hals., 173·1; AgCl, 146·1).

6 : 6′-*Dichloro*-2 : 2′ : 4′-*tribromobenzoquinoneanil*, obtained by the chromic acid method, crystallised from acetic acid in deep purple, irregular prisms, m. p. 150° (Found: Hals., 173·1; AgCl, 147·8. $C_{12}H_4ONCl_2Br_3$ requires Hals., 174·0; AgCl, 146·6). By careful dilution of its solution in concentrated sulphuric acid, 2-chloro-4 : 6-dibromoaniline was obtained.

2 : 2′ : 4′-*Trichloro*-6 : 6′-*dibromo*-4-p-*toluenesulphonyloxydiphenylamine.*—Trichlorosulphonyloxydiphenylamine was brominated by the bromine vapour–sodium borate (phosphate) method. After crystallisation from benzene, chloroform, or petroleum, the product melted at 174°. Yield, quantitative (Found: Hals., 133·5; AgCl, 120·1. $C_{19}H_{12}O_3NCl_3Br_2S$ requires Hals., 134·3; AgCl, 119·5). The *benzoyloxy*-compound, prepared similarly, formed a sticky magma, which was suspended in acetic acid and freed from bromine by passage of sulphur dioxide. On warming, the material dissolved, and then separated in colourless prisms, m. p. 134° (Found: Hals., 149·6; AgCl, 133·8. $C_{19}H_{10}ONCl_3Br_2$ requires Hals., 146·5; AgCl, 130·8). The *hydroxy*-compound, after repeated crystallisation from 75% acetic acid, formed irregular prisms, m. p. 180°, readily soluble in all other organic solvents (Found: Hals., 176·5; AgCl, 157·8. $C_{12}H_6ONCl_3Br_2$ requires Hals., 180·5; AgCl, 160·9).

* For the Carius estimation of some of the substances here described, prolonged heating at 300° was required. In such cases, Robertson's method (J., 1915, **107**, 902) frequently proved of service. For the analysis of the chlorobromo-compounds, the mixture of silver halides (the weight of which, obtained from 100 parts of the substance, is denoted by "Hals.") obtained was usually converted into silver chloride by warming in a current of chlorine.

By the chromic acid method 2 : 2′ : 4′-*trichloro*-6 : 6′-*dibromobenzoquinoneanil* was obtained in massive, black prisms, m. p. 170° after crystallisation from chloroform (Found: Hals., 181·8; AgCl, 162·5. $C_{12}H_4ONCl_3Br_2$ requires Hals., 181·4; AgCl, 161·6). The fission of this quinoneanil requires care: a solution of 0·25 g. in 25 c.c. of concentrated sulphuric acid was slowly diluted with water to 20%. A small quantity of solid (unexamined) separated, and ether extraction then removed 2 : 4-dichloro-6-bromoaniline, m. p. 78° (acetyl derivative, m. p. 217°). Chattaway and Orton (J., 1901, 79, 816) give m. p. 83° and 218°, respectively.

2 : 2′ : 4′-*Trichloro*-5-*bromo*-4-*hydroxydiphenylamine*.—Trichlorohydroxydiphenylamine in acetic acid solution containing sodium acetate was oxidised by bromine, giving quinhydrone-like complexes, but their formation was avoided when 1·85 c.c. of bromine in 25 c.c. of chloroform were added to 10 g. of the amine in 100 c.c. of boiling chloroform during 1 hour; evolution of hydrogen bromide ceased after 2·5 hours. The solution, concentrated to 25—30 c.c., deposited matted needles which, after crystallisation from petroleum, melted at 127—128° (yield, 5·9 g.); a further 2 g. were recovered from the mother-liquor (combined yields, 60%). The compound is easily soluble in aqueous caustic soda (Found: Hals., 165·0; AgCl, 152·8. $C_{12}H_7ONCl_3Br$ requires Hals., 167·4; AgCl, 155·3). The *benzoyloxy*-compound separated from pyridine; m. p. 186° (Found: Hals., 129·4; AgCl, 120·0. $C_{19}H_{11}O_2NCl_3Br$ requires Hals., 131·2; AgCl, 121·7).

When the above hydroxy-compound was sulphonylated in the usual way, and the reaction product kept for 2 hours in a freezing-mixture, a red, crystalline solid separated. Following washing with water and with light petroleum, crystallisation from slightly diluted acetic acid gave colourless prisms of 2 : 2′ : 4′-*trichloro*-5-*bromo*-4-*sulphonyloxydiphenylamine*, m. p. 114° (Found: Hals., 117·9; AgCl, 109·5. $C_{19}H_{13}O_3NCl_3BrS$ requires Hals., 119·0; AgCl, 110·1).

2 : 2′ : 4′-*Trichloro*-5-*bromobenzoquinoneanil* (mercuric oxide method) crystallised from benzene or petroleum, or a mixture of the two, in hemispherical nodules of red, spear-shaped needles, m. p. 115°. Fission by solution in 45 volumes of concentrated sulphuric acid and slow dilution to 25% strength, followed by steam distillation, gave a yellow quinone, m. p. 172°, reduction of which by sulphur dioxide in aqueous-alcoholic solution gave a colourless quinol, m. p. 169° (2-chloro-5-bromobenzoquinone and 2-chloro-5-bromoquinol both melt at 172°). Neutralisation of the acid liquor, followed by distillation in steam, gave 2 : 4-dichloroaniline, m. p. 61° (acetyl derivative, m. p. 145°).

2 : 2′ : 4′-*Trichloro*-5 : 6′-*dibromo*-4-*hydroxydiphenylamine*, prepared

by refluxing trichlorobromohydroxydiphenylamine (10 g.) and bromine (1 mol.) in 80 c.c. of chloroform for 90 minutes, separated, on cooling, in white needles, m. p. 189° after two crystallisations from chloroform (Found: Hals., 176·9; AgCl, 160·5. $C_{12}H_6ONCl_3Br_2$ requires Hals., 180·5; AgCl, 160·9). Fractions obtained from the chloroform mother-liquor appeared to contain isomerides. Attempts to sulphonylate and benzoylate this substance failed.

2 : 2′ : 4′-*Trichloro*-5 : 6′-*dibromobenzoquinoneanil* (chromic acid method) formed small, vermilion, scintillating needles, m. p. 133° (Found: Hals., 177·7; AgCl, 159·1. $C_{12}H_4ONCl_3Br_2$ requires Hals., 181·4; AgCl, 161·4). Fission gave golden-yellow plates, m. p. 165° (2-chloro-5-bromobenzoquinone melts at 172°), and on dilution to 20% strength 2 : 4-dichloro-6-bromoaniline was precipitated.

2 : 2′ : 4′-*Trichloro*-3 : 5 : 6 : 6′-*tetrabromo*-4-*hydroxydiphenylamine*.—To a solution of 4 g. of trichlorohydroxydiphenylamine in 40 c.c. of chloroform boiling under reflux, 2·8 c.c. (4 mols.) of bromine in the same solvent were slowly added; hydrogen bromide was at first rapidly evolved. The mixture was then transferred to a silica flask, with excess of bromine, and exposed to sunlight for 3½ days, the solid that had separated after 12 hours being redissolved by gentle warming. The large, thin laminæ (3·9 g.) which separated were broken up, and freed from bromine and chloroform over charcoal and potash in a vacuum; m. p. 160°. Evaporation of the mother-liquor yielded a further 3·5 g. (combined yield, 89%) (Found: Hals., 194·5; AgCl, 165·1. $C_{12}H_4ONCl_3Br_4$ requires Hals., 195·7; AgCl, 166·2). The *benzoyloxy*-compound crystallised from chloroform–acetic acid in small, elongated prisms, m. p. 163° (Found: Hals., 169·8. $C_{19}H_8O_2NCl_3Br_4$ requires Hals., 169·7). Attempts to sulphonylate the hydroxy-compound failed.

2 : 2′ : 4′-*Trichloro*-3 : 5 : 6 : 6′-*tetrabromobenzoquinoneanil* (chromic acid method) crystallised from acetic acid in slender, indigo needles, m. p. 136°. Fission and dilution gave a very sparingly soluble substance, m. p. 294°, and 2 : 4-dichloro-6-bromoaniline. The literature notes the insolubility of chlorotribromoquinone and records two values for its m. p., *viz.*, 292° and 303°.

We are indebted to the Royal Society, the Chemical Society, and the British Association for grants which have partly defrayed the cost of this research.

CCCLXXXIII.—*Substitution Products of 4-Hydroxybenzophenone and of its Methyl Ether.*

By WILLIAM BLAKEY, WALTER IDRIS JONES, and HAROLD ARCHIBALD SCARBOROUGH.

THE orientation of substituents in the benzophenone series has been investigated in but few cases, *e.g.*, the introduction of bromine (Kottenhahn, *Annalen*, 1891, **264**, 170; Kunkel, *Ber.*, 1904, **37**, 3485), the direct nitration of benzophenone and of the isomeric mononitrobenzophenones (Staedel, *Annalen*, 1878, **194**, 347; 1883, **218**, 344; 1895, **283**, 164), and the introduction of a nitro-group into certain 4-halogenobenzophenones (Montagne, *Ber.*, 1916, **49**, 2262), and it was found that the first substituent entered the unsubstituted nucleus, usually with the production of the three possible isomerides.

The nitration of 4-methylbenzophenone gave derivatives the structure of which seems to be uncertain (Zincke, *Ber.*, 1872, **5**, 685; 1874, **7**, 983; Limpricht, *Annalen*, 1895, **286**, 324).

These results and those observed in the diphenyl series show marked similarities, and it therefore seemed of interest to consider the substitution products of 4-hydroxybenzophenone and of its methyl ether.

The direct chlorination of 4-hydroxybenzophenone in acetic acid solution gave 3 : 5-*dichloro*-4-*hydroxybenzophenone*; under all the conditions tried, the same product was obtained.

The reaction of 4-hydroxybenzophenone with bromine could be regulated, and 3-bromo- and 3 : 5-dibromo-4-hydroxybenzophenone were obtained when the ketone, dissolved in acetic acid, was treated with the appropriate quantity of bromine. The same dibromo-derivative was obtained when the ketone was shaken with an aqueous bromine solution or treated in alkaline solution with bromine.

The iodination of 4-hydroxybenzophenone in alkaline solution yielded the 3-*iodo*-derivative; treatment with iodine monochloride in acetic acid solution gave 3 : 5-*di-iodo*-4-*hydroxybenzophenone*.

A single nitro-group was introduced into 4-hydroxybenzophenone by treating the ketone with nitric acid in glacial acetic acid solution at 50° or by merely dissolving it in cold nitric acid. Solution in nitric acid at 40° gave 3 : 5-dinitro-4-hydroxybenzophenone. Attempts to obtain higher substitution products seemed to result in partial oxidation.

The direct chlorination of the methyl ether could be controlled and 3-*chloro*- and 3 : 5-*dichloro*-4-*methoxybenzophenone* were isolated.

On bromination of the methyl ether, 3-*bromo*-4-*methoxybenzo-*

phenone was obtained under all conditions which did not involve a demethylation. In contrast to this, the chlorination of the monobromo-derivative proceeded smoothly and 3-*chloro*-5-*bromo*-4-*methoxybenzophenone* was obtained.

The introduction of one atom of iodine was effected with iodine monochloride, and higher iodination products than 3-iodo-4-methoxybenzophenone could not be obtained.

The formation of 3-*nitro*-4-*methoxybenzophenone* took place when the methoxybenzophenone was dissolved in fuming nitric acid. Nitration in a mixture of sulphuric and acetic acids yielded a mixture of dinitro-compounds; the formation of 3 : 3′-*dinitro*-4-*methoxybenzophenone* has been definitely established. A second isomeride is most probably 2′ : 3-dinitro-4-methoxybenzophenone, but this structure is based on a process of elimination of probable products. In addition to these isomerides there was a residue which after repeated crystallisations still seemed to be a mixture.

Trinitration products were obtained when nitration was effected in concentrated sulphuric acid solution. The formation of 3 : 3′ : 5 *trinitro*-4-*methoxybenzophenone* has been definitely established; an isomeride is shown to have two nitro-groups in the 3 : 5-positions and it is suggested that the third nitro-group is in the 2′-position. After the separation of the two pure products, a residue was obtained which could not be further purified.

The most suitable methods for the determination of the structure of the substitution products were : (*a*) oximation and conversion of the oximes into anilides. This procedure was found satisfactory provided not more than one nitro-group was present in the molecule; considerable difficulty was experienced in effecting the oximation of dinitro-derivatives, and the product could not be purified easily. (*b*) Synthesis of the substituted ketone by the Friedel–Crafts reaction was effective in the case of certain of the nitro-derivatives.

Oxidation to a substituted benzoic acid was not very satisfactory, as it was difficult to avoid complete oxidation of the molecule.

A survey of the results obtained shows that in 4-hydroxybenzophenone each ortho-position with respect to the hydroxyl group may be substituted with ease, irrespective of the nature of the substituting groups. Substitution in the opposite nucleus could not be effected before the 3 : 5-positions were filled.

The methyl ether behaves somewhat differently, in that one position only in the ortho-relationship to the methoxyl group is usually substituted. Chlorine behaves abnormally, in that both positions may be substituted by this reagent. On nitration, a second substituent enters the unsubstituted nucleus.

A comparison of these results with those obtained in the diphenyl

series shows that in each case the presence of a hydroxyl group promotes substitution in all vacant positions in the ortho-para relationship to this group; the presence of such groups as the halogens or the nitro-group inhibits substitution in the same nucleus.

The conversion of the hydroxyl group into the methoxyl group reduces the directive power, and although the first substituent enters in an ortho-position to this group, the second entering group usually goes into the opposite nucleus.

EXPERIMENTAL.

4-Methoxybenzophenone was prepared from anisole and benzoyl chloride by Gattermann's method (*Ber.*, 1890, **23**, 1204).

4-*Hydroxybenzophenone.*—The hydrolysis of all the methyl ethers was effected as follows: 5 G. of the ether and 20 c.c. of 48% hydrobromic acid were dissolved in acetic acid and refluxed for about 12 hours. Part of the acetic acid was then removed, and the residue poured into water. The acid was neutralised with ammonia, the product taken up in ether, and the hydroxy-ketone shaken out with a 10% solution of sodium hydroxide and reprecipitated with sulphuric acid. 4-Hydroxybenzophenone separated from dilute methyl alcohol in prisms, m. p. 135°.

4-Acetoxybenzophenone was prepared by acetylation in pyridine solution. It crystallised from dilute methyl alcohol in needles, m. p. 81° (Found: C, 74·8; H, 5·1. Calc. for $C_{15}H_{12}O_3$: C, 75·0; H, 5·0%).

3-*Chloro*-4-*methoxybenzophenone* was obtained when 4-methoxybenzophenone was treated with chlorine (slightly less than 1 mol.) in a cold solution of acetic acid. It separated from methyl alcohol in prisms, m. p. 98° (Found: Cl, 14·5. $C_{14}H_{11}O_2Cl$ requires Cl, 14·4%). On further chlorination in acetic acid solution, 3 : 5-dichloro-4-methoxybenzophenone (m. p. 74°) was obtained. The mono-derivative must therefore have been substituted in the 3-position.

3 : 5-*Dichloro*-4-*methoxybenzophenone.*—Into a solution of 10 g. of 4-methoxybenzophenone and 10 g. of fused sodium acetate in glacial acetic acid chlorine was passed until the gain in weight was 7 g. After some hours, the solution was poured into water. The product crystallised from alcohol in colourless needles, m. p. 74°. The same product was obtained by chlorination of the molten ketone in the presence of iodine or by chlorination in boiling carbon tetrachloride solution (Found: Cl, 25·2. $C_{14}H_{10}O_2Cl_2$ requires Cl, 25·3%).

The α-*oxime* was prepared by adding 10 g. of potassium hydroxide and 4·5 g. of hydroxylamine hydrochloride, each dissolved in the minimum quantity of water, to 6 g. of the dichloro-ketone dissolved in 100 c.c. of alcohol. The mixture was refluxed for 6 hours, the

alcohol in part removed, and the residue poured into water and neutralised with dilute hydrochloric acid. The oxime separated from alcohol in needles, m. p. 146° (Found: Cl, 23·9. $C_{14}H_{11}O_2NCl_2$ requires Cl, 24·0%).

3 : 5-*Dichloro*-4-*methoxybenzanilide*.—4 G. of the oxime, in dry ethereal solution, were treated with 7·5 g. of phosphorus pentachloride. After 12 hours, water was cautiously added and the ethereal layer was separated, washed, and dried. The *anilide*, after removal of the ether, crystallised from alcohol in pale yellow needles, m. p. 154° (Found: Cl, 23·95. $C_{14}H_{11}O_2NCl_2$ requires Cl, 24·0%).

On hydrolysis of the anilide (5 g.) with 20 c.c. of 10% hydrochloric acid for 6 hours at 140°, aniline and 3 : 5-*dichloroanisic acid* were obtained. 3 : 5-Dichloroanisic acid, prepared by the direct chlorination of anisic acid, crystallised from alcohol; m. p. 202° (Found: Cl, 32·05. $C_8H_6O_3Cl_2$ requires Cl, 32·1%). The acid was converted into the acid chloride, and the crude product added to a pyridine solution of aniline. The anilide thus obtained had m. p. 154°, alone or mixed with that prepared from the oxime.

3 : 5-*Dichloro*-4-*hydroxybenzophenone* was obtained from the methyl ether or by passing 5 g. of chlorine into a solution of 5 g. of 4-hydroxybenzophenone and 10 g. of sodium acetate in 100 c.c. of acetic acid and keeping the mixture for some hours. The product crystallised from methyl alcohol in needles, m. p. 148° (Found: Cl, 26·6. $C_{13}H_8O_2Cl_2$ requires Cl, 26·6%).

3-*Bromo*-4-*methoxybenzophenone*.—A solution of 5 g. of 4-methoxybenzophenone and 5 g. of sodium acetate in acetic acid was heated with 4·5 g. of bromine at 100° for 6 hours. The product separated from alcohol in needles, m. p. 94°. The same product was formed by bromination in the cold, in bright sunlight, or by heating together an intimate mixture of 5 g. of the ketone, 5 g. of sodium acetate, 4 g. of bromine, and 0·5 g. of pyridine (Found: Br, 27·5. $C_{14}H_{11}O_2Br$ requires Br, 27·5%).

Oximation of the ketone was carried out in the manner previously described. The α-*oxime* crystallised from alcohol in plates, m. p. 164° (Found: Br, 26·0. $C_{14}H_{12}O_2NBr$ requires Br, 26·15%). It was transformed into 3-*bromo*-4-*methoxybenzanilide*, which separated from alcohol in needles, m. p. 170° (Found: Br, 26·15. $C_{14}H_{12}O_2NBr$ requires Br, 26·15%). This anilide on hydrolysis yielded aniline and 3-bromoanisic acid and was prepared from the amine and the acid chloride.

The β-*oxime*, which remained in the mother-liquor, was precipitated with water. It separated from 30% aqueous alcohol in needles, m. p. 111·5° (Found: Br, 26·1. $C_{14}H_{12}O_2NBr$ requires Br, 26·15%). This oxime formed about 60% of the mixed oximes. On

transformation, *benzo-3-bromo-4-methoxyanilide* was obtained, which crystallised from alcohol in needles, m. p. 156° (Found : Br, 26·25. $C_{14}H_{12}O_2NBr$ requires Br, 26·15%). The anilide on hydrolysis gave 3-bromoanisidine (m. p. 56°) and was prepared from the amine and benzoyl chloride.

3-Bromo-4-hydroxybenzophenone was obtained by the hydrolysis of the methyl ether or by direct bromination of the ketone in acetic acid solution. It crystallised from alcohol in glistening needles, m. p. 183° (Found : Br, 28·75. Calc. for $C_{13}H_9O_2Br$: Br, 28·9%).

3-Chloro-5-bromo-4-methoxybenzophenone was obtained by leading chlorine into a glacial acetic acid solution of 5-bromo-4-methoxybenzophenone and fused sodium acetate, and precipitated after some hours by pouring the product into water. It separated from methyl alcohol in needles, m. p. 92° (Found : 0·1496 g. gave 0·1520 g. of silver halides. Calc. weight, 0·1523 g.). The structure assigned depends upon the fact that in no case has chlorine been introduced into the unsubstituted ring.

3 : 5-Dibromo-4-hydroxybenzophenone resulted from (*a*) direct bromination of the ketone in acetic acid solution (compare Hantzsch, *Ber.*, 1906, **39**, 3094; Kostanecki, *Ber.*, 1907, **40**, 3662); (*b*) the addition of a 5% solution of bromine in potassium bromide to the ketone dissolved in an excess of dilute potassium hydroxide, the temperature being kept below 5°; and (*c*) by shaking the ketone with bromine water. The product separated from alcohol in needles, m. p. 155°.

The same product was obtained when an intimate mixture of fused sodium acetate and 4-methoxybenzophenone was treated with bromine in a sealed tube at 140°.

3-Iodo-4-methoxybenzophenone.—10 G. of 4-methoxybenzophenone, dissolved in 100 c.c. of acetic acid, were treated with 12 g. of iodine monochloride. After 2 days, the mixture was poured into water, and the colour discharged with sulphur dioxide. The semi-solid mass crystallised from alcohol in needles, m. p. 81° (Found : I, 37·3. $C_{14}H_{11}O_2I$ requires I, 37·6%).

The *α-oxime* crystallised from alcohol in needles, m. p. 182° (Found : I, 35·9. $C_{14}H_{12}O_2NI$ requires I, 36·0%). On conversion of this oxime, *3-iodo-4-methoxybenzanilide* was obtained, which separated from alcohol in faintly yellow needles, m. p. 206° (Found : I, 35·9. $C_{14}H_{12}O_2NI$ requires I, 36·0%). The anilide on hydrolysis yielded aniline and 3-iodoanisic acid. The acid separated from alcohol in needles, m. p. 240° (Found : I, 45·55. Calc. for $C_8H_7O_3I$: I, 45·65%). A specimen of the acid was prepared from *p*-cresol for comparison.

The β-*oxime*, precipitated from the mother-liquor on addition of water, crystallised from 30% alcohol in needles, m. p. 135° (Found: I, 35·8%). This oxime, on conversion, yielded *benz*-3-*iodo*-4-*methoxyanilide*, which crystallised from alcohol in needles, m. p. 164° (Found: I, 35·9. $C_{14}H_{12}O_2NI$ requires I, 36·0%). On hydrolysis, the anilide yielded 3-iodoanisidine, which separated from alcohol–light petroleum in needles, m. p. 75° (Found: I, 51·1. Calc. for C_7H_8ONI: I, 51·0%).

The anilide was prepared from *o*-anisidine by the following stages: *o*-anisidine was converted into *o*-iodoanisole and nitrated in glacial acetic acid solution. The 2-iodo-4-nitroanisole thus obtained was reduced to the amine, which was treated with benzoyl chloride in pyridine.

3-*Iodo*-4-*hydroxybenzophenone* was obtained on the hydrolysis of the methyl ether or by treating an alkaline solution of 4-hydroxybenzophenone with a 5% solution of iodine in potassium iodide. The product separated from methyl alcohol in plates, m. p. 184° (Found: I, 39·05. $C_{13}H_9O_2I$ requires I, 39·2%).

3 : 5-*Di-iodo*-4-*hydroxybenzophenone*.—5 G. of the hydroxyketone together with 10 g. of sodium acetate were dissolved in 100 c.c. of acetic acid and treated with 9 g. of iodine monochloride. After 12 hours, the mixture was poured into water; the precipitate obtained crystallised from alcohol in feathery needles, m. p. 145° (Found: I, 57·6. $C_{13}H_8O_2I_2$ requires I, 57·7%).

3-*Nitro*-4-*methoxybenzophenone*.—A solution of 5 g. of 4-methoxybenzophenone in 50 c.c. of nitric acid (*d* 1·5) was kept for 12 hours, and then poured on ice; the semi-solid product crystallised from alcohol in yellow needles, m. p. 105° (Found: N, 5·5. $C_{14}H_{11}O_4N$ requires N, 5·45%).

An oxime was obtained when 17 g. of the nitro-compound dissolved in alcohol were treated with 14 g. of hydroxylamine hydrochloride and 11·5 g. of potassium hydroxide, each dissolved in the minimum quantity of water. A red coloration appeared in the solution and acetic acid was added until the colour became yellowish-green. After refluxing for 3 hours, the oxime was extracted in the usual way. The α-*oxime*, after repeated crystallisations from alcohol, separated in yellow plates, m. p. 179° (Found: N, 10·3. $C_{14}H_{12}O_4N_2$ requires N, 10·3%). On conversion the oxime yielded 3-*nitro*-4-*methoxybenzanilide*, which separated from alcohol in needles, m. p. 163° (Found: N, 10·3. $C_{14}H_{12}O_4N_2$ requires N, 10·3%). This anilide on hydrolysis gave 3-nitroanisic acid and aniline, and was prepared from the amine and the acid chloride.

3-Nitro-4-hydroxybenzophenone was obtained when (*a*) the methyl ether was hydrolysed, (*b*) 5 g. of 4-hydroxybenzophenone,

dissolved in a mixture of 100 c.c. of acetic acid and 20 c.c. of acetic anhydride, were treated with 1·5 c.c. of nitric acid (*d* 1·5), dissolved in 10 c.c. of acetic acid at 50—60°, and (*c*) a solution of 5 g. of the hydroxy-ketone in 100 c.c. of nitric acid (*d* 1·4) was kept at 0° for 2 hours. The product crystallised from methyl alcohol in plates, m. p. 94° (Borsche, *Ber.*, 1917, **50**, 1339, gives m. p. 120—121°) (Found: N, 5·7. Calc. for $C_{13}H_9O_4N$: N, 5·75%).

3 : 5-*Dinitro*-4-*methoxybenzophenone*.—5 G. of 4-chloro-3 : 5-dinitrobenzophenone (Ullmann, *Annalen*, 1909, **366**, 92), dissolved in dry methyl alcohol, were treated with a solution of 1 g. of sodium in methyl alcohol. After 12 hours, the product was precipitated by pouring the mixture into dilute hydrochloric acid. It separated from methyl alcohol in yellow needles, m. p. 105° (Found: C, 55·5; H, 3·4. $C_{14}H_{10}O_6N_2$ requires C, 55·6; H, 3·3%).

3 : 5-Dinitro-4-hydroxybenzophenone was prepared by Ullmann's method (*loc. cit.*) or by heating a solution of 5 g. of 4-hydroxybenzophenone in 100 c.c. of nitric acid (*d* 1·4) at 40° for 30 minutes. It crystallised from alcohol in yellow needles, m. p. 138° (Found: N, 9·85. Calc. for $C_{13}H_8O_6N_2$: N, 9·75%). The product of direct nitration did not appear to be a single substance, but no other pure compound was isolated.

3′-*Nitro*-4-*methoxybenzophenone*.—18 G. of *m*-nitrobenzoyl chloride and 10·5 g. of anisole, dissolved in 100 c.c. of carbon disulphide, were treated with 25 g. of aluminium chloride at room temperature, and the reaction completed on the water-bath. The product crystallised from alcohol in faintly yellow needles, m. p. 95° (Found: N, 5·5. $C_{14}H_{11}O_4N$ requires N, 5·45%). On hydrolysis, 3′-nitro-4-hydroxybenzophenone was obtained.

3 : 3′-*Dinitro*-4-*methoxybenzophenone*.—(*a*) A solution of 5 g. of 3′-nitro-4-methoxybenzophenone in 50 c.c. of nitric acid (*d* 1·5) was kept over-night. (*b*) 15 G. of 4-methoxybenzophenone, dissolved in a mixture of 60 c.c. each of acetic and sulphuric acids, were treated with 10 c.c. of nitric acid (*d* 1·5) below 10°; the product, which was a mixture of isomerides, was crystallised from acetic acid and then repeatedly from alcohol until a pure substance was obtained. (*c*) 5 G. of 3-nitro-4-methoxybenzophenone were nitrated, in solution in a mixture of sulphuric and acetic acids, with 2 c.c. of nitric acid (*d* 1·5). The yield was about 70% of the mixed nitration product.

It separated from alcohol in faintly yellow needles, m. p. 143° (Found: N, 9·3. $C_{14}H_{10}O_6N_2$ requires N, 9·2%).

3 : 3′-*Dinitro*-4-*hydroxybenzophenone* was obtained on demethylation. It separated from alcohol in faintly green prisms, m. p. 165° (Found: N, 9·8. $C_{13}H_8O_6N_2$ requires N, 9·75%).

The structure of these compounds follows from their method of preparation.

3 : 4′-*Dinitro*-4-*methoxybenzophenone*. — 4′-Nitro-4-methoxybenzophenone (Auwers, *Ber.*, 1903, **36**, 3891) was nitrated by dissolving it in nitric acid (*d* 1·5) and keeping the solution for 12 hours. The product separated from alcohol in small prisms, m. p. 174° (Found : N, 9·3. $C_{14}H_{10}O_6N_2$ requires N, 9·3%).

3 : 3′ : 5-*Trinitro*-4-*methoxybenzophenone*.—(*a*) A solution of 10 g. of 4-methoxybenzophenone in a mixture of equal volumes of sulphuric acid and nitric acid (*d* 1·5) was kept for 2 days. The product was a mixture of isomerides, which were separated by successive crystallisations from acetic acid, toluene, and acetic acid. (*b*) 3 : 5-Dinitro-4-methoxybenzophenone was nitrated under the same conditions and the isomerides were separated. (*c*) 3 : 3′-Dinitro-4-methoxybenzophenone on nitration gave an almost quantitative yield of the trinitro-compound. This isomeride formed about 65% of the crude nitration product and was sparingly soluble in toluene; it separated from acetic acid in prisms, m. p. 184° (Found : N, 12·05. $C_{14}H_9O_8N_3$ requires N, 12·1%). The structure assigned is based on three observations : (1) on prolonged oxidation with chromic anhydride in acetic acid solution, a small quantity of *m*-nitrobenzoic acid (m. p. 140°) was isolated, (2) on further nitration the two dinitro-4-methoxybenzophenones both yielded the same product, and (3) 3 : 3′-dinitro-4-methoxybenzophenone yielded one trinitro-compound only.

2′(?) : 3-*Dinitro*-4-*methoxybenzophenone* was obtained when the 3 : 3′-dinitro-compound had all been removed from the crude nitration product. It was crystallised from toluene and then from acetic acid, separating in needles, m. p. 125° (Found : N, 9·35. $C_{14}H_{10}O_6N_2$ requires N, 9·3%).

2′(?) : 3 : 5-*Trinitro*-4-*methoxybenzophenone* was obtained from the crude nitration products of 4-methoxybenzophenone and of 3 : 5-dinitro-4-methoxybenzophenone. It crystallised from toluene in glistening, light yellow plates, m. p. 142° (Found : N, 12·1. $C_{14}H_9O_8N_3$ requires N, 12·1%).

A definite structure cannot be assigned to these compounds, as all attempts to prepare a pure specimen of 2′-nitro-4-methoxybenzophenone failed. Three out of the four most probable dinitro-4-methoxybenzophenones, however, have been obtained in a state of purity and the dinitro-4-methoxybenzophenone, m. p. 125°, was not identical with any of these compounds.

THE UNIVERSITY CHEMICAL LABORATORIES,
CAMBRIDGE.

[*Received, August 31st*, 1927.]

CCCLXXXIV.—*The Temperature Effects of Mixing Non-aqueous Liquids.*

By WALTER MATTHEW MADGIN, JOHN BUTTERY PEEL, and HENRY VINCENT AIRD BRISCOE.

A GENERAL survey of the temperature changes occurring on mixing 628 pairs chosen from 37 non-aqueous liquids has shown that these changes are frequently of considerable magnitude (Madgin and Briscoe, *J. Soc. Chem. Ind.*, 1927, **46**, 107T). The present paper describes the further investigation of these changes in selected cases, undertaken in the expectation that some light might thereby be thrown upon the nature of liquids and liquid mixtures.

Relationship of Thermal Changes to the Polarity of the Constituent Liquids.—It has frequently been assumed (*e.g.*, Hildebrand, "Solubility," p. 85) that solubility is largely influenced by the relative polarity of the molecules concerned. The idea seems to be that a liquid composed of strongly polar molecules may easily dissolve another very polar liquid, but that the strong attraction between such polar molecules may hinder the interposition of non-polar molecules, and thus may even cause immiscibility with a non-polar liquid.

Detailed examination of the cases included in our original survey leads to the conclusion that there are many groups of liquids for which the relative values of the thermal effect of mixing differ widely from those to be expected from considerations of relative polarity. For example, hexane, benzene, and toluene are all very slightly polar by ordinary standards, and their polarities, as measured by the dielectric constant (*D.C.* = 1·85, 2·27, 2·34, respectively), increase slightly in the order named. In most cases the thermal effect of hexane with other liquids is more negative than that of benzene, which is again more negative than that of toluene. This is illustrated by the fact (Madgin and Briscoe, *loc. cit.*) that the number of positive heats of mixing given by hexane, benzene, and toluene, respectively, with the same set of other liquids is 0, 7, and 12. But in the case of the alcohols and carbon disulphide, benzene gives a greater decrease of temperature than either hexane or toluene; with alcohols, except methyl alcohol, toluene gives a greater negative effect than hexane; with methyl alcohol and carbon disulphide, hexane gives the greatest negative effect. These effects are not then in accordance with the order of dielectric constant.

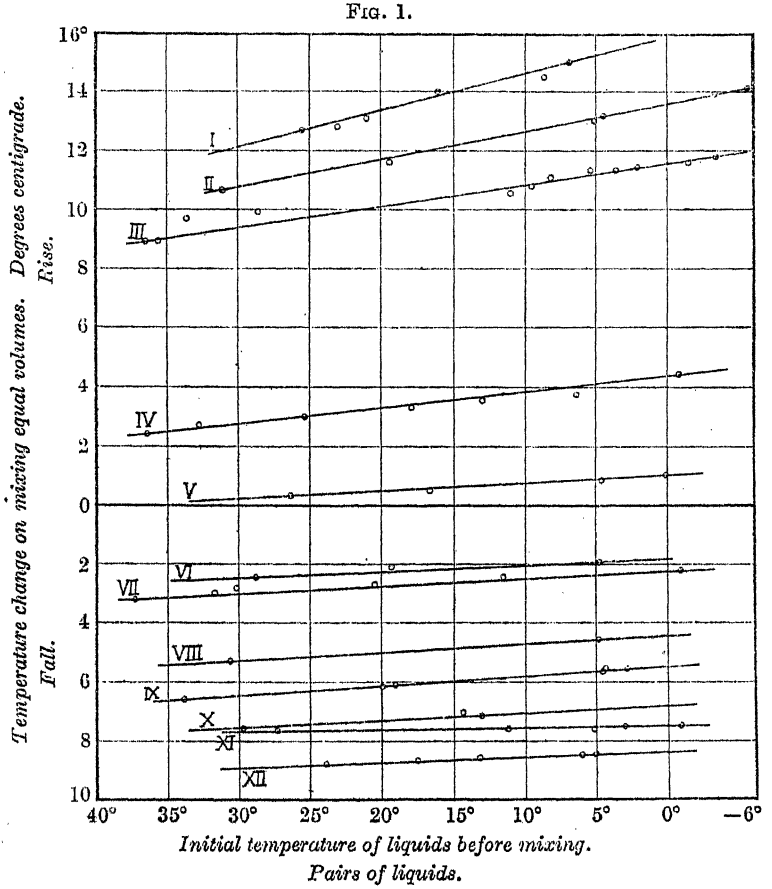
Again, ethyl iodide generally gives a greater negative effect than ethyl bromide, which accords with the greater polarity of the former corresponding with the *D.C.* values: 9·4, 7·4; but exceptions

to this order occur in the heat effects with certain alcohols and carbon disulphide. Comparing the results of mixing ethylene dibromide, ethylene dichloride, chloroform, and bromoform with other liquids, it is noticeable that the chloro-compound generally gives the more positive heat of mixing, but exceptions occur in admixtures with ethyl and methyl iodides, with tetrachloroethane, and with aniline and carbon disulphide.

The doubt whether polarity can be assigned as a major cause of the temperature effects is intensified when we consider the cases in Table I and also that of water and ethyl alcohol (both having a

TABLE I.

	Dielectric constant.	Temperature change on mixing equal volumes.
Methyl acetate	7·1	
Ethyl iodide	7·4	− 5·1°
Ether	4·3	
Chloroform	5·1	+ 14·2
Acetone	21	
Chloroform	5·1	+ 12·65
Acetone	21	
Carbon disulphide	2·6	− 9·75
Acetone	21	
Ethyl alcohol	25	− 6·95



high *D.C.* and giving a rise of temperature on mixing), for it is apparent that either positive or negative heats of mixing may occur (*a*) with two liquids of small and similar *D.C.*, (*b*) with two liquids having respectively large and small *D.C.*'s, and (*c*) with two liquids both having large *D.C.*'s. Hence there seems to be no simple relationship between the heat of mixing and the polarity of the constituent molecules.

Effect of Variations of Initial Temperature on the Temperature Change on Mixing.—The literature contains very few references to investigations on the manner in which the temperature change on mixing varies with the initial temperature of the liquids mixed. Three isolated cases, two including water as one liquid, were investigated by Bussy and Buignet (*Ann. Chim. Phys.*, 1865, **4**, 5), and five cases, of which three included aniline as one liquid, have been investigated by Kremann and others (Kremann, *Monatsh.*, 1906, **27**, 91; Kremann and Pilch, *ibid.*, 1910, **31**, 203; Kremann, Meingast, and Guge, *ibid.*, 1914, **35**, 1235).

Therefore, as our general survey provided the necessary material for selection, it seemed well worth while to examine more widely the general trend of the thermal change with temperature for a series of mixtures ranging from those with large positive to those with large negative temperature changes on mixing. For this purpose, the apparatus used was a silvered Dewar tube (1″ diam. × 7″ deep

nternally) with narrow observation windows of the full height on opposite sides, provided near the mouth with three internal projections, on which rested the flange of a test-tube of such length that its thinly-blown closed end was about $\frac{1}{2}''$ from the bottom of the

FIG. 1.

Pairs of liquids.

I *o-Chlorophenol : aniline.* II *Chloroform : ether.* III *Chloroform : acetone.* IV *Chloroform : toluene.* V *Ether : toluene.* VI *Acetone : ether.* VII *Chloroform : hexane.* VIII *Ethyl alcohol : methyl acetate.* IX *Acetone : hexane.* X *Carbon disulphide : aniline.* XI *Carbon disulphide : ethyl oxalate.* XII *Carbon disulphide : acetone.*

Dewar tube. One liquid (10 c.c.) was placed in the Dewar tube, the other (10 c.c.) was within the test-tube : both were previously brought approximately to the desired temperature. In the test-tube were also a thermometer (− 20° to + 50° by 0·1°) and a pointed glass rod; when the tubes and liquids had attained the same constant temperature, the end of the test-tube was pierced by the

glass rod, the liquids were well mixed, and the temperature change was noted. To facilitate mixing, the denser of the two liquids was always put inside the test-tube. Twelve pairs of liquids were thus examined over a range of temperature; in most cases 6—8 observations were made, in some as many as 12. The whole of the observations are plotted in Fig. 1, and Table II gives for each pair of liquids (1) the temperature change from an initial temperature of 5°, (2) that from an initial temperature of 30°, and (3) the difference due to this change of 25° in the initial temperature.

TABLE II.

Pair of liquids.	1.	2.	3.	Pair of liquids.	1.	2.	3.
I	15·2	12·1	3·1	VII	−2·35	−3·0	0·65
II	13·1	10·8	2·3	VIII	−4·6	−5·3	0·7
III	11·15	9·4	1·75	IX	−5·65	−6·5	0·85
IV	4·1	2·8	1·3	X	−6·9	−7·6	0·7
V	0·9	0·2	0·7	XI	−7·6	−7·7	0·1
VI	−1·9	−2·4	0·5	XII	−8·5	−8·9	0·4

Inspection of the table shows at once that, whether the temperature change is positive or negative, its variation with initial temperature is always in the same direction; the temperature change is more positive (or less negative) the lower the initial temperature. On the other hand, the *magnitude* of the variation in temperature change obviously varies considerably throughout the series of mixtures, being generally greater the more positive (or less negative) the temperature change for a given initial temperature.

These observations receive a simple interpretation if, supposing each of the two liquids A and B to contain complex (A_x and B_y) and simple molecules, we assume that the latter, on admixture, may associate to form compound molecules, according to the scheme

$$\left.\begin{matrix} A_x \rightleftharpoons xA \\ B_y \rightleftharpoons yB \end{matrix}\right\} \rightleftharpoons zA_nB_m$$

and that the dissociations to the simple molecules are endothermic. The data here recorded are consistent with the view that alteration of the initial temperature changes the thermal effect in the A_nB_m equilibrium more than that in the A_x and B_y equilibria. This may occur through a change in the heat of reaction or through a shift of equilibrium, or for both of these reasons.

On entirely different grounds, Bramley (J., 1916, **109**, 43) reached a similar conclusion, which, therefore, whilst clearly needing further investigation, has a certain measure of probability.

Acknowledgment is made of a grant from the Department of Scientific and Industrial Research enabling the participation in

this work of one of us (J. B. P.), who has made a large number of the determinations of temperature change on which the present paper is based.

ARMSTRONG COLLEGE, UNIVERSITY OF DURHAM,

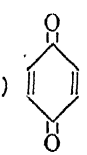
CCCLXXXV.—*The Parachor and Chemical Constitution. Part VI. Some Cases of Supposed Ring-chain Tautomerism.*



By FREDERICK BASIL GARNER and SAMUEL SUGDEN.

THE strictly additive character of the parachor sets obvious limits to its application to problems of chemical constitution, for a change in position of a radical or of a linkage in the molecule has no effect upon the value of this constant. If, however, two isomeric substances differ in structure by the replacement of a double bond by a ring, they should exhibit differences in parachor which will be greater the greater the number of atoms in the ring. The conversion of a double bond into a four-membered ring should give a decrease in the parachor of 11·6 units, whilst the corresponding figures for five- and six-membered rings are 14·7 and 17·1, respectively (see values for ring constants, Sugden and Wilkins, this vol., p. 142).

In this paper, the evidence of the parachor as to the structure of quinones, acid chlorides, and benzils is presented. Other substances in which similar structural changes have been postulated will be considered in later papers.

(1) *Quinones.*

Most of the reactions of *p*-quinones are represented by the formula (I), but the peroxide formula (II) has been suggested on chemical grounds by Graebe (*Annalen*, 1868, **146**, 1), whilst Hartley and Leonard (J., 1909, **95**, 34) and Haakh (*J. pr. Chem.*, 1910, **82**, 546), from a study of absorption spectra, and Binder (*Chem.-Ztg.*, 1921, **45**, 1114), from heats of combustion, also prefer formula (II).

(I.)  (II.) 

$>C(-COCl)-C(-COCl)<$ (III.)

$>C(-CCl_2-)C(=O)-CO-<$ (IV.)

We have measured the parachors of *p*-benzoquinone and tolu-

quinone with the following results, from which it is evident that the liquid substances contain little or none of the peroxide form.

TABLE I.

	[P], obs.	[P], calc. (diketone).	[P], calc. (peroxide).
p-Benzoquinone.....	236·8	236·1	219·0
Toluquinone	272·0	275·1	258·0

(2) *Acid Chlorides.*

The chlorides of dibasic acids would normally be assigned formula (III); in some reactions, however, these substances behave as if they possessed the structure (IV).

Auger (*Ann. Chim.*, 1891, **22**, 36), on chemical evidence, considered that succinyl chloride was a mixture of the two forms, the unsymmetrical chloride being in large excess. This view was criticised by Morrell (J., 1914, **105**, 1733), who maintained that this substance should be represented by the symmetrical formula. Ott (*Annalen*, 1912, **392**, 245) agreed with this, although his determinations of molecular volume seemed to indicate the existence of an equilibrium mixture of the two forms.

Phthalyl chloride offers a still more interesting example, for it has been obtained in two isomeric modifications melting at 15° and 88·5° (Ott, *loc. cit.*; Scheiber, *Ber.*, 1913, **46**, 2368; Csányi, *Monatsh.*, 1919, **40**, 81). Ott (*loc. cit.*) and Pfeiffer (*Ber.*, 1922, **55**, 413) have shown that the less stable high-melting modification has probably the unsymmetrical formula, whilst the low-melting form has the symmetrical structure.

We have prepared and examined succinyl chloride and the two forms of phthalyl chloride, with the results shown in Table II.

TABLE II.

Substance.	[P], obs.	[P], calc. (symmetrical).	[P], calc. (unsymmetrical).
Succinyl chloride	282·6	282·6	267·9
Phthalyl chloride, m. p. 13° ...	373·9	377·5	362·8
Phthalyl chloride, m. p. 88·5°	367·8	377·5	362·8

For succinyl chloride, the parachor shows clearly that the liquid has the symmetrical formula and cannot contain an appreciable amount of the unsymmetrical modification. With phthalyl chloride, a difference in the expected direction is found between the two isomerides, but the parachors are not in very good agreement with the predicted value in either case. This is probably to be explained by interconversion of the isomerides (compare Csányi, *loc. cit.*); the high-melting form is rapidly changed to the low-melting form at temperatures above its m. p. and shows a pro-

gressive change of density when kept at 90° for an hour. The figure given for this substance therefore represents a mixture containing a little of the low-melting isomeride (see p. 2881). We were unable to prepare the low-melting form with a m. p. higher than 13° (Csányi gives 15°), and this may also have contained a little of the other isomeride. In general, therefore, the parachor confirms the conclusions of Ott and Pfeiffer as to the structure of the two forms of this substance.

(3) *Benzils.*

Benzil and its derivatives may be formulated either as diketones (V) or as peroxides (VI). From its reactions and colour, benzil itself is usually assumed to have the ketonic structure. Certain

(V.) (VI.)

alkyloxy-derivatives of benzil are white, or very pale yellow in colour (Irvine, J., 1907, **91**, 536), and the view has been expressed, notably by Schönberg and his collaborators (Schönberg and Kraemer, *Ber.*, 1922, **55**, 1174; Schönberg and Malchow, *ibid.*, p. 3746; Schönberg and Bleyberg, *ibid.*, p. 3753), that these derivatives should be represented by the peroxide formula (VI). It should be noted, however, that on fusion these substances give yellow liquids which are supposed by Schönberg to contain an equilibrium mixture of the two forms.

We have prepared and measured 2 : 2′-dimethoxybenzil (Irvine's white benzil) with the results shown in Table III. It will be seen that the parachors found are in good agreement with the values calculated for the diketone formula in both cases, and show no indication of the presence of even a small proportion of the isomeride having the peroxide structure.

TABLE III.

2 : 2′-Dimethoxybenzil	596·8	594·0	582·4

EXPERIMENTAL.

In the course of this work new measurements have been made of the surface tension and density of *p*-benzoquinone, toluquinone, succinyl chloride, phthalyl chloride, benzil, and 2 : 2′-dimethoxybenzil. Surface tensions were determined by the method of maximum bubble pressure (Sugden, J., 1922, **121**, 858; 1924, **125**, 27). The constants for the bubbler used are: App. 14, $r_2 = 0{\cdot}177$ cm., $A = 0{\cdot}001020$. Densities were determined with the U-shaped pyknometer described previously (J., 1924, **125**,

1171), and are recorded in g. per c.c. All temperatures quoted are corrected by comparison with a standard thermometer with an N.P.L. certificate and are also corrected for exposed stem.

The tables are set out in the same manner as those given in earlier papers of this series and do not need further description. For all the substances studied in the present paper, d is very small and has been neglected.

p-*Benzoquinone*, $C_6H_4O_2$, $M = 108{\cdot}0$. A commercial specimen was purified by sublimation and melted at 115·5° (corr.). Some difficulty was encountered in the density determinations owing to the rapid sublimation of the substance into the cooler parts of the pyknometer; this sublimate was therefore removed and the tube reweighed after each volume determination. Densities determined: $D_4^{122°}$ 1·085, $D_4^{132°}$ 1·074, $D_4^{141·5}$ 1·064, $D_4^{160·5°}$ 1·044, whence $D_4^{t°} = 1{\cdot}214 - 0{\cdot}00106t$.

					Mean 236·8

* A correction factor; see J., 1924, **125**, 31.

Toluquinone (2-methyl-1 : 4-benzoquinone), $C_7H_6O_2$, $M = 122{\cdot}1$, was recrystallised from dilute alcohol and melted sharply at 67° (corr.). In the density measurements, errors due to sublimation were avoided by adopting the procedure described for benzoquinone. Densities determined: $D_4^{75·5°}$ 1·081, $D_4^{89·5°}$ 1·069, $D_4^{103·5°}$ 1·056, $D_4^{114·5°}$ 1·045, $D_4^{127·5°}$ 1·034, whence $D_4^{t°} = 1{\cdot}152 - 0{\cdot}000926t$.

Succinyl chloride, $C_4H_4O_2Cl_2$, $M = 155{\cdot}0$, was prepared by the action of phosphorus pentachloride on succinic acid and purified by repeated distillation under diminished pressure and freezing. The final product melted at 18·5° (corr.) and boiled at 95° (corr.)/20 mm. Densities determined: $D_4^{21°}$ 1·371, $D_4^{49°}$ 1·339, $D_4^{66°}$ 1·320, $D_4^{83·5°}$ 1·301, whence $D_4^{t°} = 1{\cdot}394 - 0{\cdot}00112t$.

t.	P.	D.	ϕ.	γ.	Parachor.

79·5	2992	1·305	1·0522	32·21	282·9
					Mean 282·6

as-*Phthalyl chloride*, $C_8H_4O_2Cl_2$, $M = 203{\cdot}0$. Crude phthalyl chloride was prepared by the action of phosphorus pentachloride on phthalic anhydride and converted into the unsymmetrical form by heating with freshly prepared aluminium chloride (Ott, *loc. cit.*). The crude product was purified as described by Scheiber (*loc. cit.*) and Csányi (*loc. cit.*) by slow crystallisation from ligroin and mechanical separation of the prisms of the chloride from the needles of phthalic anhydride. After four crystallisations, a pure product was obtained, m. p. 88·5° (corr.).

This substance is transformed into the symmetrical modification at an appreciable rate even at temperatures just above the melting point. The stable form has a smaller density (1·327 at 90°), so that the transformation can be followed by the change in density. The following results were obtained when the pyknometer containing the unsymmetrical chloride was kept at 90° :

	First series.				Second series.			
Time (mins.) after melting	7	27	47	67	13	22	39	50
$D_4^{90°}$	1·351	1·349	1·347	1·346	1·350	1·348	1·347	1·346

At the end of the experiment the substance was cooled rapidly and its m. p. found to be 81—83°, so that a considerable transformation had taken place. The crystals in the pyknometer (about 2 g.) required about 30 minutes in the bath at 90° to melt completely; it is evident, therefore, that the highest density found (1·351) is still a little lower than that of the pure substance at this temperature; the parachor will therefore be a little too large. The two isomerides have almost the same surface tension at 90°; hence no change in this constant with time was found for the unsymmetrical chloride.

t.	*P*.	*D*.	ϕ.	γ.	Parachor.
90°	3358	1·351	1·0482	35·88	367·8

s-*Phthalyl chloride*, $C_8H_4O_2Cl_2$, $M = 203{\cdot}0$. This substance is difficult to free from phthalic anhydride except by crystallisation from ligroin in a cold room (compare Csányi, *loc. cit.*). As such a room was not available, we converted the purified unsymmetrical form into the symmetrical modification by heating at 150° for 1 hour. The product was fractionated under diminished pressure and the specimen used had b. p. 150° (corr.)/23 mm. and m. p. 13° (corr.). (Csányi gives 15°, but we were unable to obtain a product with this melting point after repeated freezings.) Densities determined: $D_4^{17·5°}$ 1·403, $D_4^{36·5°}$ 1·381, $D_4^{58°}$ 1·360, $D_4^{88·5°}$ 1·349, $D_4^{90°}$ 1·327, whence $D_4^t = 1{\cdot}420 - 0{\cdot}00104t$.

					Mean 480·8

2 : 2′-*Dimethoxybenzil*, $C_{16}H_{14}O_4$, $M = 270·2$. *o*-Methoxybenzaldehyde was first prepared by the careful methylation of salicylaldehyde with methyl sulphate: The aldehyde (1 mol.) and methyl sulphate (2 mols.) were mixed and mechanically stirred while caustic soda (5 mols.), dissolved in its own weight of water, was slowly added. The reaction vessel was well cooled and the addition of caustic soda stopped for a time when half of it had been added, the mixture having become a stiff cream; the addition of the remaining caustic soda caused the evolution of considerable heat, and the mixture became thinner. The stirring was continued for some hours after all the alkali had been added, and the mixture allowed to stand over-night. The crude product was separated, washed well with water, dissolved in ether, and the solution dried over calcium chloride. Finally, two distillations in a vacuum gave a pure product, b. p. 122°/20 mm., m. p. 37° (corr.).

The aldehyde was converted into the benzil, as described by Irvine (*loc. cit.*). The specimen used melted sharply at 130° (corr.). Densities determined: $D_4^{130°}$ 1·128, $D_4^{133°}$ 1·126, $D_4^{140°}$ 1·116, $D_4^{147·5°}$ 1·115, $D_4^{165°}$ 1·104, $D_4^{168·5°}$ 1·101, $D_4^{187°}$ 1·086, whence $D_4^{t°} = 1·217 - 0·00069t$.

Summary.

(1) Measurements have been made of the surface tension and density of quinone, toluquinone, succinyl chloride, the two forms of phthalyl chloride, benzil, and 2 : 2′-dimethoxybenzil.

(2) The parachors calculated from these observations indicate that, except in the case of phthalyl chloride, these substances have the normal structure, and in the liquid state cannot contain more than a small amount of the isomeride in which a new ring is formed by tautomeric change.

(3) The parachors of the phthalyl chlorides indicate that the lower-melting form has the symmetrical structure, whilst the higher-melting form has the unsymmetrical structure.

One of us (S. S.) is indebted to the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the cost of this investigation.

BIRKBECK COLLEGE (UNIVERSITY OF LONDON),

CCCLXXXVI.—*The Chemical Nature of Precipitated Basic Cupric Carbonate.*

By JACK REGINALD IRONS HEPBURN.

THE author has previously studied (J., 1925, **127**, 1007) the mechanism of the changes which occur when precipitated cupric carbonate is kept in contact with the resulting solution. Special attention has now been directed towards the initial process which occurs on admixture of solutions of copper sulphate and sodium carbonate, the concentrations of which are systematically varied, with the object of gaining definite information as to the chemical nature of precipitated cupric carbonate, the composition of which is well known to depend on certain arbitrary factors, such as temperature of precipitation, relative proportions of admixed reagents, and time elapsing between precipitation and analysis. Serious analytical discrepancies have also been found to arise through inefficient mixing of the reacting solutions. In order to minimise such variations in the composition of the precipitate, a special mode of procedure was adopted in the present work.

If an excess of copper sulphate is used in the precipitation, and more especially if the sodium carbonate is added to the copper sulphate, the precipitate contains basic sulphate admixed with the basic carbonate. If the copper sulphate is added to excess of sodium carbonate, the precipitate consists of the basic carbonate, and the solution may contain carbonic acid, sodium hydrogen carbonate, or sodium carbonate, or mixtures of these compounds, according to the excess of sodium carbonate employed. On the other hand, with efficient stirring, and if the copper sulphate is

added to an equimolecular proportion of the sodium carbonate, the precipitate contains a relatively small percentage of basic sulphate, whilst the solution contains only carbonic acid and a small amount of dissolved copper.

The possibility of decomposition of the precipitate through subsequent drying or other further treatment was minimised by carrying out the analyses immediately after the reaction. The results thus obtained were reproducible, the effect of small temperature changes being unimportant.

In order to render the investigation as complete as possible, determinations have been made of copper and carbonic acid in the precipitate and in the solution after the reaction; of sodium carbonate remaining in solution, and adsorbed in the precipitate; and of adsorbed sulphate.

EXPERIMENTAL.

The solutions employed in the precipitations were all prepared by dilution from *M*-solutions. The cupric sulphate (A.R.) was used to standardise the sodium thiosulphate used in the subsequent copper estimations, and in the preparation of the *M*-cupric chloride solution. The cupric chloride employed was free from sulphate, but contained 22·9% of water; the solution was therefore made a little stronger than *M*, titrated against the standard thiosulphate solution, and diluted with the calculated amount of water. The *M*-sodium carbonate solution was standardised against the oxalic acid used in the carbon dioxide estimations, which had been previously standardised against pure sodium carbonate from bicarbonate. The oxalic acid was also employed in the estimations of sodium carbonate in solution. The potassium carbonate was prepared from bicarbonate and its titration against the oxalic acid confirmed the accuracy of the previous standardisation against sodium carbonate (Titration found: 27·65 c.c. Calc.: 27·67 c.c.). The barium hydroxide solution used in the estimations of carbon dioxide was preserved in an apparatus for titration in the absence of carbon dioxide. It was standardised against the oxalic acid.

The more dilute solutions were prepared in every case by dilution with water free from carbon dioxide and air. The volumes of the solutions employed were adjusted to yield a convenient quantity of precipitate, and varied from a minimum of 50 c.c. to a maximum of 1000 c.c. Equimolecular quantities of sodium carbonate and copper sulphate were used.

The experimental method adopted in the precipitations was similar to that described by Gröger (*Z. anorg. Chem.*, 1900, **24**, 127). The solution of copper sulphate was added in a fine stream

to that of sodium carbonate, violent mechanical stirring being employed throughout the addition. All the precipitations were carried out at room temperature (20°). The solution was filtered immediately after flocculation (5—10 minutes) through a Buchner funnel by means of the water-pump, and the precipitate was washed rapidly with cold water free from carbon dioxide and air.

Analysis.—(a) *Precipitate.* The moist precipitate was transferred to an apparatus for the estimation of carbon dioxide in carbonates (following the author's modification of Van Slyke's method, *Analyst*, 1926, **51**, 622), and analysed at once, loss of carbon dioxide from the precipitate through exposure to the air being thus eliminated. Copper was determined in the hydrochloric acid solution (remaining after the carbon dioxide estimation) by dilution, addition of sodium acetate in excess and of potassium iodide, and titration against standard sodium thiosulphate. Each determination was carried out in duplicate, except in Expts. 7 and 8 (Table I), where the amount of precipitate obtained was insufficient.

In the estimations of the adsorbed material in the precipitate, about 1 g. of the air-dried material was ignited to cupric oxide, extracted with boiling water, the filtrate concentrated, and titrated against 0·1*N*-oxalic acid for sodium carbonate (compare Applebey and Lane, J., 1918, **113**, 611). The remaining precipitate was dissolved in hydrochloric acid and added to the aqueous extract; the sulphate in the combined solution was then estimated as barium sulphate. (The solution was made up to 100 c.c. and 10 c.c. were titrated against the standard thiosulphate to determine the copper present, the remaining 90 c.c. being employed in the sulphate estimation.)

(b) *Filtrate.* A large volume of the filtrate was concentrated, whereby the copper was completely precipitated, with evolution of carbon dioxide; it was filtered off, dissolved in acetic acid, and titrated as usual. This filtrate was further concentrated and its sodium carbonate was estimated by titration in boiling solution against standard oxalic acid, phenolphthalein being used as indicator. Carbon dioxide in solution was determined by difference.

The results of the complete series of experiments (over a concentration range of *M* to 0·00625*M*) are given in Table I. The carbon dioxide content of the precipitate appears to vary continuously with the concentration of the reagents employed in the precipitation. The percentage of adsorbed copper sulphate at concentrations varying from 0·5*M* to 0·05*M* is small and erratic in nature; its variation is parallel to that in the concentration of the sodium carbonate remaining in solution (see Table V). The

percentage of adsorbed sodium carbonate is negligible. It seems probable that these small quantities of adsorbed material play no essential part in the reaction, and they have therefore been ignored in the following discussion.

The solubility of carbon dioxide in water at 20° corresponds with a concentration of 0·039*M* (Landolt–Börnstein, Tables, 5th Edn., 1923, 768). The solution resulting from admixture of approximately 0·25*M*-solutions of copper sulphate and sodium carbonate should therefore (from calculations based on the composition of the precipitate) be saturated with carbon dioxide; no effervescence occurred, however, on admixture of such solutions at 20°, whilst the effervescence was very slight in the case of 0·5*M*-solutions, and violent with *M*-solutions. The liquid in equilibrium with the precipitate from 0·5*M*-solutions appears, therefore, to be supersaturated with carbon dioxide, the concentration of carbon dioxide deduced from the composition of the precipitate being 0·119*M*. It was observed that the analytical figures for the precipitates from 0·5*M*-solutions and above were more variable than those for precipitates from more dilute solutions. This would be in accordance with the essential instability of supersaturated solutions and their sensitiveness towards small temperature changes. It will be noted particularly that the carbon dioxide content of the precipitates increases continuously until the concentration 0·5*M* is reached, but oscillates when this concentration is exceeded, suggesting a definite connexion between the concentrations of carbon dioxide in the liquid and the solid phases. It has accordingly been assumed that the concentration 0·119*M* for carbon dioxide in equilibrium with the precipitate was the maximum value possible.

All the experiments of Table I were carried out with copper sulphate and sodium carbonate. Precipitations with 0·5*M*- and 0·05*M*-cupric chloride and sodium carbonate, and with 0·5*M*- and 0·05*M*-copper sulphate and potassium carbonate, were also carried out, in order to ascertain whether the composition of the precipitated basic cupric carbonate was influenced to any extent by the acid and basic radicals associated with the cupric and carbonate ions (Table II). Although the results are not identical, and indicate some specific action of foreign ions, the composition of the precipitate approximates to the same value in each case.

Discussion.

The composition and the chemical nature of precipitated cupric carbonate have been investigated previously by several authors, and there is some divergency in the views expressed by them.

Gröger (*loc. cit.*) has studied the effect upon the carbon dioxide content of precipitated cupric carbonate, of steadily increasing the molecular proportion of sodium carbonate relative to copper sulphate. In his experiments, all the precipitations were carried out with *N*-solutions, and the concentration was not systematically varied as in the author's experiments, but the method of procedure was otherwise very similar. The products were air-dried before analysis. When the molecular ratio $Na_2CO_3 : CuSO_4$ was increased from 1·1 : 1 to 2 : 1, the carbon dioxide content was very much lowered (from $2CuO,1·012CO_2$ to $2CuO,0·802CO_2$). With a molecular ratio of 4 : 1 the carbon dioxide content was reduced still further ($2CuO,0·748CO_2$). The composition of the precipitate from approximately equimolecular quantities (1·1 : 1) of 0·5 *M*-solutions corresponds with $2CuO,1·012CO_2$, in close agreement with the author's result at this concentration, $2CuO,1·052CO_2$.

Employing sodium bicarbonate in place of the normal carbonate, Gröger found the carbon dioxide content of the precipitate to be increased—with approximately equimolecular solutions, the composition of the product corresponded with $2CuO,1·244CO_2$. He apparently regards the precipitated basic cupric carbonate as the decomposition product of the normal carbonate, for he states

(*loc. cit.*, p. 134) that it is not improbable that normal cupric carbonate is first formed and passes into the basic carbonate with loss of carbon dioxide. The high results for the carbon dioxide content of precipitates from sodium bicarbonate are held to agree with this view, by increasing the available carbon dioxide content of the reagent used, and so diminishing the extent of the decomposition. On the other hand, Gröger formulates the above product from bicarbonate as a definite compound, $8CuO,5CO_2,7H_2O$.

Pickering (J., 1909, **95**, 1409) attempted to ascertain the composition of precipitated basic cupric carbonate by adding sodium carbonate to a solution of copper sulphate sufficiently weak to ensure the retention of any carbon dioxide liberated (0·05% of copper). He found that alkalinity was attained when 1·61 mols. of sodium carbonate had been added per mol. of copper sulphate, and thence deduced the formula $5CuO,2CO_2$ (or $2CuO,0{\cdot}80CO_2$) for the precipitated substance. Pickering apparently assumes that the composition of the precipitate is independent of the concentration employed in the precipitation. This assumption has already been shown by the author to be untenable. Further, since the sodium carbonate was added to the copper sulphate, Pickering's compound undoubtedly contained basic sulphate.

Dunnicliff and Lal (J., 1918, **113**, 718) claimed to have prepared two new basic carbonates by precipitation from cupric sulphate–sodium carbonate mixtures of stated concentration, under standard conditions. Their method consisted in the addition of a cold 10% solution of sodium carbonate to a half-saturated solution of copper sulphate. The precipitate was kept for 24 hours, washed free from sulphate, and dried at 96° to constant weight. The mean of a number of analyses led to the formula $13CuO,5CO_2,9H_2O$. The second compound, prepared by adding a mixture of 5% sodium carbonate and 5% sodium bicarbonate solutions to the copper sulphate solution, corresponded to the formula $7CuO,2CO_2,5H_2O$.

The underlying idea in the experiments of Dunnicliff and Lal appears to be that any substance of constant composition which can be prepared under standard conditions is a definite compound, but, as judged by the author's results, these so-called compounds probably form points in a continuous curve; further, they appear to have no well-marked individuality or characteristics which distinguish them from other precipitates as definite compounds.

Mond and Heberlein (J., 1919, **115**, 908) have determined the composition of basic cupric carbonate precipitated from approximately 0·05*M*-solutions, under different conditions. The results indicate, contrary to those of Gröger, that the composition of the precipitated basic cupric carbonate was constant and independent

of the molecular proportion of cupric sulphate and sodium carbonate, in mixtures containing amounts in the proportion of 1 : 1 and lower. The molecular ratio in the precipitate was $CuO : CO_2 = 2{\cdot}26 : 1$ (or $2CuO,0{\cdot}885CO_2$). The amount of adsorbed material was relatively large, as is to be expected in the absence of an efficient stirrer. They concluded that no well-defined compound of copper is obtained by precipitation, the composition altering according to the conditions.

From theoretical considerations, there are a number of possibilities as to the chemical nature of the precipitated basic cupric carbonate. The simplest (Pickering; Dunnicliff and Lal) is to assume that a definite compound, or series of compounds, is formed. This view appears to be untenable in the light of the present experiments. A second view (Gröger) regards the substances as a mixture of the normal carbonate and the hydrated oxide. The various products are then regarded as due to the partial decomposition of the normal carbonate, and the variations of composition observed are attributed to greater or less decomposition, under given experimental conditions. It follows from this view, by the application of the mass-action equation $[CuO][CO_2]/[CuCO_3] = K$, that the concentration of the carbon dioxide in solution (or of carbonic acid), after precipitation, should possess a constant value, independent of the concentrations of the initial solutions employed in the precipitations; for, since both the normal cupric carbonate and the hydrated oxide may be regarded as very sparingly soluble in water, their active masses in solution would be constant.

It follows further, from this argument, that the amount of carbon dioxide retained in the precipitate at any particular initial concentration will diminish as the concentration of the precipitating solution is diminished, in order that this limiting concentration of carbon dioxide may be attained, after which no further loss of carbon dioxide from the precipitate should take place. Further, it appears that at a certain limiting value, *i.e.*, an initial concentration which will yield a concentration of carbon dioxide in the mother-liquor just equal to the equilibrium value, the precipitate should consist of the hydrated oxide only, and be free from carbon dioxide.

The experimental results for the concentration of carbon dioxide in the mother-liquor indicate, however, that this concentration diminishes steadily with the initial concentration of the reagents employed; the experimental result is therefore directly opposed to that derived from a consideration of the theoretical basis of Gröger's idea. A similar result follows if the basic cupric carbonate is regarded as the product of hydrolysis of the normal carbonate.

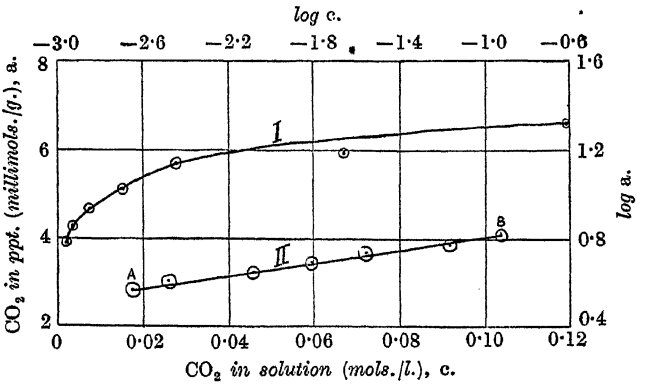
Free (*J. Amer. Chem. Soc.*, 1908, **30**, 1366) has suggested that the precipitated basic cupric carbonates might be regarded as solid solutions of carbonic acid with hydrated cupric oxide. This view does not appear to be very probable.

Certain basic salts produced by precipitation have been subjected to phase-rule studies (compare Britton, J., 1925, **127**, 2796), and the results have been held to be comparable with those obtained in initial precipitation processes. It appears to be a condition of such studies—more particularly those employing Schreinemakers's method of residues—that the liquid phase should be in equilibrium with a definite solid phase (or phases), *i.e.*, a well-characterised (probably crystalline) substance. In cases where a definite product is not obtained (*e.g.*, a colloidal substance, as obtained by Carter and Hartshorne, J., 1923, **123**, 2223, in their study of the system ferric oxide–phosphoric acid) the phase-rule method yields no definite result. Further, sufficient time must be allowed in phase-rule studies to enable a definite equilibrium to be reached. When such a state has been attained, the solid phase in equilibrium with the liquid is generally found to be crystalline (compare Carter and Hartshorne, *loc. cit.*).

It appears, therefore, that the initial product in a precipitation change must be distinguished from that obtained in a phase-rule study, or, in the particular case under investigation, that the initial precipitate is entirely different in nature from the stable basic carbonate, malachite, which is obtained under special conditions (compare J., 1925, **127**, 1007).

For the particular conditions maintained in the author's experiments, the final products of the precipitation at each concentration (neglecting small amounts of fortuitous impurities) consisted of a solid phase containing cupric oxide and a liquid phase containing carbon dioxide together with sodium sulphate. When the concentration of carbon dioxide in solution is plotted against the carbon dioxide content of the precipitate, Curve I (Fig. 1), is obtained. The carbon dioxide content, a, of the solid phase is evidently a continuous function of that in the liquid phase, c; further there is an exponential relation between these two magnitudes. When the logarithms of the two quantities are plotted, the points obtained lie, within the limits of experimental error, along a straight line (Curve II; Fig. 1). These results, therefore, are in accordance with the criteria usually applied to adsorption effects.

According to Freundlich ("Colloid and Capillary Chemistry," 1926, p. 172), the general form of the adsorption isotherm is represented by the equation



$$a = \alpha(c)^{1/n} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where $1/n$ has a value between 0·1 and 0·5, whilst the constant α may vary within wide limits. [The concentration c is given in mols. per litre, whilst the quantity a is calculated in millimols. per g. of adsorbent (anhydrous cupric oxide).] The value of $1/n$ was calculated to be 0·130 from the co-ordinates of the points A and B, both of which fell on the logarithmic line. From this value and the observed values of a and c, α was found to be 8·75, by substitution in (1). Hence

$$a = 8{\cdot}75c^{0{\cdot}130} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

By use of this equation, the theoretical values for a have been calculated at the concentrations actually employed, and compared

FIG. 1.

For Curve I, use ordinary co-ordinates.
For Curve II, use logarithmic co-ordinates.

with the experimental figures (Table III, columns 2 and 3). The agreement appears to be satisfactory.

TABLE III.

Equil. conc. of CO_2 in soltn. (mols./l.).	CO_2 in precipitate (millimols. per g.). Found.	Calc.	Equil. conc. of CO_2 in soltn. (mols./l.).	CO_2 in precipitate (millimols. per g.). Found.	Calc.

Further, the values for $1/n$ are within the limits laid down by Freundlich for typical adsorptions, but somewhat lower than the average (0·3—0·5), whilst the constant α is in both cases well within the range of values usual for such phenomena. A further parallelism appears in the nature of the adsorbed substance. The cases of adsorption from aqueous solution which have been investigated most thoroughly are those of the weak organic acids by charcoal, and in the present case the adsorbed substance is apparently carbonic acid, a weak acid the strength of which is of the same order of magnitude as those of the organic acids.

The precipitated cupric oxide appears to be present, when initially precipitated, in a very finely divided condition, as is indicated by the abnormally large solubility in the carbon dioxide in solution. Such a large effective surface would facilitate large and rapid adsorption.

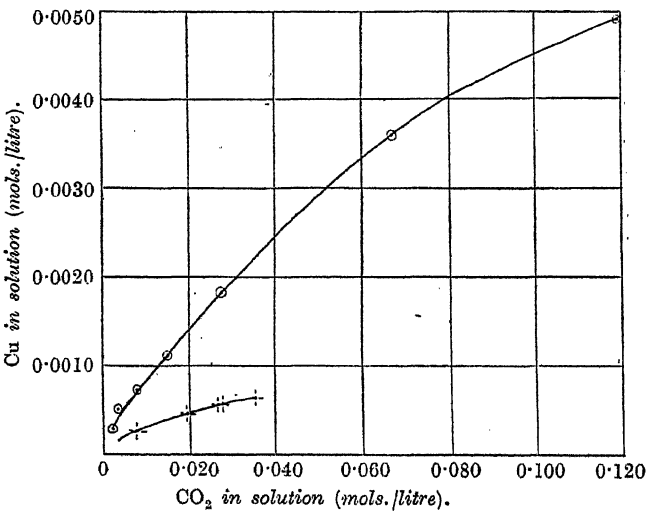
The author therefore puts forward the view that the formation of precipitated cupric carbonate is due, not to dissociation of the normal carbonate, but to adsorption of un-ionised carbonic acid by hydrated cupric oxide in a very active state.

The fact that the composition of the basic cupric carbonate precipitated from 0·5*M*-solutions approximates to the formula $2CuO,CO_2$, independently of the particular salt of copper employed suggests that a definite compound is produced at this concentration. Further, this composition represents the maximum value for the

carbon dioxide content when the precipitations are carried out with sodium carbonate and copper sulphate. According to the views put forward by the author, however, the agreement of the analytical figures at this concentration with the formula for malachite is only a coincidence. The carbon dioxide content of the precipitate is conditioned by its concentration in the liquid phase, and the maximum value of this concentration is further limited by the solubility of carbon dioxide in water, which may, however, be affected by the formation of supersaturated solutions. If the solubility of carbon dioxide in water could be made to exceed this value, the carbon dioxide content of the precipitate would be expected to be higher. This prediction finds support in Gröger's results for precipitations with bicarbonate: in the presence of sodium bicarbonate the solubility of carbon dioxide is increased, and the concentration of un-ionised carbonic acid is further increased by the excess of bicarbonate ions, according to the relation $[H^{\cdot}][HCO_3']/[H_2CO_3] = K_1$. Actually, under these conditions the carbon dioxide content of the precipitate was increased.

The author has carried out a number of experiments with the object of approaching the equilibrium from the other side, *viz.*, from hydrated cupric oxide and aqueous solutions of carbon dioxide, but certain difficulties rendered it impossible to obtain definite results. Primarily, it was not found possible to prepare hydrated cupric oxide free from notable amounts of cupric sulphate, without the occurrence of blackening, due to traces of alkali. It is thought that more definite results might be obtained by the use of a more stable hydrogel, *e.g.*, hydrated ferric oxide.

The idea that certain basic salts might be adsorption compounds has recently been tentatively put forward by Britton (J., 1926, 125) to explain the fact that the thorium hydroxide precipitated from thorium nitrate by addition of potassium chromate contained large amounts of chromic anhydride, the presence of which was attributed to "a process akin to adsorption, in which the chemical tendencies of the weak acid and the weak base played an important part." Although no further experimental verification of this statement was adduced, the idea is analogous to that now suggested by the author.



The Copper in Solution.

At every concentration at which the precipitation was carried out, it was found that a definite concentration of copper in solution was attained, after precipitation, dependent upon the concentration of carbon dioxide in the final solution. The relation between these two concentrations is represented by a smooth curve, shown in Fig. 2. The regularity of the results is striking, in view of the fact

that the carbon dioxide contents of the precipitates obtained at each concentration were widely divergent, the value of x in the formula $2CuO,xCO_2$ varying from 1·052 to 0·623; in spite of this, these precipitates behave in the same way as regards their solubility in aqueous solutions of carbon dioxide, which suggests that they are of very similar chemical nature. Such would be the case if each precipitate consisted of hydrated cupric oxide with variable quantities of adsorbed carbon dioxide.

Mond and Heberlein (*loc. cit.*) have determined the concentration of copper in the solution remaining after a precipitation from

FIG. 2.

⊙ *Author* (*see Table V*). ⊹ *Free.*

0·05*M*-solutions of cupric sulphate and sodium carbonate. They found this concentration to be 0·0032*M* (representing 8·0% of the total copper originally in solution), whereas the author's experiments at 0·05*M* gave 0·0011*M* (representing 4·42% of the original copper). Their corresponding concentrations of sodium carbonate remaining in the mother-liquor were also much higher than those found by the author. It is suggested that these high results are to be attributed to incomplete mixing owing to the lack of an efficient stirrer.

According to Mond and Heberlein, the dissolved copper is present in colloidal solution as the basic sulphate, and the sodium sulphate present in the solution may be removed by dialysis; they also state that the basic carbonate itself is not appreciably soluble in

water in the presence of carbon dioxide. In the author's opinion, these views are based upon insufficient experimental evidence, for the statement that the substance in solution is the basic sulphate appears to be founded upon one analysis of the precipitate formed after expelling carbon dioxide from the solution by boiling, whereby any carbon dioxide in the precipitate would also be removed. The black precipitate so produced contained $SO_3 : CuO = 1 : 4$.

The copper in solution is completely precipitated by boiling and expelling the carbon dioxide, the solution is colourless and not opalescent, and on exposure to air in an open vessel it loses carbon dioxide rapidly, with film formation of the basic carbonate on the surface. Under such conditions, it is difficult to understand how Mond and Heberlein were able to dialyse such a solution without decomposition and precipitation through loss of carbon dioxide.

Previous determinations of the solubility of basic cupric carbonate in aqueous solutions of carbon dioxide have been carried out by Free (*loc. cit.*). Precipitated basic cupric carbonate was agitated with a solution of carbon dioxide of known concentration, and the concentration of copper in solution was estimated after equilibrium had been attained. It was found that freshly precipitated basic cupric carbonate was more soluble in aqueous carbon dioxide solutions than the stable crystalline basic salt (malachite), and that the solubility of the freshly precipitated substance steadily decreased with time, finally reaching constancy at the value representing the solubility of malachite in the particular concentration of carbon dioxide. At the same time it was observed that the substance had been transformed into malachite.

The maximum value obtained by Free in any experiment was 107 parts of copper per million parts (or 0·00167 g.-atom per litre), in a solution of carbon dioxide containing 1200 parts per million. The author's result at this carbon dioxide concentration corresponds with 0·0018 g.-atom per litre. The agreement for freshly precipitated basic cupric carbonate is therefore satisfactory.

The author's results for the concentration of copper in solution are approximately three times as high as those obtained by Free for malachite (*e.g.*, for a solution containing 0·0275 mol. of CO_2 per litre, the concentration of Cu in solution was 0·0018 g.-atom per litre, whereas Free's result for a solution containing 0·0278 mol. of CO_2 per litre was 0·00054 g.-atom of Cu per litre). It is probable, therefore, that the freshly precipitated basic cupric carbonate is in a very finely divided condition, since below a certain limit of particle size the solubility of such precipitates is known to increase with the degree of dispersity. It may be observed, in this connexion, that Seyler (*Analyst*, 1908, **33**, 454) has attributed

the regularities found in Free's results to the formation of cupric bicarbonate in solution, and has attempted to show, by the application of ionic principles, that the solubility relationships are in accordance with this assumption.

Summary.

The effect of systematic variation in the concentration of the precipitants (copper sulphate and sodium carbonate) on the carbon dioxide content of precipitated basic cupric carbonate has been studied. The solutions employed were equimolecular, and the concentration ranged from M to $0{\cdot}00625M$. The results obtained indicate that the carbon dioxide content of the precipitate is a continuous function of the concentration of carbon dioxide in solution, and that these two magnitudes are capable of representation by a Freundlich adsorption equation. The view is therefore advanced that the formation of basic cupric carbonate is due to an adsorption process, the absorbent consisting of hydrated cupric oxide in a very active state, and the adsorbed material being un-ionised carbonic acid.

The author wishes to thank Dr. T. J. Drakeley for facilities provided during the course of this work.

NOTES.

A Simple Form of Automatic Syphon. By DOUGLAS CREESE HARRISON.

THE syphon is made of glass tubing of diameter not greater than 5 mm. About eight capillaries of diameters varying between about ¼ mm. and 1 mm. and about 20 cm. long are drawn from the same tubing and placed inside the glass tube near one end. The tube is then heated not too strongly and bent to form the syphon, with the capillaries inside the bend and projecting about 7 cm. into the shorter limb of the syphon. The longer limb (which should extend well below the ends of the capillaries) is warmed and molten paraffin wax is drawn into it to within about 4 cm. of the ends of the capillaries. The wax is allowed to run down and the excess shaken out, so that, when cool, a thin, even layer remains on the inside of the tube. The wax serves to retain the drops of liquid drawn

FIG. 1.

through the capillaries by surface tension, until, within a few seconds, they have accumulated to form a column of liquid heavy enough to draw liquid over the bend of the large tube. The height to which the liquid can be raised in starting the syphon will depend, of course, on the surface tension of the liquid and the cross-section of the capillaries. It is advantageous to use a number of capillaries of various diameters, since the liquid will rise more rapidly and to a greater height in the smaller capillaries and, as the liquid begins to accumulate in the longer tube, the pull exerted by gravity will assist the syphoning of the liquid in the larger capillaries. In this way the flow will become faster and faster until the liquid is drawn over the bend and syphons in the large tube. The capillaries occupy only a small part of the tube and so allow a rapid flow of liquid through the syphon.—SHEFFIELD UNIVERSITY. [*Received, August 18th*, 1927.]

The Preparation of Triacetonamine Hydrate. By FRANCIS FRANCIS.

THE following method was devised some years ago, but was not described at the time, since it was desired to investigate the other products of the reaction and to increase materially the yield of the base.

Into a mixture of 2½ kg. of acetone and 800 g. of fused calcium chloride in a large round-bottom flask provided with an efficient condenser, ammonia is passed at intervals until the whole of the chloride has been converted into a liquid complex. After 3 days the product is gently boiled on a water-bath until the liquid calcium chloride–ammonia compound has decomposed and resolidified, ammonia being evolved. The dark, strongly smelling liquid is then decanted from the solid or pasty chloride, and distilled until a thermometer in the vapour registers 75°; the distillate consists chiefly of acetone. The residue is placed in a freezing mixture of ice and hydrochloric acid, and when the temperature has fallen to 1—2° an amount of water is added, with vigorous stirring, corresponding to a yield of 28% of triacetonamine calculated on the acetone used, *i.e.*, the amount taken less that distilled off. Triacetonamine hydrate separates in a crystalline condition as the temperature falls; after being pressed between filter-paper and recrystallised several times from undried ether, it is obtained in large, well-formed, slightly yellow crystals (yield, 20—26%, calculated on the acetone used).

The conversion of the hydrate into nitrosotriacetonamine is carried out in the usual manner and the yield is quantitative. The extreme ease with which this nitrosoamine is decomposed catalytic-

ally by alkalis, giving a nearly quantitative yield of phorone, renders this an elegant method for the preparation of this unsaturated ketone (J., 1912, **101**, 2358).—THE UNIVERSITY, BRISTOL. [*Received, September 15th*, 1927.]

7-Hydroxy-3-phenylcoumarin. By WILSON BAKER.

AN attempt was made to synthesise 3-phenylchromones (*iso*flavones; Baker and Robinson, J., 1925, **127**, 1981; 1926, 2713) by condensing ethyl α-formylphenylacetate with resorcinol or phloroglucinol in presence of phosphoric anhydride. By analogy with ethyl acetoacetate and its derivatives, chromones should be produced (see papers by Simonis and collaborators, *Ber.*, 1913, **46**, 2015; 1914, **47**, 692, 2229, etc.), but the first condensation gave only 7-hydroxy-3-phenylcoumarin, which has also been prepared (Dey and Row, *J. Indian Chem. Soc.*, 1924, **1**, 121; Bargellini, *Gazzetta*, 1927, **57**, 459) from resorcylaldehyde, sodium phenylacetate, and acetic anhydride.

Jacobson and Ghosh (J., 1915, **107**, 1057) and Ghosh (J., 1916, **109**, 114) describe the reactions between ethyl α-formylphenylacetate and resorcinol, in presence of acetic acid and zinc chloride, and between formylphenylacetonitrile and resorcinol in presence of phosphoryl chloride, and the isolation in both cases of a substance, m. p. 131°, described by them as 7-hydroxy-3-phenylchromone. Since such condensations are now known to give coumarins (Baker and Robinson, J., 1925, **127**, 1981; Baker, *ibid.*, p. 2349; Bargellini, *Gazzetta*, 1925, **55**, 945), and the substance, m. p. 131°, could not be identical with 7-hydroxy-3-phenylcoumarin, which melts at 207—208°, the experiments were repeated, with the result that both gave the same product, m. p. 207—208°, identical in all respects with 7-hydroxy-3-phenylcoumarin. The product, m. p. 131°, is, therefore, not the product of these condensations, and its description is doubtless due to confusion of specimens in the laboratory.

7-Hydroxy-3-phenylcoumarin.—Ethyl α-formylphenylacetate (15 g.), xylene (75 c.c.), and resorcinol (50 g.) were heated at 160° for 2 hours, phosphoric anhydride (50 g.) being gradually added. The product, boiled with water to expel the xylene, was converted into the acetyl derivative, which, after twice recrystallising from acetic acid (charcoal), separated in colourless, flat prisms, m. p. 184—185°. No trace of an *iso*flavone could be detected in the mother-liquors. Hydrolysis produced 7-hydroxy-3-phenylcoumarin, which separated from alcohol in prisms, m. p. 207—208°, containing alcohol of crystallisation. The methyl ether, prepared by the action of methyl sulphate, crystallised from alcohol in colourless, nacreous plates, m. p. 124° (Bargellini, *loc. cit.*, gives m. p. 118—120°) (Found:

C, 76·0; H, 4·6. Calc.: C, 76·2; H, 4·8%). These compounds give yellow solutions in concentrated sulphuric acid, which exhibit an intense bluish-green fluorescence.

Condensation of Ethyl α-Formylphenylacetate with Phloroglucinol.—The two substances (15 g. of each), treated as previously described, gave an *acetyl* derivative (0·6 g.) which crystallised from acetic acid in hair-like, colourless needles, m. p. 255—256° (Found: C, 73·7, 73·6, 73·7; H, 4·2, 3·8, 4·6%; *M*, by Rast's method, 434, 416). Hydrolysis with potassium carbonate in 50% alcohol gave a phenolic substance which crystallised from alcohol in pale yellow prisms, m. p. 308—310° (decomp.) (Found: C, 72·2; H, 4·5%). This compound of high molecular weight is not identical with the 5 : 7-dihydroxy-3-phenylcoumarin prepared by Bargellini (*loc. cit.*). A number of empirical formulæ agree with the analyses, but without further experiments the selection of a definite formula is not possible. The phenolic *compound* gave with ferric chloride in alcoholic solution a yellow colour, and, like its acetyl derivative, dissolved in concentrated sulphuric acid to a bright yellow solution devoid of fluorescence.—THE UNIVERSITY, MANCHESTER. [*Received, September 13th*, 1927.]

A Double Compound of Chromic and Hydrogen Chlorides. By JAMES RIDDICK PARTINGTON and SIDNEY KEENLYSIDE TWEEDY.

IF a concentrated solution of dark green chromic chloride is mixed with an equal volume of ether and slowly saturated with hydrogen chloride at 0°, the dark green chloride is precipitated. If the saturation is rapid, however, and the cooling bath is dispensed with, the solution becomes warm and besides dark green chromic chloride a heliotrope substance is precipitated. If the mixture is filtered with the aid of a pump, the green chloride often forms a layer of remarkably fine crystals on top of the heliotrope substance. The latter compound may be obtained in a fairly pure state if the stream of gas is stopped when the liquid is homogeneous and brownish-green, and after a while collects at the bottom of the vessel. The mother-liquor is decanted, the residue mixed with a large excess of ether, and after filtration the substance is air-dried. A further crop may be obtained by passing more hydrogen chloride into the mother-liquor, but after three such precipitations the product becomes largely contaminated with dark green chromic chloride. The substance may conveniently be washed with dry ether in a Soxhlet extractor (Found: Cr, 17·8, 17·3; Cl, 44·7, 44·9%. Constant values could not be obtained, showing that the product was never pure).

When freshly precipitated violet chromic chloride is washed with acetone in a Soxhlet extractor, if the acetone is warm when it falls upon the salt the surface of the latter becomes covered with a layer of the heliotrope substance, which in turn becomes covered with a layer of dark green chromic chloride. It would appear, then, that the heliotrope compound is also formed by the action of hydrogen chloride on the violet chloride when warm, since this acid is present in the freshly precipitated chloride.

The analyses agree roughly with the formula $CrCl_3,HCl,6H_2O$, which requires Cr, 17·2; Cl, 46·9%. Contamination with green or violet chromic chloride would cause the chromium content to increase and the chlorine content to decrease. No salts of this general formula have been described, but Larsson (*Z. anorg. Chem.*, 1920, **110**, 153) prepared two salts of composition $CrCl_3,MCl,5H_2O$, where M = Cs and Rb. A compound of this formula with M = H would require Cr, 18·2; Cl, 49·8%. The analyses will not fit in with any other type of double chloride formed by chromic chloride. Until the heliotrope substance can be prepared in a pure state, it can only be said that it is probably a double compound of the formula $CrCl_3,HCl,xH_2O$, where $x = 5$ or 6. The analyses and the method of preparation support the value $x = 6$.

Recoura (*Compt. rend.*, 1886, **102**, 922; *Ann. Chim. Phys.*, 1887, **10**, 49) records that when hydrogen chloride is passed into a chromic chloride solution for some days the latter turns brown and then red, and a soluble compound $CrCl_3,xHCl$ is formed, where x is greater than unity. On addition of ether, however, it is precipitated in unstable, green needles.

The heliotrope substance is insoluble in methyl and ethyl alcohols and dissolves in water to give a pink solution which immediately turns green, although of a different shade from that given by solutions of dark green chromic chloride. If a fragment of the substance is treated with a drop of water and observed under the microscope, it is seen that the process of solution is accompanied by very vigorous turbulence and agitation. It is not proposed at present to investigate the compound any further.—EAST LONDON COLLEGE, LONDON, E. 1. [*Received, October 6th*, 1927.]

The Viscosities of Chromic Anhydride Solutions. By JAMES RIDDICK PARTINGTON and SIDNEY KEENLYSIDE TWEEDY.

CHROMIC anhydride prepared and purified by the authors' method (J., 1926, 1142) had m. p. 193°. Melting points between 170° and 196° have been recorded in the literature. Both capillary-tube and test-tube methods were employed and the thermometer was com-

pared with a standard instrument before use. Groschuff states (*Z. anorg. Chem.*, 1908, **58**, 108) that chromic anhydride supercools to the extent of 26°; our specimens, however, all solidified sharply within a degree or so of the m. p.

The viscosities of solutions of the anhydride were determined with an Ostwald viscometer as modified by Martin (*Bull. Soc. chim. Belg.*, 1925, **34**, 81). The instrument was standardised with conductivity water, and similar water, which had been stored in a Pyrex flask, was used for preparing the solutions. These were obtained by successive dilution. w is the weight of anhydride in 100 g. of water, η is the viscosity of the solution, and η_{H_2O} that of water (in dyne/cm.^{2}).

w.	η/η_{H_2O}.	η.	w.	η/η_{H_2O}.	η.

			16·55	1·027	0·006945

The readings marked with asterisks appear to be 1—2% too high; they do not lie on the smooth curve passing through the other points. The figures for 40° are probably less trustworthy than those at the lower temperatures, as the thermostat was not automatically controlled at this temperature.

The absolute viscosities, η, were calculated with the aid of Leroux's values for the viscosity of water (*Ann. Physique*, 1925, **4**, 163). If these values are plotted on a very large scale, it is seen that Leroux's results for 2·5° (0·01648) and 7·5° (0·01419 dyne/cm.^{2}) are probably too high by about 0·00015 and 0·0002 dyne/cm.^{2}, respectively. The following equation, which is of the type proposed by Slotte (*Ann. Physik*, 1888, **34**, 28), represents the curve with fair accuracy between 10·9° and 30°:

$$\eta_{H_2O}\ (\text{dyne/cm.}^2) = \frac{0{\cdot}633161}{T - 241{\cdot}307} - 0{\cdot}00207155$$

where $T = t + 273$, t being in degrees Centigrade. The closeness of the observed and calculated values is of the order accepted by Thorpe and Rodger (*Phil. Trans.*, 1894, *A*, **185**, 397):

Change of Properties of Substances on Drying. By HERBERT BRERETON BAKER.

MY attention has been directed to a paper by D. Balarew (*J. pr. Chem.*, 1927, **116**, 57). The author sealed up various liquids in

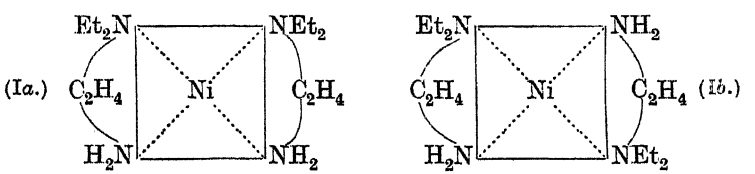
U-tubes, a liquid in one limb and sublimed phosphorus pentoxide in the other, and kept them for 3½ years. He states that subsequent examination of all the liquids, which included hexane and benzene, showed the presence of phosphoric acid, and he suggests that the rise in boiling point which I have found may be due to the presence of this substance or its esters. Apart from the fact that the rise in boiling point which I mentioned (26° in the case of benzene, lately increased to 38°) could not be accounted for by the presence of such an impurity, it was distinctly stated in my paper (J., 1922, **121**, 572) that " In every case the liquid distilled from the dried apparatus was tested for the presence of phosphoric acid, and no trace could be detected." If Balarew's phosphorus pentoxide were not free from the volatile trioxide, his results could be understood.—IMPERIAL COLLEGE, LONDON, S.W. 7. [*Received, November 3rd*, 1927.]

The Dimorphism of 2-Chloroaceto-p-toluidide. By MAURICE SCHOFIELD.

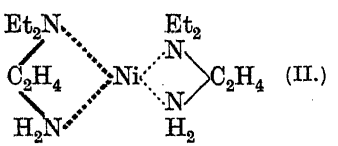
2-CHLORO-*p*-NITROTOLUENE (80 g.), m. p. 62·5°, obtained by chlorinating *p*-nitrotoluene (100 g.) at 57—59° in presence of anhydrous ferric chloride (4 g.) and in absence of sunlight and moisture, isolated by pouring the product into water, and crystallised from methylated spirit, was reduced at 60—70° with water (350 c.c.), iron powder (in slight excess; added during 2½ hours), and a little hydrochloric acid. The 2-chloro-*p*-toluidine thus obtained, b. p. 238—240°, m. p. 18°, was acetylated with acetic anhydride and acetic acid. The2-chloroaceto-*p*-toluidide obtained (Found: C, 58·8; H, 5·5; N, 7·5. Calc. for $C_9H_{10}ONCl$: C, 58·8; H, 5·6; N, 7·6%) crystallised from benzene, alcohol, carbon disulphide, ether, and toluene in needles, m. p. 83°. This form, however, crystallised from light petroleum (b. p. 60—80°), in which it was sparingly soluble, in plates, m. p. 104°, and even when it was refluxed with a small quantity of this solvent a bulky, feathery mass, m. p. 104°, was obtained (Found: C, 58·7; H, 5·6; N, 7·7%). The reverse change was effected by crystallising the 104° form from benzene. After the molten 83° form had been kept at 120° for several minutes, solidification occurred at 93° after super-cooling to 89°. No crystallisation took place above 93° if the melt had been kept at 120° for longer periods. Freezing points up to 101° were given by a melt kept under similar conditions and seeded with the 104° form.

Kunckell and Lillig (*J. pr. Chem.*, 1912, **86**, 517) describe 2-chloroaceto-*p*-toluidide as crystallising from benzene in needles, m. p. 104°. —WOLVERHAMPTON AND STAFFORDSHIRE TECHNICAL COLLEGE, WOLVERHAMPTON. [*Received, October 8th*, 1927.]

CCCLXXXVII.—*The Complex Salts of Nickel with Various Aliphatic Diamines.*



By FREDERICK GEORGE MANN.

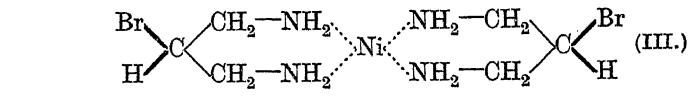


WERNER first suggested (*Z. anorg. Chem.*, 1893, **3**, 298) that when a metal shows a co-ordination number of 6, as in hexamminocobaltic chloride, $[Co(NH_3)_6]Cl_3$, the co-ordinated groups lie at the apices of a regular octahedron described around the metallic atom. The resolution into optically active forms of various complex salts of eight different metals (Co, Cr, Rh, Fe, Pt, Ir, Ru, and Al : also As), all having a co-ordination number of 6, leaves little doubt of the correctness of Werner's views.

Very great uncertainty still exists, however, with regard to the configuration of the complex salts of metals having a co-ordination number of 4, *e.g.*, tetramminonickelous chloride, $[Ni(NH_3)_4]Cl_2$. Biltz and Fetkenheuer (*Z. anorg. Chem.*, 1914, **89**, 121) claim to have prepared two distinct forms of the neutral non-ionic dichlorodiamminocobalt, $[Cl_2Co(NH_3)_2]$, and of the corresponding dibromo- and di-iodo-compounds, a result which would indicate that the four co-ordinated groups lie at the corners of a square with the metallic atom at the centre. This configuration would also explain the existence of two distinct forms of nickel iodate dihydrate, $[(H_2O)_2Ni(IO_3)_2]$ (Meusser, *Ber.*, 1901, **34**, 2438). Tschugaev (*Ber.*, 1906, **39**, 3192), however, failed to detect any similar *cis-trans*-isomerism in a series of salts such as bissuccinimidobismethylaminenickel, $[(C_4H_4O_2N)_2Ni(CH_3{\cdot}NH_2)_2]$. Moreover, the existence of the stable salts, $\beta\beta'\beta''$-triaminotriethylaminenickel thiocyanate, $[NiN(C_2H_4{\cdot}NH_2)_3](SCN)_2$, and $\gamma\gamma'\gamma''$-triaminotripropylaminenickel thiocyanate (Mann and Pope, J., 1926, 482, 489) is more easily explained by assuming that the four co-ordination valencies of the nickel atom are directed to the apices of a regular tetrahedron. Schlesinger (*Ber.*, 1925, **58**, 1877) found that copper, of co-ordination number 4, combines with certain bisimino-carboxylic acids to give compounds existing in two forms, and concludes that the copper complex has therefore the uniplanar configuration, a deduction opposed by Reihlen (*Z. anorg. Chem.*, 1926, **151**, 72), who considers the isomerism to be due to the presence of the two asymmetric nitrogen atoms in these compounds. Moreover, the recent resolution into optically active forms of 4-co-ordination derivatives of copper, zinc, and beryllium by Mills and Gotts (J., 1926, 3121) shows that such metallic complexes have the tetrahedral configuration, thus confirming the conclusions of Lowry and Burgess (J., 1924, **125**, 2081) with regard to the beryllium complex. On the other hand,

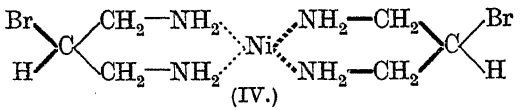
the existence of two forms of many derivatives of bivalent platinum and palladium, *e.g.*, dichlorodiamminoplatinum, $[Cl_2Pt(NH_3)_2]$, led Werner (*loc. cit.*, p. 310) to consider that here the complex was uniplanar and the two forms *cis-trans*-isomerides. Reihlen and Nestle (*Annalen*, 1926, **447**, 211) consider these compounds to be merely polymeric forms having the tetrahedral configuration,* a conclusion opposed on experimental grounds by Grunberg (*Z. anorg. Chem.*, 1926, **157**, 299) and Hantzsch (*Ber.*, 1926, **59**, 2761). Finally, the uniplanar configuration has been given to the dimethyltelluronium dihalides by Vernon (J., 1920, **117**, 90) to explain the existence of two isomeric forms.

Attempts were therefore made to obtain more decisive evidence with regard to the configuration of the 4-co-ordination nickel complex by preparing certain complex salts which, if possessing the uniplanar configuration, should show *cis-trans*-isomerism, and, if possessing the tetrahedral configuration, should be resolvable into optically active forms. Nickel was first combined with β-aminotriethylamine to give *bis-β-aminotriethylaminenickelous thiocyanate*, $[Ni\{(C_2H_5)_2N\cdot C_2H_4\cdot NH_2\}_2](SCN)_2$. This compound, if possessing the uniplanar configuration, should exist in the *cis* (I*a*)



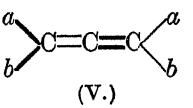
and the *trans* (I*b*) form, whilst if possessing the tetrahedral configuration (II),† it should be resolvable into optically active forms owing to its dissymmetric nature. No evidence of *cis-trans*-isomerism could be detected in this compound, whilst the presence of the tertiary nitrogen atoms rendered the complex so unstable that attempts at resolution could not be completed.

In order to avoid the presence of tertiary nitrogen atoms, a new type of complex salt was prepared by co-ordinating nickel with β-bromo-αγ-diaminopropane to give *bis-β-bromo-αγ-diaminopropane-*



* Reihlen goes further and states (*Annalen*, 1926, **448**, 316) that all 4-co-ordination elements have the tetrahedral configuration.

† The thick bonds are in the plane of the paper, the thin ones at right angles to it.



nickelous thiocyanate, $[\{(NH_2\cdot CH_2)_2CHBr\}_2Ni](SCN)_2$. If this complex has the uniplanar configuration, the two co-ordinated ring systems lie in one plane, which is at right angles to that in which the terminal bromine and hydrogen atoms lie : the complex should therefore show *cis-trans*-isomerism according as the two bromine atoms are both on one side of the co-ordinated plane (III) or are on opposite sides, respectively. If, however, the complex has the

(III.)

(IV.)

(V.)

tetrahedral configuration, the two ring systems are at right angles to each other (IV) : the complex thus possesses molecular dissymmetry, being structurally of the same type as the allene compounds (V), and should be resolvable into optically active forms. Here again, however, the highly crystalline dithiocyanate showed no signs of *cis-trans*-isomerism, whilst attempts at resolution failed because of the labile character of the bromine atoms; *e.g.*, the bis-β-bromo-αγ-diaminopropanenickelous thiocyanate in hot aqueous solution changed rapidly into the highly crystalline *bis-β-thiocyano-αγ-diaminopropanenickelous thiocyanate*,

$$[\{(NH_2\cdot CH_2)_2CH(SCN)\}_2Ni](SCN)_2.$$

Although this compound is of the required type for the purposes of this investigation, its low solubility in water made it unsuitable for use. Attempts were made to join a more stable group to the central carbon atom, and in particular to prepare αγ-diamino-*iso*propyl methyl ether, $(NH_2\cdot CH_2)_2CH\cdot O\cdot CH_3$. αγ-Dichlorohydrin reacts readily with potassium phthalimide to give αγ-diphthalimido-*iso*propyl alcohol, $(C_6H_4<^{CO}_{CO}>N\cdot CH_2)_2CH\cdot OH$: the hydroxyl group is, however, so well protected (probably sterically) that it is extremely inert and could not be methylated. Dichlorohydrin was itself methylated to give dichloro*iso*propyl methyl ether (Hess and Fink, *Ber.*, 1915, **48**, 2003), but the chlorine atoms were now extremely inert and would not react with potassium phthalimide even when heated in a sealed tube at 180° for 4 hours.

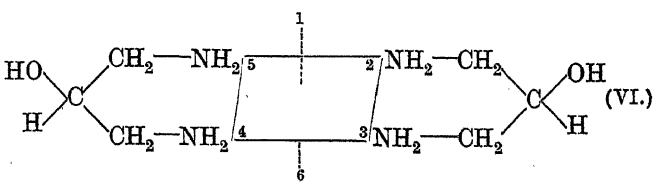
Nickel was next combined with the easily obtained αγ-diamino-*iso*propyl alcohol to give *bis-αγ-diamino-β-hydroxypropanenickelous thiocyanate*, $[\{(NH_2\cdot CH_2)_2CH\cdot OH\}_2Ni](SCN)_2$. Since, however, bivalent nickel may show a co-ordination number of 4 or of 6, it is difficult to decide whether in this compound the nickel has a

co-ordination number of 4 and is combined solely with the four amino-groups, or of 6 and is combined with the four amino-groups and with the two hydroxyl groups. It was found, however, that the diamine co-ordinates with cobalt to give *dihydroxybis-αγ-diamino-β-hydroxypropanecobaltic monochloride*,

$$[\{(NH_2\cdot CH_2)_2CH\cdot OH\}_2Co(OH)_2]Cl,$$

a compound in which the alcohol molecules must be co-ordinated by the amino-groups alone, and it was considered probable that the same held true of the above nickel compound, which should therefore be of the desired type. Again, however, no trace of *cis-trans*-isomerism was detected, and all attempts at resolution failed.

β-*Methyltrimethylenediamine* was now synthesised by converting β-methyltrimethylene dibromide into the corresponding *diphthalimido*-compound and hydrolysing it. The diamine was combined with nickel to give *bis-β-methyltrimethylenediaminenickelous thiocyanate*, $[\{CH_3\cdot CH(CH_2\cdot NH_2)_2\}_2Ni](SCN)_2$. This compound, although highly crystalline, showed no evidence of *cis-trans*-isomerism, and all attempts at resolution again failed.



These repeated failures to resolve the nickel compounds may have been due either to the complex possessing the uniplanar configuration, or to the complex, if dissymmetric, undergoing such rapid racemisation that no evidence of resolution could be detected. The latter is presumably the reason for repeated failures in the past to resolve 6-co-ordination nickel derivatives, *e.g.*, trisethylenediaminenickel salts, and also tristriaminotriethylaminebisnickelous salts (Mann and Pope, *loc. cit.*, p. 486).

An interesting point arises here. It is well known that the complex compounds of nickel in which the metal has a co-ordination number of 4 are much more stable than those in which the co-ordination number is 6: yet nickel will combine with three molecules of the simplest aliphatic diamines, *e.g.*, ethylenediamine and propylenediamine, to give compounds such as trisethylenediaminenickel chloride, $[Ni\,en_3]Cl_2$, which are sufficiently stable to be isolated and sometimes even recrystallised, in spite of the fact that the metal here has a co-ordination number of 6. Yet in the present investigation it was found that even if a nickel salt (nickel chloride in aqueous solution: nickel succinimide in alcoholic solution) was treated with a very large excess of the various diamines employed, *viz.*, β-aminotriethylamine, αγ-diamino*iso*propyl alcohol, and β-methyltrimethylenediamine, only two molecules of the diamine co-ordinated with the metal and no trace of a compound in which the metal had a co-ordination number of 6 could be isolated. Similarly *roseo*cobaltic chloride on treatment with a large excess of diamino*iso*propyl alcohol gave always dihydroxybisdiaminohydroxy-

propanecobaltic monochloride, and again no compound in which three molecules of the diamine co-ordinated with the cobalt atom could be prepared. Many similar instances have previously been recorded. Thus nickel combines with only two molecules of dimethylglyoxime, to give $[Ni(ON{:}CMe{\cdot}CMe{:}N{\cdot}OH)_2]$, and never with three molecules, whilst cobalt will give diamminobisdimethylglyoximecobaltic monochloride, $[(ON{:}CMe{\cdot}CMe{:}N{\cdot}OH)_2Co(NH_3)_2]Cl$, but will not combine with three molecules of the dioxime. Dicyanodiamidine gives diaquobisdicyanodiamidinenickel,

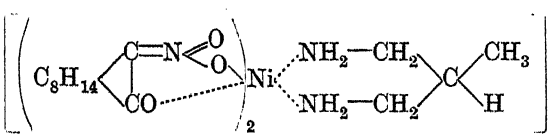
$$[\{NH_2{\cdot}(NH{:})C{\cdot}N{\cdot}CO{\cdot}NH_2\}_2Ni(H_2O)_2],$$

but the two molecules of water cannot be replaced by a third molecule of the diamidine. This inability of nickel * to combine with more than two molecules of any but the simplest double-bridging groups cannot be ascribed to the general instability of 6-co-ordination nickel compounds, since tristriaminotriethylaminebisnickelous tetraiodide is a very stable compound, in spite of the presence of two weakly co-ordinating aliphatic tertiary nitrogen atoms: it is more probably due to the difficult access of the third molecule of the diamine. Thus if, when nickel is treated with an excess of, *e.g.*, diamino*iso*propyl alcohol, two molecules of the diamine co-ordinate first to give a 4-co-ordination complex having the uniplanar configuration (VI), co-ordination of a third molecule of the diamine

(VI.)

would involve bridging the potential 1 : 6-positions, which is structurally probably impossible. Similarly, with tervalent cobalt it is probable that the first two molecules of the diamine again occupy the 2 : 3- and 4 : 5-positions respectively; whence the distant 1- and 6-positions have to be occupied by simple unbridged groups as in dihydroxybisdiaminohydroxypropanecobaltic chloride and diamminobisdimethylglyoximecobaltic chloride.

Although the extreme difficulty of co-ordinating a third double-bridging group to the nickel atom can thus be explained on the assumption that the 4-co-ordination nickel complex has the uniplanar configuration, it is, on the other hand, significant that in the present investigation the five different complex salts showed no



* Tervalent cobalt does not always share this inability: it will combine, *e.g.*, with 3 molecules of α-nitroso-β-naphthol (Morgan and Smith, J., 1921, **119**, 704).

evidence of *cis-trans*-isomerism, although all were highly crystalline compounds in which such isomerism should have been easily detected. The evidence for the configuration of the nickel complex thus remains conflicting.

A novel and apparently quite general reaction of 4-co-ordination nickel salts arose in the present investigation. Werner, in order to resolve certain complex salts of chromium (*Ber.*, 1912, **45**, 865), had recourse to crystallisation of the camphornitronates of the complex, prepared by simple double decomposition with the normal salts. Similar attempts were made with these nickel complex salts, since crystallisation of the camphorsulphonates had failed to effect resolution. When, however, bis-β-methyltrimethylenediaminenickelous nitrate is treated in cold aqueous solution with an excess of ammonium nitrocamphor, ammonia is at once liberated, the solution changes in colour from deep blue to green, and a rapid precipitation of the green, neutral, non-ionic *biscamphornitronate-β-methyltrimethylenediaminenickel* occurs, in accordance with the equation

$$[Ni\{CH_3\cdot CH(CH_2\cdot NH_2)_2\}_2](NO_3)_2 + 2C_{10}H_{14}O\cdot NO_2NH_4 = [(C_{10}H_{14}O\cdot NO_2)_2Ni\{CH_3\cdot CH(CH_2\cdot NH_2)_2\}] + CH_3\cdot CH(CH_2\cdot NH_2,HNO_3)_2 + 2NH_3.$$

A precisely similar reaction occurs with the corresponding compounds of β-aminotriethylamine and diamino*iso*propyl alcohol, thus providing further evidence that the latter diamine occupies only two co-ordination positions, *i.e.*, is co-ordinated by the amino-groups alone and not by the hydroxyl group. The three compounds so obtained are soluble in the usual organic liquids, but insoluble in water, a property common to many neutral, non-ionic co-ordination compounds. It is probable that in these compounds the ketonic group in the camphor molecule is also linked by a subsidiary valency to the nickel atom, which has therefore a co-ordination number of 6 (VII). In this case the complex as a whole becomes

(VII.)

dissymmetric (in addition to the dissymmetric character of the constituent camphor residues) and the recrystallised compounds in solution might be expected to show mutarotation owing to slow racemisation of the complex itself. No such mutarotation was shown in chloroform solution, however, by the three compounds of this type available.

It is obvious that the new diamine, β-methyltrimethylenediamine, should prove extremely useful in the solution of various problems connected with the stereochemistry of complex salts. Its use will unfortunately be limited, because the preparation of β-methyltrimethylene dibromide is extremely slow and tedious and the yield of the diphthalimido-compound is very small owing to side reactions. The diamine, however, co-ordinates with bivalent platinum to give *bis*-β-*methyltrimethylenediamineplatinous chloride*, $[Pt\{CH_3\cdot CH(CH_2\cdot NH_2)_2\}_2]Cl_2$. This compound is now being further investigated, since the occurrence of *cis-trans*-isomerism or of optical activity would solve the vexed question of the configuration of the complex platinous salts.

Experimental.

All rotations given in this paper have been measured at 15° in a 4-dcm. polarimeter tube.

The Complex Salts of β-*Aminotriethylamine.*

β-*Aminotriethylamine*, $N(C_2H_5)_2\cdot CH_2\cdot CH_2\cdot NH_2$.—In view of the low solubility of phthal-β-bromoethylimide in diethylamine, Ristenpart's preparation of this base can with advantage be modified as follows : Phthal-β-bromoethylimide (23 g.), diethylamine (18·3 c.c.), and anhydrous xylene (50 c.c.) were confined in a round-bottomed bottle and heated at 100° for 10 hours, diethylamine hydrobromide slowly crystallising from the clear solution. The cold mixture was acidified with hydrochloric acid (1 : 1 by vol.), the xylene removed by steam distillation, and the residue hydrolysed by boiling under reflux, with the addition of fresh acid, for 3 hours. The product was then made alkaline and steam-distilled. The mixture of bases which separated when the distillate was saturated with potassium hydroxide was dried over fresh potash and then fractionally distilled. β-Aminotriethylamine was obtained as a colourless liquid, b. p. 144—146°.

Bis-β-*aminotriethylaminenickelous Thiocyanate.*—β-Aminotriethylamine (15·8 c.c.; 3 mols.) was added to a solution of nickel succinimide (15·0 g.) in hot absolute alcohol (500 c.c.), and the whole boiled under reflux for 4 hours. The cooled filtrate from the concentrated solution, when treated with an equal volume of a saturated alcoholic solution (90%) of potassium thiocyanate, yielded almost immediately the above *thiocyanate*, which, after 3 hours, was washed with water, alcohol, and ether (yield 10·4 g., *i.e.*, 68% calculated on the nickel taken). The yield was considerably decreased if the alcohol used in the preparation was not absolute, or if the above large excess of the amine was not employed. In spite of this excess,

no compound in which the nickel had combined with more than two molecules of the amine could be isolated. The thiocyanate crystallised from absolute alcohol in lilac-blue needles, m. p. 213—214° (decomp.) after shrinking at 204° (Found: C, 41·5; H, 8·0; N, 20·7; Ni, 14·4. $C_{14}H_{32}N_6S_2Ni$ requires C, 41·3; H, 7·9; N, 20·65; Ni, 14·4%).

The *chloroplatinate*, $[\{N(C_2H_5)_2\cdot C_2H_4\cdot NH_2\}_2Ni]PtCl_6$, was precipitated on addition of a solution of the thiocyanate (0·5 g.) in acetone (35 c.c.) to a solution of sodium chloroplatinate (0·9 g.) in water (5 c.c.) and acetone (30 c.c.), and was obtained, after being washed with water, acetone and ether, as an apricot-coloured powder, insoluble in boiling water and alcohol. It darkens at 165—168° and shrinks to a plastic rod at 179—181° (Found: C, 20·4; H, 4·6. $C_{12}H_{32}N_4Cl_6NiPt$ requires C, 20·6; H, 4·6%).

Attempted Preparation of the d-*Camphor-β-sulphonate of the Complex.*—Hot solutions of bisaminotriethylaminenickelous thiocyanate (5 g.) in alcohol (300 c.c.) and of silver *d*-camphorsulphonate (8·3 g.) in alcohol (100 c.c.) were mixed, boiled for 5 minutes, and filtered. The fine, very pale blue, crystalline precipitate deposited on cooling was difficult to filter off and recrystallise. Eventually, 1 g. portions were dissolved in a little boiling absolute alcohol, and the solutions filtered quickly. The filtrates deposited very pale blue (almost white) crystals, m. p. 175—176°. This very pale blue colour is characteristic of many neutral non-ionic nickel complex salts, such as nickel succinimide, $[(H_2O)_2Ni(NC_4H_4O_2)_2]$: the camphorsulphonate, moreover, in alcoholic solution gave no precipitate with sodium chloroplatinate, although the chloroplatinate of the complex $[\{N(C_2H_5)_2\cdot C_2H_4\cdot NH_2\}_2Ni]''$ is insoluble in alcohol. It is probable, therefore, that the camphorsulphonate radicals had entered the complex, and the nickel had thus increased its co-ordination number to 6, giving the neutral non-ionic *bis*-d-*camphorsulphonatebisaminotriethylaminenickel*,

$$[(C_{10}H_{15}O\cdot SO_3)_2Ni\{N(C_2H_5)_2\cdot C_2H_4\cdot NH_2\}_2]$$

(Found: N, 7·4; S, 8·4; Ni, 7·45. $C_{32}H_{62}O_8N_4S_2Ni$ requires N, 7·4; S, 8·5; Ni, 7·8%).

The d-*α-bromocamphor-π-sulphonate* was obtained from the thiocyanate (5 g. in hot alcohol, 300 c.c.) and silver *d*-α-bromocamphor-π-sulphonate (10·7 g. in alcohol, 150 c.c.), the conditions and difficulties of the preparation being similar to those described above. Also, for reasons similar to those mentioned above, the very pale blue product, m. p. 165—168° (decomp.), probably has the constitution $[(C_{10}H_{14}BrO\cdot SO_3)_2Ni\{N(C_2H_5)_2\cdot C_2H_4\cdot NH_2\}_2]$ (Found: N, 5·9; Ni, 6·7, 6·65. $C_{32}H_{60}O_8N_4S_2Br_2Ni$ requires N, 6·15; Ni, 6·4%).

The alcoholic solution from which this compound originally separated was concentrated and cooled, and the precipitate of the nickel complex compound filtered off. The filtrate was evaporated to dryness, and the residue twice recrystallised from benzene, from which the d-*α-bromocamphorsulphonate* of *β-aminotriethylammonium hydroxide*, $(C_{10}H_{14}OBr\cdot SO_3H,NH_2\cdot C_2H_4)\cdot NH(C_2H_5)_2\cdot OH$ separated in white crystals, m. p. 80—82° (Found: C, 43·5; H, 7·4; N, 6·5; Br, 17·9. $C_{16}H_{33}O_5N_2BrS$ requires C, 43·15; H, 7·5; N, 6·3; Br, 17·95%). The identity of this compound was confirmed by mixed melting-point determinations with the product obtained by treating bromocamphorsulphonic acid in alcoholic solution with an excess of the base, evaporating the solution to dryness, and recrystallising the residue from benzene. The presence of this compound in the original preparation shows that further decomposition of the complex occurs in hot alcoholic solution, the diamine being split off from the metal and becoming partially neutralised by the sulphonic acid.

Bis-d-*camphornitronateaminotriethylaminenickel*,

$$[(C_{10}H_{14}O\cdot NO_2)_2NiN(C_2H_5)_2\cdot C_2H_4\cdot NH_2].$$

—Finely-powdered silver *d*-camphornitronate (4·5 g.) was added to a solution of bis-β-aminotriethylaminenickelous thiocyanate (3·0 g.) in boiling alcohol (300 c.c.). After being boiled for 10 minutes and filtered, the deep olive-green solution was evaporated under reduced pressure to small bulk, again filtered, and then diluted with a little hot water. The precipitate was recrystallised from hot aqueous alcohol (95%), and the product thus obtained in deep olive-green crystals, m. p. 258—260° (decomp.) after softening at 248° (Found: C, 54·9; H, 7·6; N, 9·8. $C_{26}H_{44}O_6N_4Ni$ requires C, 55·0; H, 7·8; N, 9·9%). A 0·212% solution in chloroform had $\alpha_{5461} + 2·33°$, whence $[\alpha]_{5461} + 275°$, and $[M]_{5461} + 1560°$: this rotation remained unchanged for 20 hours.

The Complex Salts of β-Bromo-αγ-diaminopropane.

β-Bromo-αγ-diaminopropane, $(NH_2\cdot CH_2)_2CHBr$.—Gabriel's preparation of the dihydrobromide of this base (*Ber.*, 1889, **22**, 225) was modified as follows: A mixture of diphthalimido*iso*propyl alcohol (7·0 g.) and a saturated solution of hydrogen bromide in acetic acid (23 c.c.) was heated in a sealed tube at 100° for 30 hours with occasional shaking. After cooling, the precipitate was filtered off, washed with alcohol, and recrystallised from acetic acid, from which *αγ-diphthalimido*iso*propyl bromide* separated in colourless crystals, m. p. 196—198° (Found: N, 6·6; Br, 19·2. $C_{19}H_{13}O_4N_2Br$ requires N, 6·8; Br, 19·3%). This compound was boiled under reflux with hydrobromic acid of constant b. p., and the clear solution

was chilled, filtered from phthalic acid, and evaporated until, on cooling, the dihydrobromide of β-bromo-αγ-diaminopropane crystallised. The latter, when washed with alcohol and dried, was pure.

Bis-β-bromo-αγ-diaminopropanenickelous Thiocyanate.—A solution of β-bromo-αγ-diaminopropane dihydrobromide (13·0 g.) in 15% aqueous sodium hydroxide (19·0 c.c.) was added to one of nickel succinimide (6·0 g.) in boiling alcohol (240 c.c.), the green colour of the nickel solution changing at once to blue. The solution was boiled for 15 minutes, filtered, reduced to small bulk, and treated with a saturated solution of potassium thiocyanate in 95% alcohol. The precipitate was filtered off after 2 hours and washed with water, alcohol and ether. The *thiocyanate* was thus obtained as a fine pink powder, m. p. 200—203° (decomp.) after shrinking and darkening at 160°. It is insoluble in all the usual organic liquids, and is decomposed by hot water (Found: C, 20·0; H, 3·8; Br, 33·2; Ni, 12·2. $C_8H_{18}N_6Br_2S_2Ni$ requires C, 20·0; H, 3·8; Br, 33·25; Ni, 12·2%). If this compound is kept in contact with the original solution for more than 2 hours, it becomes contaminated with deep blue crystals of *bis-β-thiocyano-αγ-diaminopropanenickelous thiocyanate*. The latter compound was obtained pure by boiling bis-β-bromo-αγ-diaminopropanenickelous thiocyanate with water, a deep blue solution being obtained. The concentrated solution on quick cooling gave a fine blue, crystalline powder, whilst the dilute solution on slow cooling gave deep blue, heavy prisms; both deposits, after being washed with water, alcohol and ether, had m. p. 247—248° (decomp.) (Found: C, 27·5, 27·6; H, 4·4, 4·3; S, 29·4; Ni, 13·4. $C_{10}H_{18}N_8S_4Ni$ requires C, 27·5; H, 4·15; S, 29·3; Ni, 13·4%).

αγ-Dichloro*iso*propyl methyl ether, $(CH_2Cl)_2CH{\cdot}O{\cdot}CH_3$, was obtained as a colourless liquid, b. p. 66·5—67°/24 mm., having a characteristic peppermint-like odour (Found: C, 33·5; H, 5·7. Calc. for $C_4H_8OCl_2$: C, 33·6; H, 5·6%). When it was heated with an excess of potassium phthalimide in a sealed tube at 180° for 4 hours, much remained unchanged and no diphthalimido-derivative could be isolated.

*The Complex Salts of αγ-Diamino*iso*propyl Alcohol.*

*αγ-Diamino*iso*propyl Alcohol Dihydrochloride,* $(CH_2{\cdot}NH_2,HCl)_2CH{\cdot}OH$.—Diphthalimido*iso*propyl alcohol, prepared by Gabriel's method (*Ber.*, 1889, **22**, 224), was boiled under reflux with concentrated hydrochloric acid; the clear solution obtained, when chilled, filtered, and evaporated, gave the pure crystalline dihydrochloride.

Dihydroxybis-αγ-diamino-β-hydroxypropanecobaltic Monochloride.—A solution of diamino*iso*propyl alcohol dihydrochloride (12·2 g.; 2 mols.) in 10% aqueous sodium hydroxide (59 c.c.) was added to a mixture of *roseo*-cobaltic chloride (10 g.) and water (150 c.c.), and the whole heated under reflux on a water-bath for 3 hours, ammonia being freely evolved. The solution was then boiled for 30 minutes, filtered, and evaporated until crystals appeared. After cooling, the latter were collected and recrystallised from hot water, the *cobaltic monochloride* separating in dark red needles (Found: C, 23·6; H, 7·2; N, 17·9; Cl, 11·6. $C_6H_{22}O_4N_4ClCo$ requires C, 23·3; H, 7·2; N, 18·1; Cl, 11·5%). If the original solution was treated with potassium thiocyanate before the chloride started to crystallise, the corresponding *monothiocyanate* separated; after recrystallisation from water, it was obtained in fine, dark red crystals, decomp. 240—250° after shrinking at about 230° (Found: C, 25·2; H, 6·7; N, 21·0. $C_7H_{22}O_4N_5SCo$ requires C, 25·3; H, 6·7; N, 21·1%). A solution of the pure chloride, when treated with potassium iodide, gave the *monoiodide*, which also recrystallised from water in deep red leaflets (Found: C, 18·1; H, 5·5; I, 31·5. $C_6H_{22}O_4N_4ICo$ requires C, 18·0; H, 5·5; I, 31·7%).

Bis-αγ-diamino-β-hydroxypropanenickelous Thiocyanate.—A solution of diamino*iso*propyl alcohol dihydrochloride (17 g.) in water (50 c.c.) was treated with 10% aqueous sodium hydroxide (80·5 c.c.), and the whole added to a solution of hydrated nickel chloride (12 g.) in water (100 c.c.). The solution so obtained was heated under reflux on a water-bath for 4 hours, filtered, and concentrated. The addition of potassium thiocyanate solution gave the *thiocyanate* as a violet precipitate, which separated from hot water as a pale violet, crystalline powder, m. p. (to a clear blue liquid) 161—163° after shrinking at 105° (Found: C, 27·2; H, 5·6; N, 23·4; Ni, 16·7. $C_8H_{20}O_2N_6S_2Ni$ requires C, 27·1; H, 5·7; N, 23·7; Ni, 16·5%).

The original solution, when diluted with potassium iodide solution, slowly deposited the corresponding *di-iodide*, which separated from water, in which it was very soluble, in deep bluish-violet crystals, m. p. 239—242° (decomp.) (Found: C, 14·7; H, 4·1; I, 51·4. $C_6H_{20}O_2N_4I_2Ni$ requires C, 14·6; H, 4·1; I, 51·5%).

Bis-αγ-diamino-β-hydroxypropanenickelous d-*Camphor-β-sulphonate*, $[\{(CH_2{\cdot}NH_2)_2CH{\cdot}OH\}_2Ni](C_{10}H_{15}O{\cdot}SO_3)_2$.—Hot aqueous solutions of the thiocyanate (10 g.) and of silver *d*-camphorsulphonate (19·2 g.) were mixed, boiled for 5 minutes, filtered, and evaporated to dryness. The powdered residue was recrystallised from alcohol (charcoal), and the d-*camphor-β-sulphonate* obtained in pale lilac-blue crystals (Found: N, 8·2, 8·1; Ni, 8·6. $C_{26}H_{50}O_{10}N_4S_2Ni$ requires N, 8·0; Ni, 8·4%).

This camphorsulphonate was recrystallised seven times from alcohol, and its rotation for the mercury violet line (the only light which would penetrate the deep violet solutions) was then compared with those of the actual specimens of highly purified zinc and magnesium dicamphorsulphonates which Graham (J., 1912, **101**, 746) had prepared for rotatory determinations. The following readings were all made at 15° in a 4-dcm. tube. $\lambda = 4062$; c = concentration of the solution in g./100 c.c.; A denotes $C_{10}H_{15}O{\cdot}SO_3$.

Substance.	c.	α.	$[\alpha]$.	$[M]$.
$[\{(CH_2{\cdot}NH_2)_2CH{\cdot}OH\}_2Ni]A_2$ ...	1·7466	+3·60°	+51·5°	+361°
$MgA_2,6H_2O$	1·8824	+4·60	+61·1	+363
$ZnA_2,6H_2O$	1·8699	+4·25	+56·8	+361

These results show that the activity of the complex nickel salt is due solely to the camphorsulphonate radicals, and not to the complex itself. This was confirmed by reconverting the camphorsulphonate into the thiocyanate: the latter was inactive.

Bis-d-*camphornitronate*-$\alpha\gamma$-*diamino*-β-*hydroxypropanenickel*, $[(C_{10}H_{14}O{\cdot}NO_2)_2Ni\{(CH_2{\cdot}NH_2)_2CH{\cdot}OH\}]$.—Hot aqueous solutions of the above thiocyanate and of silver nitrate (2 mols.) were mixed, boiled for 5 minutes, filtered, concentrated and chilled, a solution of the very soluble bis-$\alpha\gamma$-diamino-β-hydroxypropanenickelous nitrate being thus obtained. The addition of a concentrated cold aqueous solution of ammonium nitrocamphor (2·5 mols.) caused the violet colour to change immediately to green, and the solution, after 12 hours, deposited a fine, green precipitate. This, when dry, was soluble in nearly all the usual organic solvents: it was finally recrystallised from anhydrous benzene, from which *bis*-d-*camphornitronate*-$\alpha\gamma$-*diamino*-β-*hydroxypropanenickel* separated as a fine, olive-green powder with a molecule of benzene of crystallisation (Found: C, 56·5; H, 7·2; Ni, 9·3; C_6H_6, 12·3. $C_{29}H_{44}O_7N_4Ni$ requires C, 56·25; H, 7·2; Ni, 9·5; C_6H_6, 12·6%), which was lost in a vacuum at 80°, leaving the pure product as an olive-green powder; this shrank and blackened up to 210° (Found: C, 51·2; H, 7·0; Ni, 10·8. $C_{23}H_{38}O_7N_4Ni$ requires C, 51·0; H, 7·05; Ni, 10·85%). A 0·272% solution of the benzene-free material in chloroform had $\alpha_{5461} + 2{\cdot}89°$, whence $[\alpha]_{5461} + 266°$ and $[M]_{5461} + 1440°$. No change in rotation occurred during 20 hours.

The Complex Salts of β-*Methyltrimethylenediamine.*

$\alpha\gamma$-*Diphthalimido*-β-*methylpropane*, $CH_3{\cdot}CH(CH_2{\cdot}N{:}C_2O_2{:}C_6H_4)_2$.—A uniform mixture of potassium phthalimide (32 g.) and β-methyltrimethylene dibromide (Faworski, *Annalen*, 1907, **354**, 384) (10 c.c.) was heated at 175—180° for 6 hours. The cold product was pulverised and extracted twice with boiling carbon tetrachloride

(200 + 80 c.c.), giving 16 + 1·5 g. of the crude diphthalimido-compound and leaving a residue of potassium bromide and a small quantity of phthalimide. The phthalimido-compound was twice crystallised from boiling alcohol (400 c.c. each time), and *αγ-diphthalimido-β-methylpropane* obtained in fine, white, crystalline scales, m. p. 169—171° (Found: C, 68·8; H, 4·8; N, 8·1. $C_{20}H_{16}O_4N_2$ requires C, 68·9; H, 4·6; N, 8·05%).

β-Methyltrimethylenediamine Dihydrochloride,

$$CH_3{\cdot}CH(CH_2{\cdot}NH_2,HCl)_2.$$

—αγ-Diphthalimido-β-methylpropane (12 g.) and concentrated hydrochloric acid (50 c.c.), heated in a sealed tube at 160° for 18 hours, the tube being inverted from time to time to mix the contents, gave a clear pale brown solution; this, when cold, was filtered from phthalic acid and concentrated. The *dihydrochloride* was now obtained in three successive crops by (*a*) crystallisation from the concentrated aqueous solution, (*b*) diluting the filtrate from the first crop with alcohol, and (*c*) further dilution with ether [Found: (*a*) Cl, 43·9, (*b*) C, 29·8; H, 8·7; Cl, 44·0, (*c*) Cl, 43·9. $C_4H_{14}N_2Cl_2$ requires C, 29·8; H, 8·8; Cl, 44·0%]. It separated in deliquescent, fine, white crystals, m. p. 195—197°, very soluble in water, but insoluble in alcohol and ether.

The *dihydrobromide* was similarly obtained by means of concentrated hydrobromic acid, and separated, when the final concentrated solution was diluted with alcohol, in colourless needles, m. p. 227—229° (decomp.) (Found: Br, 64·0. $C_4H_{14}N_2Br_2$ requires Br, 64·0%).

The *dibenzoyl* derivative, $CH_3{\cdot}CH(CH_2{\cdot}NHBz)_2$, prepared in the usual way, after crystallising twice from benzene and once from acetone, was obtained in fine, white crystals, which melted with effervescence at 92—93°, rapidly resolidified, and remelted at 136—138° (Found: C, 73·2; H, 6·85. $C_{18}H_{20}O_2N_2$ requires C, 73·0; H, 6·8%).

Bis-β-methyltrimethylenediaminenickelous Thiocyanate.—A mixture of a solution of β-methyltrimethylenediamine dihydrochloride (9·0 g.; 2·2 mols.) in 10% aqueous sodium hydroxide (20 c.c.) with a solution of nickel succinimide (10 g.) in boiling alcohol (300 c.c.) rapidly became blue. It was boiled under reflux for 1 hour, filtered from a small quantity of an apple-green precipitate, and concentrated. The cold solution, on treatment with a concentrated aqueous solution of potassium thiocyanate, rapidly gave a bluish-red precipitate of the thiocyanate of the nickel complex. The latter can be recrystallised quickly from hot water, but prolonged boiling causes the precipitation of a green sludge. After two recrystallisations, the *thiocyanate* was obtained in deep blue needles,

m. p. 226—228° (decomp.) (Found: C, 33·9; H, 6·9; N, 24·0. $C_{10}H_{24}N_6S_2Ni$ requires C, 34·2; H, 6·9; N, 23·9%).

Bis-β-methyltrimethylenediaminenickelous d-*Camphor-β-sulphonate*, $[Ni\{CH_3\cdot CH(CH_2\cdot NH_2)_2\}_2](C_{10}H_{15}O\cdot SO_3)_2$.—Solutions of the above thiocyanate (6 g.) in hot water (120 c.c.) and of silver *d*-camphorsulphonate (11·8 g.) in water (100 c.c.) were slowly mixed and then boiled for 5 minutes. Filtration gave a clear blue solution which, when concentrated and chilled, furnished the d-*camphorsulphonate* in fine, lilac-blue scales. These were recrystallised twice from alcohol, and then had m. p. 287—288° (decomp.) (Found: C, 48·5; H, 7·7; N, 8·05; Ni, 8·4. $C_{28}H_{54}O_8N_4S_2Ni$ requires C, 48·2; H, 7·8; N, 8·0; Ni, 8·4%). This material was recrystallised seven times from alcohol, and so obtained as pale blue, minute crystals (Found: C, 48·3; H, 7·7%): a 1·098% aqueous solution had $\alpha_{4062} + 2·11°$, whence $[\alpha]_{4062} + 48·0°$ and $[M]_{4062} + 335°$. This sulphonate was reconverted in cold aqueous solution into the thiocyanate, which was inactive. A further preparation of the camphorsulphonate was recrystallised six times from water, and so obtained as the *monohydrate* (Found: C, 46·8; H, 8·2.

$$C_{28}H_{54}O_8N_4S_2Ni,H_2O$$

requires C, 47·0; H, 7·9%): this, in 1·059% aqueous solution, had $\alpha_{4062} + 2·17°$, whence $[\alpha]_{4062} + 51·2°$ and $[M]_{4062} + 366°$, but once again furnished an inactive thiocyanate.

Bis-d-*camphornitronate-β-methyltrimethylenediaminenickel*, $[(C_{10}H_{14}O\cdot NO_2)_2Ni\{CH_3\cdot CH(CH_2\cdot NH_2)_2\}]$.—A solution of the *d*-camphorsulphonate (5 g.) in water (50 c.c.) was treated with an excess of ammonium nitrocamphor (3·5 g.), also dissolved in water (25 c.c.). A green precipitate rapidly appeared, and the solution smelt strongly of ammonia. The precipitate was washed with water and recrystallised from alcohol, from which the *nitronate* separated in fine, olive-green crystals, m. p. 293—295° (decomp.) (Found: C, 53·4; H, 7·4; Ni, 10·8. $C_{24}H_{40}O_6N_4Ni$ requires C, 53·4; H, 7·5; Ni, 10·9%). A 0·273% solution in chloroform had $\alpha_{5461} + 3·52°$, whence $[\alpha]_{5461} + 322°$ and $[M]_{5461} + 1736°$: the activity remained unchanged for 24 hours. This compound is only slightly soluble in water, but is soluble in nearly all the usual organic solvents.

The Complex Salts of β-Methyltrimethylenediamine with Bivalent Platinum.—A solution of ammonium chloroplatinite (4 g.) in water (20 c.c.) was added to one of methyltrimethylenediamine dihydrochloride (5·4 g.; 3 mols.) in 10% aqueous sodium hydroxide (12·8 c.c.). A pale yellow precipitate slowly separated, and after 2 hours the mixture was heated under reflux on a water-bath for a further 8 hours, and then chilled. The precipitate was filtered off and recrystallised from hot water, from which *dichloro-β-methyl*-

methylenediamineplatinum, $[Cl_2Pt\{CH_3\cdot CH(CH_2\cdot NH_2)_2\}]$, separated in very pale yellow crystals, m. p. 273—276° (decomp.) (Found: C, 13·5; H, 3·45; Pt, 55·0. $C_4H_{12}N_2Cl_2Pt$ requires C, 13·5; H, 3·4; Pt, 55·1%). The original filtrate was now evaporated to about half its original volume, and on quick cooling, *bis*-β-*methyltrimethylenediamineplatinous chloride*, $[Pt\{CH_3\cdot CH(CH_2\cdot NH_2)_2\}_2]Cl_2$, separated as a fine, white, crystalline powder, m. p. 266—267° (decomp.) after darkening at about 240° (Found: C, 21·4; H, 5·45; Pt, 44·2. $C_8H_{24}N_4Cl_2Pt$ requires C, 21·7; H, 5·5; Pt, 44·1%). The filtrate, on standing several days, deposited a mixture of colourless crystals of sodium chloride and very pale yellow crystals of the platinous dichloride compound. The latter could be very easily separated by hand, and no indication of *cis-trans*-isomeric forms could be detected.

THE UNIVERSITY CHEMICAL LABORATORY,
CAMBRIDGE. [*Received, August 29th*, 1927.]

CCCLXXXVIII.—*The Nature of the Alternating Effect in Carbon Chains. Part XXII. An Attempt further to define the Probable Mechanism of Orientation in Aromatic Substitution.*

By CHRISTOPHER KELK INGOLD and FLORENCE RUTH SHAW.

RECENT studies of reactivity transmission have led to the recognition in aromatic substitutions of orienting effects originating in the following combinations of inductively propagated electronic strain (I,⟶) and tautomeric or electromeric transformations (T,↷) * (for summary see *Ann. Reports*, 1926, p. 129):

Type				
Symbol	(1) $+I$	(2) $-I$	(3) $-I+T$	(4) $+I+T$
Examples	Toluene.	Phenylammonium ions. Phenylsulphones.	Halogenobenzenes. Phenylthionium ions.	Phenoxide ion.

On the other hand, previous results provide little positive information with regard to the paths whereby the effects thus arising traverse the nucleus. It is possible that the inductive and the

* For reasons given elsewhere, the possible combinations represented by $+I-T$ and $-I-T$ will not here be separately discussed, and it is also unnecessary for our present purpose to consider superimposed polar orientation through space.

tautomeric disturbances travel by different routes and influence the reactivity in the various positions of the nucleus in different relative degrees. The one clearly established circumstance is that both types of disturbance affect primarily the ortho- and para-positions.

The paucity of information on this subject is partly due to the fact that a knowledge of the proportions in which isomerides are formed in substitutions furnishes only one of the two kinds of data which are necessary for an analysis of the influence of orienting groups on the reactivity in each nuclear position. The other, consisting of the relative velocities of the total substitutions ($o + m + p$) of different substances, is, in general, not available. In this paper, a preliminary analysis of certain cases is attempted with the aid of new experimental data.

Before proceeding to details, it is desirable to define the terms employed. By the phrase "the reactivity in a given nuclear position" is meant the velocity, relative to some standard, of the substitution which occurs in that position under the conditions of the comparison. The effect of an orienting group on the reactivity of each nuclear position may therefore be defined as the number of molecules substituted during a small element of time at the given nuclear carbon atom, divided by the number which would have been substituted during the same element of time at the same carbon atom had the orienting group been absent. This ratio may be termed the "coefficient of activation" (F) for the orienting group and the nuclear position considered.

The results recorded below refer to nitration. It is, of course, certain that the relative reactivities of different nuclear carbon atoms will be found to vary with the nature of the substitution studied (*e.g.*, nitration and mercuration). Nevertheless there are good grounds for the belief that the broad, qualitative conclusions (which alone it is desired to indicate in this preliminary communication) will be found to apply, without serious alteration, to the behaviour of the nucleus in a large class of substitution reactions.

Case 1. *Type* + I. *Example: Toluene.*—Toluene is nitrated to the extent of approximately 59% in its ortho-positions, 4% in its meta-positions, and 37% in its para-position. The disparity between the *op*-substitution on the one hand and *m*-substitution on the other is universally regarded as indicating the *op*-orienting tendency of the methyl group; but it may have arisen in various ways. For instance, the orienting group may have caused an increase in *op*-reactivity accompanied by a decrease of *m*-reactivity (alternation, in fact); or it may have given rise to an increase

op-reactivity, and left the *m*-position unaffected; or it may have produced a large increase in *op*-reactivity and a smaller increase in *m*-reactivity; and there are other possibilities. Actually each of the three alternatives mentioned has been assumed or implied in one or other of the theories of aromatic substitution which have been under discussion in recent years.

It is known from Wibaut's experiments (*Rec. trav. chim.*, 1915, **34**, 241) that toluene nitrates much more rapidly than benzene; but this does not decide the question at issue. Our study of the relative velocities of nitration of benzene and toluene has led to the conclusion that whilst the reactivity of each ortho- or para-carbon atom in toluene is increased roughly 30-fold, that of each meta-carbon atom is increased 2-fold by the directive action of the methyl group.

Benzene and toluene, both in excess, were nitrated together in a homogeneous solution; the reaction was allowed to proceed to completion and the product analysed. This method has an advantage over the alternative of carrying out parallel nitrations with benzene and toluene separately, inasmuch as uncertainties arising from imperfect, and consequently unequal, temperature control are avoided. The molecular ratio, R, in which the hydrocarbons are nitrated is not the ratio of the velocities, *ceteris paribus*, of the respective total substitutions, but may be used to determine it as follows.

It is assumed that the reactions are carried out in unit volume which does not change appreciably during the process. If x_0, y_0, and z_0 are the initial amounts of benzene, toluene, and nitric acid, respectively, and x and y are the quantities of benzene and toluene remaining after a time t, then at any moment

$$-dx/dt = k_x x\{x + y - (x_0 + y_0) + z_0\}$$

and

$$-dy/dt = k_y y\{x + y - (x_0 + y_0) + z_0\}.$$

These equations assume that the reactions are bimolecular and irreversible. This has been shown to be the case for the nitration of a considerable number of substances, including benzene, nitrobenzene, chlorobenzene, *op*-dinitrotoluene, and the three nitrobenzoic acids (Holleman and de Bruyn, *Rec. trav. chim.*, 1900, **19**, 79, 188, 364; 1901, **20**, 206, 352; Martinsen, *Z. physikal. Chem.*, 1905, **50**, 385; 1907, **59**, 605; Wibaut, *loc. cit.*). Phenol, however, is an exception, which is not surprising (Martinsen, *loc. cit.*; Klemenc, *Monatsh.*, 1914, **35**, 85; Arnall, J., 1923, **123**, 3111).

The above equations on simultaneous integration give

$$k_y/k_x = (\log y_\infty - \log y_0)/(\log x_\infty - \log x_0)$$

where x_∞ and y_∞ are the ultimate values of x and y, respectively. The two equations necessary to evaluate x_∞ and y_∞ are

$$x_\infty + y_\infty = x_0 + y_0 - z_0$$

and

$$R = (y_0 - y_\infty)/(x_0 - x_\infty),$$

and the final expression for the ratio of the velocities of the total substitutions is

$$\frac{k_y}{k_x} = \log\left\{1 - \frac{z_0}{y_0}\left(\frac{R}{1+R}\right)\right\} \Big/ \log\left\{1 - \frac{z_0}{x_0}\left(\frac{1}{1+R}\right)\right\}.$$

Naturally, the formula applies generally to the simultaneous nitration of pairs of aromatic substances, provided the assumptions made during its derivation are fulfilled. Even if they are not accurately fulfilled, the general conclusions still hold, for the replacement of k_y/k_x by R, which must in any case represent a too conservative estimate of the ratio of the speeds, leads to the same conclusions. If ω, μ, and π represent the proportions of the individual nitrotoluenes in the total nitrotoluenes produced, the respective coefficients of activation are

$$F_{\text{ortho}} = 3\omega k_y/k_x; \quad F_{\text{meta}} = 3\mu k_y/k_x \; ; \quad F_{\text{para}} = 6\pi k_y/k_x,$$

and on substituting the numerical data, we find

$$F_{\text{ortho}} = 27{\cdot}6 \; ; \quad F_{\text{para}} = 34{\cdot}6; \quad F_{\text{meta}} = 2{\cdot}1.$$

Case 2. *Type* — I. *Examples: Benzyltrimethylammonium Salts and Benzoic Acid.*—The examples mentioned have been chosen to represent this type (which includes all benzene derivatives in which *m*-substitution is known to predominate) because the first corresponds, we consider, with the simple inductive effect, whilst the second theoretically admits of a superimposed electromeric change, and might by some be considered as belonging more properly to one of the categories mentioned in the footnote on p. 2918.

The notoriously slower velocity of many *m*-oriented, as compared with the majority of *op*-oriented, substitutions, taken together with the observations of Martinsen (*loc. cit.*), who has shown, *inter alia*, that the introduction of a carboxyl, sulphonic acid, or nitro-group into a benzene derivative already containing one or more orienting groups diminishes the velocity of further substitution, leaves little doubt that in *m*-substitutions generally the *op*-positions escape an equivalent amount of attack owing to the deactivating influence of the directing substituent. Strictly, the point is unproved, but it is rendered sufficiently probable by the existing evidence to warrant its adoption as a working hypothesis. The question remains as to whether, either generally throughout the category, or in individual

cases, the *m*-position is activated, deactivated, or left unaffected. In certain examples in which a positive pole is attached to the nucleus the answer is clearly that the *m*-position, like the *op*-positions, is deactivated. For the substances mentioned in the head-line, we find that the coefficient of meta-activation is an extremely small fraction of unity, the *o*- and *p*-reactivity factors being smaller still, and we believe that this state of affairs is general amongst *m*-substituting benzene derivatives.

Case 3. *Type* $-\mathrm{I}+\mathrm{T}$. *Examples: The Halogenobenzenes, etc.*—This type includes the halogenobenzenes, the alkyl- and acyl-oxybenzenes, the acyl-, acyl-alkyl, and diacyl-aminobenzenes, nitrosobenzene, phenyl sulphoxides, phenylthionium salts, and all other compounds in which the atom attached to the ring attracts electrons more strongly than hydrogen ($-I$), but at the same time possesses unshared electrons which can be shared with the nucleus ($+T$).

In all the investigated instances, predominating *op*-substitution is the rule; but a substantial amount of simultaneous *m*-substitution is not theoretically impossible, since examples can be conceived in which the inductive process might effectively compete with tautomeric action. In the series of orienting groups NRR′, OR, I, Br, Cl, F (R = alkyl) the tautomeric effect diminishes and the inductive effect increases towards fluorine, but even in fluorobenzene the substitution is almost exclusively ortho-para. On the other hand, the velocity of substitution diminishes throughout the series to such an extent that the right-hand members become qualitatively differentiated from the left-hand members, and from the *op*-orienting groups, belonging to Case 1, which act by simple induction ($+I$). That is to say, the category under consideration provides examples of *op*-orienting groups which, unlike all other *op*-orienting groups, diminish the velocity of substitution: their coefficients of activation are fractional. In this respect they resemble the *m*-orienting groups of Case 2, but are distinguished from them by the fact that for the groups of Case 3 the meta-deactivation is even stronger than the *op*-deactivation, whereas the reverse holds for Case 2. From the left of the above series up to and including iodobenzene the values of k_y/k_x are greater than unity; for bromobenzene (0·2), chlorobenzene (0·01), and fluorobenzene (0·002) they are fractional, and the values given, although approximate, establish the order of the compounds.

The position assigned to the NHAc-group is based on nitration with a neutral reagent in a neutral or feebly acid medium (acetyl nitrate in acetic anhydride; Ingold and Ingold, J., 1926, 1310). The nitration of acetanilide with nitric acid in sulphuric acid as

solvent is interesting inasmuch as the same salt-forming process which absorbs the unshared electrons also charges, and enhances the electron affinity of the nitrogen atom, so that on increasing the strength of sulphuric acid the circumstances of Case 3 continuously approach those of Case 2; this takes place with corresponding changes in the coefficients of activation, which become fractional, and, as Noelting and Collins's experiments indicate, in the proportions of the isomerides (*Ber.*, 1884, **17**, 262).

Case 4. *Type* + I + T. *Example: The Phenoxide Ion.*—The general conditions affecting the substitution of the phenoxide ion are attested by known results. In particular, the high *op*-reactivity of the ion in comparison with undissociated phenol is well illustrated by the recent experiments of Soper and Smith (J., 1926, 1582).

Discussion and Conclusions.—Consideration of the facts summarised above has led us to the following conclusions:

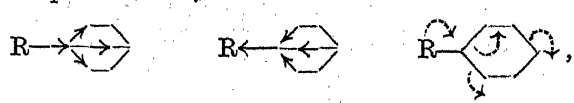
(i) That whereas inductive effects of either sign operate primarily on the ortho- and para-positions, an appreciable second-order effect, always of the same sign as the primary effect, is relayed on to the meta-position.

(ii) That whereas tautomeric effects also operate powerfully on the ortho- and para-positions, no similarly appreciable second-order effect reaches the meta-position.

(iii) That whilst inductive effects give rise to an essentially permanent (not necessarily constant) molecular condition, the tautomeric effect (apart, possibly, from a small permanent residuum) is essentially temporary in character, assuming much greater importance at the moment of attack by a reagent than in the quiescent period preceding it.

Conclusion (i) is reached directly from the consideration of Cases 1 and 2. It implies that *m*-substitution in Case 1 arises from second-order *m*-activation, and in Case 2 from second-order *m*-deactivation, which explains the velocity relations. A consistent deduction is that, as *op*-deactivation increases, the proportion of the effect relayed to the *m*-position decreases, so that the *m*-directive power of a group (Case 2) runs *inversely* as the velocity of *m*-substitution. This is certainly true for a series such as CO_2H(80%), NO_2(93%), $\overset{+}{N}Me_3$(100% meta), in which the velocities rapidly diminish towards $\overset{+}{N}Me_3$ and the figures in brackets represent the proportion of meta-nitration.

Conclusion (ii) follows from Case 3. Considering the series (p. 2922) NRR′, OR, . . ., Cl, F, the term $-I$ may for many purposes be neglected in the left-hand members in comparison with $+T$, which produces strong *op*-activation but no *m*-activation which



detectable in comparison. Again, if one imagines an extension of the series from NRR′ (*T* strong), through F (*T* weak), towards an extreme representative, such as $\overset{+}{\text{N}}$RR′R″, of Case 2,

$$\text{NRR}' \ldots \underset{\longleftarrow \text{increasing } -I \longrightarrow}{\overset{\longrightarrow \text{decreasing } T \longleftarrow}{(a) \ldots \text{F} \ldots (b)}} \ldots \overset{+}{\text{N}}\text{RR}'\text{R}''$$

the change over (*a*) from *op*-activation to *op*-deactivation occurs higher in the series than the change (*b*) from *op*- to *m*-substitution. For groups lying near the first of these critical positions (*a*) in the filled-in series, it is obvious that whilst the tautomeric effect can annul or reverse the strong *op*-deactivation arising from inductive action, it cannot reverse the relatively feeble *m*-deactivation. Indeed it seems to us that the condition of the whole group lying between the critical points (*a*) and (*b*) can be interpreted only along the lines indicated. The application to Case 4 is that appreciable *m*-substitution might arise if the inductive effect (+ *I*) were sufficiently powerful. Arnall's claim (J., 1924, **125**, 811) to have established 2—3% of *m*-substitution in the nitration of phenol might, if confirmed, be an indication in this direction. For systems of groups falling wholly within any one of Cases 1, 3 and 4, *op*-directive power must run parallel with the velocity of *op*-substitution, but no such simple rule can be laid down for the comparison of groups belonging to the different cases.

Conclusion (iii) is tentative, and is introduced because it appears necessary for the reconciliation of conclusions (i) and (ii). That inductive effects give rise to a permanent condition of electronic strain agrees with the known data relating to the molecular dipole moments of benzene derivatives, and it is consistent with our knowledge of reactivity transmission that a fractional part of charges arising on the ortho- and para-carbon atoms should be transmitted to the meta-carbon atom. On the other hand, it is difficult to see how *op*-charges which would be produced by the tautomeric effect can avoid similar transmission to the *m*-position, unless it be that they are "externally neutralised," that is, unless the electron displacements become large only at those moments when the reagent molecule which excites them is already committed to ortho- or para-attack.

The above interpretation, which is consistent with the following graphical representations,

is regarded as partly modifying, and partly giving definition to, the views originally expressed by Ingold and Ingold (*loc. cit.*), and as formulating in a more general way than has hitherto been possible the main principles which underlie the more recent communications from this laboratory on the subject of aromatic substitution. Only benzene substitutions are here dealt with, but the more important applications to naphthalene, quinoline, and certain other simple aromatic systems are sufficiently obvious. It will also be understood that the types discussed grade into one another, and in developing the work we shall investigate ω-halogenated and ω-carboxylated toluenes in order to emphasise this point.

Experimental.

Benzene was purified in the usual way. Toluene was purified by distillation, partial solidification (Ramsay), drying, and re-distillation (b. p. 110·4—110·8°). The other substances mentioned below were purified by distillation or crystallisation.

Toluene (1 mol.) and benzene (1 mol.) were nitrated together in a solution prepared from nitric acid (0·4 mol.) and acetic anhydride, the experiment being otherwise carried out as described by Holleman (*Rec. trav. chim.*, 1914, **33**, 1). Preliminary experiments had shown that for our purpose density determinations made with a moderately large pyknometer provided a more satisfactory method of analysis than measurements of refractive index. Accordingly, pure toluene was nitrated, without benzene, under the conditions indicated, and the mixed mononitro-derivatives were freed from unchanged toluene by distillation until the density remained constant. Mixtures of this product with similarly purified nitrobenzene had the following densities (d) at 25°; p denotes the percentage of nitrobenzene:

p	0·00	1·89	3·66	5·57	9·64	12·05	21·3	100·0
d	1·1526	1·1529	1·1537	1·1551	1·1566	1·1572	1·1616	1·1985

These points all lie on or close to the straight line represented by the equation $d = 1{\cdot}1526 + 0{\cdot}000459p$. The products of the mixed nitrations were likewise distilled to constant density to remove benzene and toluene, and the densities determined. They were d_{25}· 1·1555(i) and 1·1558(ii), which correspond with 6·3%(i) and 6·9%(ii) of nitrobenzene, that is, with 7·0(i) and 7·6(ii) molecules % of nitrobenzene. The agreement being apparently as good as could be expected from the method, the mean value, 7·3 molecules %, which gives $R_{Me} = 12{\cdot}7$, was used to calculate from the formula on p. 2921 that $k_y/k_x = 15{\cdot}7$. From this figure, by means of Holleman's data for the proportions of the isomerides (*loc. cit.*), the coefficients given in the introduction are obtained.

The investigation of the halogenobenzenes was carried out similarly with the following differences: (*a*) 1·0 mol. of nitric acid was used for the preparation of the acetyl nitrate solution, (*b*) the temperature of nitration was 45°, (*c*) the method of analysis was suited to the individual case. The product obtained from the experiments with fluorobenzene was distilled to remove unchanged benzene and fluorobenzene, and the remaining binary mixture hydrolysed with boiling sodium hydroxide solution to remove the fluorine as fluoride ion from the nitrofluorobenzenes—a process which is quantitative. The products obtained from chlorobenzene and bromobenzene were distilled to remove benzene, and the remaining ternary mixtures were hydrolysed under conditions known to be appropriate in each case. The liberated halide ions were estimated, and the residual binary mixtures insoluble in alkali submitted to ultimate analysis. By means of these methods, concordant determinations gave the following values: $R_F = 0{\cdot}0107$, $R_{Cl} = 0{\cdot}027$, $R_{Br} = 0{\cdot}36$, whence the figures given in the introduction were calculated. Competitive nitration of benzene and iodobenzene gave iodonitrobenzenes exclusively (R_I large), and anisole behaved similarly.

Since the medium used in the above experiments does not dissolve benzyltrimethylammonium picrate or benzoic acid sufficiently, a mixture of pure acetic acid and sulphuric acid in equimolecular proportion (15 mols. of each) was used as solvent for the nitration of these substances. The temperature was 0°. In each case, the benzene alone was nitrated and the other substance was recovered pure and unaccompanied by any trace of its nitro-derivatives; this was proved by m. p. and mixed m. p., and, for benzoic acid, confirmed by sublimation. In the course of the nitration of benzyltrimethylammonium picrate, picric acid separated from solution, but we do not regard this as invalidating the experiment, since the benzyltrimethylammonium ion remained dissolved.

The nitration of acetanilide was similarly investigated with identical results.

THE UNIVERSITY, LEEDS. [*Received, October 28th*, 1927.]

CCCLXXXIX.—*Melting Points of the Substituted Amides of Dibasic Acids.*

By CUTHBERT RICHMOND BARNICOAT.

THE members of homologous series usually show a fairly regular variation in physical properties as each series is ascended. The mono- and the di-basic acids are exceptions, as their melting points

rise and fall alternately. Biach (*Z. Physik*, 1904, **50**, 43) pointed out that this alternation is really quite general, as it appears in at least sixteen series of compounds. By plotting the melting points against the number of carbon atoms in the chain, two distinct curves, not necessarily exhibiting rise and fall, are obtained in each case, and those compounds containing an even number of carbon atoms lie on the higher curve. This phenomenon, evident even in the paraffins, appears to be due to something inherent in the carbon chain itself.

Robertson (J., 1908, **93**, 1033; 1919, **115**, 1210) has shown that the amides and substituted amides of the monobasic fatty acids exhibit this irregularity to an even more marked extent than the acids themselves. The investigations did not extend to dibasic acids, and it is to the study of the corresponding compounds of these that this work is confined.

EXPERIMENTAL.

The method of preparation of these substances was much the same as that described in Robertson's papers (*loc. cit.*).

The acids were from Kahlbaum, except the three highest members which were prepared by Lumsden and Walker's method (J., 1901, **79**, 1191).

All the melting-point determinations were made by the capillary-tube method in a castor-oil bath, and are uncorrected. The same standardised thermometer was used throughout.

The compounds not containing bromine were analysed by Kjeldahl's method, and the bromo-derivatives by the chromic acid method (Robertson, J., 1915, **107**, 902).

In Table I are the redetermined values of the melting points of compounds which were already known.

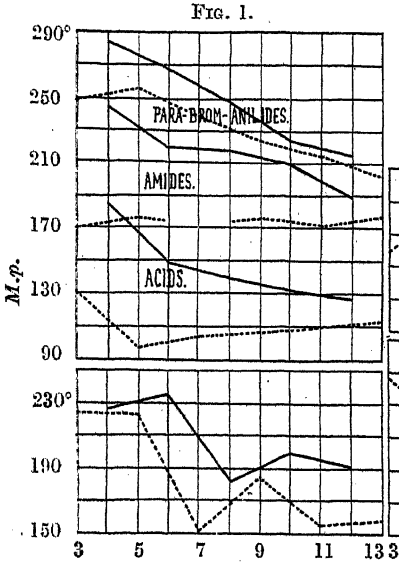
Remarks.—Acids. The differences in melting point of adjacent members are considerably greater than those between the corresponding monobasic acids, and the two curves tend to converge. A minimum is obtained at the fifth member (Fig. 1).



Amides. The curves resemble those of the acids, as the terminal groups are somewhat similar. The melting points are on the average 70° higher, and the differences between corresponding members more marked (Fig. 1).

Anilides. The introduction of a phenyl group causes a striking change in the nature of the curves (Fig. 2), that of the odd series

showing greater irregularity than its fellow, and less marked alternation results (*i.e.*, the curves lie closer together). Alternation appears to exhibit an unusual arrangement in fours.

o-*Toluidides* (Fig. 3). There is a marked similarity between these and the two following series, with substituted phenyl groups in the chain. A pronounced maximum is attained at the fifth member. The relative variation between the odd and the even series decreases slightly. The initial irregularity is apparently due to the unsymmetrical arrangement of the *o*-tolyl ring distorting

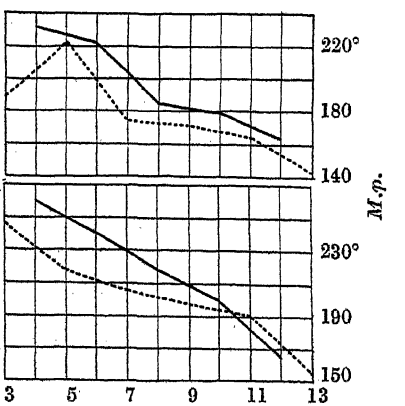


FIG. 1.

Number of carbon atoms in chain.

FIG. 2. *Anilides.*

FIG. 3. o-*Toluidides.*

Number of carbon atoms in chain.

FIG. 4. p-*Toluidides.*

the molecule, particularly when the chain is short and the end groups are in close proximity.

p-*Toluidides* (Fig. 4). The curves show slightly greater variation and the molecule is symmetrical, causing irregularity to be absent.

p-*Bromoanilides* (Fig. 1). The bromine atom has the most marked influence of all the substituents, producing curves almost devoid of irregularity.

I wish to thank Professor P. W. Robertson for his advice and for the interest he has taken in this work.

VICTORIA UNIVERSITY COLLEGE,
WELLINGTON, NEW ZEALAND.

[*Received, April 27th,* 1927.]

CCCXC.—*Aromatic Thionyl and Chlorothionyl Derivatives. Part III. Some Reactions of Thionylalizarin.*

By ALBERT GREEN.

SINCE thionylalizarin appears to be the most reactive of the thionyl compounds previously examined (J., 1924, **125**, 1450; 1926, 2198; this vol., pp. 500, 554, 2341), a further study of its reactions has been carried out.

It is now shown that although the interaction between the thionyl compound and *weak* organic acids provides a general method of preparing the corresponding 2-acyl derivatives of alizarin, yet with the stronger organic acids the thionyl derivative reverts to alizarin. The following acids yield 2-monoacyl derivatives: acetic (*loc. cit.*), phenylacetic, phenoxyacetic, cinnamic, benzoic, *o*-toluic, *m*-bromobenzoic, and *p*-bromobenzoic. Monochloroacetic acid gives a mixture of alizarin and a substance having the appearance of its monochloroacetate, whilst with dichloroacetic, trichloroacetic, and dibromoacetic acids thionylalizarin gives alizarin only.

It is thus clear that the reaction which a thionyl compound undergoes with an organic acid depends on the nature of that acid. The nature of the thionyl compound is also a factor, for while the thionyl derivatives of alizarin and of pyrocatechol are quantitatively converted into their monoacetates (*loc. cit.*) by acetic acid, yet under the same conditions thionylhystazarin (*loc. cit.*) gives hystazarin only.

Diacyl derivatives are obtained by the action of benzoic anhydride, benzoyl chloride and acetyl chloride, but succinic and phthalic anhydrides react neither with thionylalizarin nor with alizarin itself. This may be accounted for by the fact that the production of alizarin succinate (or phthalate) would necessitate the formation of a cyclic structure of eight atoms. Dibenzoylalizarin has been obtained in two crystalline modifications, melting at 160° (labile) and at 187° respectively.

The thionyl compound is rapidly decomposed, with evolution of sulphur dioxide, by boiling absolute ethyl alcohol and by hot phenol and in both cases the products are pure alizarin.

In attempts to prepare ethers by the condensation of thionylalizarin with alkyl halides and with alkyl sulphates no reaction was observed.

Thionylalizarin reacts readily with hot primary aromatic amines, with evolution of sulphur dioxide, to give alizarin, which then undergoes further slow reaction with the bases to yield secondary

amines. For example, in one experiment, the product obtained after boiling thionylalizarin in dry aniline for 1 hour contained less than 1% of nitrogen, gave the reactions of alizarin and melted at 265—268°. This melting point was raised to 275—277° by admixture with pure alizarin. Similar results were obtained with other aromatic amines, and the reaction was not investigated further.

EXPERIMENTAL.

Interaction of Thionylalizarin with Acids, Acid Anhydrides, and Acid Chlorides.—Methods. A. In the case of the lower-melting acids, a slight excess was heated with thionylalizarin at 150—170°. When the evolution of sulphur dioxide was no longer vigorous (usually 10 to 15 minutes), the melt was allowed to cool, boiled with ether to remove any unchanged acid, and the residue was recrystallised from benzene or absolute alcohol. Yields of 90 to 95% of the pure products were obtained.

B. The acid or anhydride and thionylalizarin were heated in dry nitrobenzene at 170° for 40 to 60 minutes. On cooling, a portion of the product usually crystallised. A further quantity was obtained by adding ether to the solution and allowing it to stand. The yields averaged 60%.

C. Benzoyl chloride reacted vigorously at its boiling point with thionylalizarin, and dibenzoylalizarin, m. p. 187°, crystallised on cooling. With acetyl chloride no reaction was observed after 4 hours' boiling, but when the substances were heated in a sealed tube at 150—170° for 2 hours, diacetylalizarin was obtained in 80% yield.

Alizarin benzoates. 2-Monobenzoylalizarin (methods *A* and *B*) was obtained from absolute alcohol in small, chrome-coloured needles, m. p. 208—210° (D.R.-P. 297,261 gives 214—216°). When mixed with a specimen prepared from alizarin and the theoretical amount of benzoyl chloride in pyridine solution, it showed the same m. p. (Found: C, 73·3; H, 3·6. Calc. for $C_{21}H_{12}O_5$: C, 73·3; H, 3·5%).

Dibenzoylalizarin (*B* and *C*). When prepared from the thionyl compound and benzoic anhydride in nitrobenzene solution, *dibenzoylalizarin* separated in clusters of small, pale chrome crystals, m. p. 160°, which was unchanged by further immediate crystallisation from benzene (Found: C, 74·8; H, 3·7. $C_{28}H_{16}O_6$ requires C, 75·0; H, 3·6%). This labile form, on being kept for a week in contact with a little of the original nitrobenzene solution, was transformed to the stable modification, which consisted of stout, primrose prisms, m. p. 187° (Found: C, 74·9; H, 3·7%) (compare Barnett and Cook, J., 1922, **121**, 1389). Other preparations of this derivative from

alizarin and benzoyl chloride in pyridine gave the higher-melting form.

The following 2-*monoacyl* derivatives of alizarin were also prepared. The methods of preparation are indicated, and the calculated values for C, H, and Br are given in brackets after the found values.

2-Acyl derivatives of alizarin.	Appearance and m. p.	Recrystallisation solvent and analyses.
Phenylacetyl (*A*) ...	Greenish-yellow needles, m. p. 165°.	Benzene. 73·7; 4·0 (73·7; 3·9).
Phenoxyacetyl (*A*) ...	Small, yellow needles, m. p. 179°.	Benzene. 70·7; 3·7 (70·6; 3·7).
Cinnamoyl (*A* and *B*)	Golden-yellow prisms, m. p. 209°.	Benzene. 74·5; 3·7 (74·6; 3·8).
o-*Toluoyl* (*A*)	Fine, ochre needles, m. p. 192°.	Benzene or absolute alcohol. 73·7; 3·9 (73·7; 3·9).
m-*Bromobenzoyl* (*A*)	Small, greenish-yellow needles, m. p. 214°.	Toluene. Br, 18·7 (18·9).
p-*Bromobenzoyl* (*B*)	Greenish-yellow needles, m. p. 195°.	Benzene. Br, 18·9 (18·9).

Condensations with Halogen-substituted Acetic Acids.—(1) *Monochloroacetic acid.* Thionylalizarin (2 g.) was treated with the carefully purified acid, according to method *A*. The product, crystallised from benzene, consisted of 1·6 g. of an intimate mixture of fine, yellow needles, which closely resembled the monoacyl compounds previously examined, and of fine, reddish-brown flakes. The mixture contained 5·8% of chlorine (the monochloroacetate requires 11·2%). Similar results were obtained by varying the experimental conditions. After repeated extraction of the mixtures with light petroleum, a residue of pure alizarin was obtained; m. p. 288°, either alone or mixed with an authentic specimen.

(2) Thoroughly dried and purified dichloro-, trichloro-, and dibromo-acetic acids in all experiments gave theoretical yields of halogen-free alizarin, which was identified by mixed melting-point determinations with the pure substance, and by conversion into the diacetate.

The products from alcoholic and phenolic solutions of thionylalizarin were shown to be alizarin in the same manner.

The author wishes to thank the Research Fund Committee of the Chemical Society for a grant which has defrayed part of the cost of this research.

CCCXCI.—*The Isomerism of the Oximes. Part XXXII. Sulphates.*

By Oscar L. Brady and Alan D. Whitehead.

Luxmoore (J., 1896, **69**, 180) showed that α-benzaldoxime could be converted into the β-isomeride by means of concentrated sulphuric acid and isolated both the α- and the β-benzaldoxime sulphate, $C_6H_5{\cdot}CH{:}NOH,H_2SO_4$. The α-oxime sulphate regenerated the α-oxime on decomposition with aqueous ammonia at 0°, and on keeping rapidly changed to the β-oxime sulphate; this gave the β-oxime on treatment with alkalis. A number of other aromatic aldoxime sulphates have now been prepared and Luxmoore's method of converting the α- into the β-oxime has been investigated in the hope that it would prove more convenient than the usual procedure through the hydrochloride. Further, it was thought that it might be possible, through the sulphate, to bring about isomeric change in those oximes which do not form hydrochlorides (Brady and Dunn, J., 1915, **107**, 1862; Brady and Manjunath, J., 1924, **125**, 1068).

When α- *o*-, *m*-, or *p*-nitro- or α-*p*-methoxy-benzaldoxime is dissolved in concentrated sulphuric acid, the sulphate of the α-oxime is first formed, and the solution on neutralisation with sodium carbonate regenerates the α-oxime; if the solution be kept for some time or heated to 100°, or if the temperature rises too much during the dissolution owing to the heat of reaction, the sulphate of the β-oxime is produced, and the solution on neutralisation gives the β-oxime. Provided that the temperature is kept low, the dry sulphates of these oximes, isolated by various means from the freshly prepared solutions, consist mainly of the α-form, differing in this respect from the hydrochlorides, since, although the α-hydrochloride of *p*-methoxybenzaldoxime can be obtained at — 10°, those of *m*- and *p*-nitrobenzaldoxime are stable only at very low temperatures (Brady and Dunn, J., 1916, **109**, 680; 1923, **123**, 1798). The solid sulphate from benzaldoxime consisted of the β-form (compare Luxmoore, *loc. cit.*). In the case of α-*o*-methoxybenzaldoxime, which cannot be converted into the β-isomeride through the hydrochloride, sulphate formation likewise failed to bring about the change; α-*o*-chlorobenzaldoxime, which yields the β-form only with difficulty through the hydrochloride, gave only an α-sulphate; 3 : 4-methylenedioxybenzaldoxime gave an α-sulphate which could not be converted into the β-form owing to decomposition of the methylene group on heating or keeping. α-6-Nitro-3 : 4-methylenedioxybenzaldoxime and α-6-bromo-3 : 4-dimethoxybenzaldoxime

which do not form hydrochlorides, gave α-sulphates, but these compounds did not change to the β-forms.

When solutions of α-benzaldoxime, *o*-, *m*-, and *p*-nitro-, and *p*-methoxy-benzaldoximes in concentrated sulphuric acid were heated for a short time at 100°, cooled, and poured into a large excess of sodium carbonate solution, products were obtained which on crystallisation gave fairly satisfactory yields of the β-oximes. This method is probably the quickest way of preparing small amounts of the β-oximes, but does not work well with quantities much above 2 grams; it seems that owing to the longer time required for neutralisation when larger quantities are used, as in the case of the hydrochlorides, partial reversion of the β- to the α-oxime takes place.

Prolonged heating of aldoximes with concentrated sulphuric acid results in the formation of the corresponding amides. It is impossible to decide at present whether this is a Beckmann change (I) or dehydration to nitrile followed by addition of water in another way (II), since the nitrile on similar treatment yields the amide.
